Table 3.32. Postexposure Prophylaxis (PEP) for People Exposed to Measles Who Are NOT Pregnant or Immunocompromised

Measles		PEP Type Depending on Time After Initial Exposure		
Age Range	Immune Status ^a	≤3 days (≤72 hours)	4–6 days	>6 days
All ages (≥6 mo)	Immune	• PEP not indicated. Exposed person has documented immunity.		
<6 mo	Nonimmune (because of age ^b)	• Administer immune globulin intramuscular (IGIM) ^c • Home quarantine ^d		• PEP not indicated (too late). • Home quarantine ^d
6–11 mo	Nonimmune	• Administer MMR vaccine (MMR vaccine preferred over immune globulin [IG]) • No quarantine needed. ^e	• Administer IGIM ^c • Home quarantine ^d	• PEP not indicated (too late). • Home quarantine ^d
≥12 mo	Nonimmune	• Administer MMR vaccine • No quarantine needed ^e	• IG PEP usually not administered ^f • Home quarantine, ^d then administer MMR vaccine to protect from future exposures	
≥12 mo	1 dose of MMR vaccine	• Administer 2 nd MMR vaccine dose if ≥28 days from the first dose • No quarantine needed (person had 1 dose when exposed)		

Adapted from a table developed by New York City Department of Health: www1.nyc.gov/assets/doh/downloads/pdf/imm/pep-measles-providers.pdf. Additional source: Centers for Disease Control and Prevention. Prevention of measles, rubella, congenital rubella syndrome, and mumps, 2013. *MMWR Recomm Rep*. 2013;62(RR-4):1-34; and Gastanaduy P, Redd S, Clemmons N, et al. Chapter 7: Measles. In: Roush SW, Baldy LM, Kirkconnell Hall MA, eds. *Manual for the Surveillance of Vaccine-Preventable Diseases*. Centers for Disease Control and Prevention. Page last reviewed May 13, 2019. Available at: www.cdc.gov/vaccines/pubs/s0urv-manual/chpt07-measles.html

^aAcceptable evidence of immunity includes written documentation of age-appropriate vaccination, laboratory evidence of immunity, laboratory confirmation of disease, or birth before 1957.

^bMMR vaccine is not indicated in this age group.

^cDosing of IGIM is 0.5 mL/kg of body weight (max dose 15 mL).

^dThe quarantine period is 21 days after the last exposure; most health departments would extend the monitoring period to 28 days if IG is administered as PEP, because IG can prolong the incubation period. Decisions on whether exposed persons who received IG as PEP appropriately (ie, within 6-day window) should return to settings such as child care, school, or work (ie, not be quarantined) should include consideration of the immune status and intensity of contacts in the setting and presence of high-risk individuals. These persons should be excluded from health care settings.

^eQuarantine is not needed for persons who received MMR as PEP appropriately (ie, within the 3-day window), although these persons should be excluded from health care settings for 21 days.

^fIGIM is recommended for infants <12 months of age, and IG administered intravenously is recommended for nonimmune pregnant people and severely immunocompromised persons. IGIM can be given to other persons (eg, ≥12 months of age) who do not have evidence of measles immunity, but priority should be given to persons exposed in settings with intense, prolonged, close contact (eg, household, child care, classroom).

Table 3.33. Postexposure Prophylaxis (PEP) for People Exposed to Measles Who ARE Pregnant or Immunocompromised

Category	Measles Immune Status ^a	PEP Type Depending on Time After Initial Exposure		
		≤3 days (≤72 hours)	4–6 days	>6 days
Severely immunocompromised ^b	IG recommended regardless of measles immune status	• Administer immune globulin intravenous (IGIV)^c • Home quarantine^d		• PEP not indicated (too late) • Home quarantine^d
Pregnant	Immune	• PEP not indicated		
	Nonimmune	• Administer IGIV^c • Home quarantine^d		• PEP not indicated (too late) • Home quarantine^d

Adapted from a table developed by New York City Department of Health: www1.nyc.gov/assets/doh/downloads/pdf/imm/pep-measles-providers.pdf. Additional source: Centers for Disease Control and Prevention. Prevention of measles, rubella, congenital rubella syndrome, and mumps, 2013. *MMWR Recomm Rep*. 2013;62(RR-4):1-34; and Gastanaduy P, Redd S, Clemmons N, et al. Chapter 7: Measles. In: Roush SW, Baldy LM, Kirkconnell Hall MA, eds. *Manual for the Surveillance of Vaccine-Preventable Diseases*. Centers for Disease Control and Prevention. Page last reviewed May 13, 2019. Available at: www.cdc.gov/vaccines/pubs/s0urv-manual/chpt07-measles.html

^aAcceptable evidence of immunity includes written documentation of age-appropriate vaccination, laboratory evidence of immunity, laboratory confirmation of disease, or birth before 1957.

^bThe degree of altered immunocompetence in a patient should be determined by a physician. Severely immunocompromised patients include patients with severe primary immunodeficiency; patients who have received a hematopoietic cell transplant until at least 12 months after finishing all immunosuppressive treatment, or longer in patients who have developed graft-versus-host disease; patients on treatment for acute lymphoblastic leukemia (ALL) within and until at least 6 months after completion of immunosuppressive chemotherapy; and patients with HIV with severe immunosuppression, which for children ≤5 years is defined as CD4+ T-lymphocyte percentage <15% and for children >5 years and adolescents is defined as a CD4+ T-lymphocyte percentage <15% **or** a CD4+ T-lymphocyte count <200 lymphocytes/mm³, and those who have not received MMR vaccine since receiving effective antiretroviral therapy. Additional severely immunocompromising conditions and medications are provided in Rubin LG, Levin MJ, Ljungman P, et al. 2013 IDSA Clinical practice guideline for vaccination of the immunocompromised host. *Clin Infect Dis*. 2014;58(3):e44-e100.

^cDosing of IGIV is 400 mg/kg of body weight.

^dThe quarantine period is 21 days after the last exposure; most health departments would extend the monitoring period to 28 days if IG is administered as PEP because IG can prolong the incubation period. Decisions on whether exposed persons who received IG as PEP appropriately (ie, within 6-day window) should return to settings such as child care, school, or work (ie, not be quarantined) should include consideration of the immune status and intensity of contacts in the setting and presence of high-risk individuals. These persons should be excluded from health care settings.

Use of Immune Globulin. Either immune globulin intramuscular (IGIM) or immune globulin intravenous (IGIV) can be administered within 6 days of exposure to prevent or modify measles in people who do not have evidence of measles immunity. Concentrations of measles antibodies in IGIM or IGIV products produced internationally may be different from those of products available in the United States. The recommended dose of IGIM is 0.50 mL/kg (maximum 15 mL). IGIV is the recommended IG preparation for pregnant people without evidence of measles immunity and for severely immunocompromised hosts, regardless of immunologic or vaccination status, including patients with severe primary immunodeficiency; patients who have received a hematopoietic cell transplant, until at least 12 months after finishing all immunosuppressive treatment or longer in patients who have developed graft-versus-host disease; patients undergoing treatment for acute lymphoblastic leukemia, within and until at least 6 months after completion of immunosuppressive chemotherapy; people who have received a solid organ transplant; people with human immunodeficiency virus (HIV) infection who have severe immunosuppression (for people ≤ 5 years of age, defined as a CD4+ T-lymphocyte percentage $< 15\%$; for people > 5 years of age, defined as a CD4+ T-lymphocyte percentage $< 15\%$ **or** a CD4+ T-lymphocyte count < 200 lymphocytes/mm³); and patients younger than 12 months whose birthing parent received biologic response modifiers during pregnancy.^{1,2} IGIV is recommended for these people because they may be at higher risk of severe measles and complications. IGIV also is recommended for people who weigh > 30 kg, who would receive less than the recommended dose with IGIM preparations since the maximum volume administered is 15 mL. IGIV is administered at a dose of 400 mg/kg. For patients who already are receiving IGIV at regularly scheduled intervals, the usual dose of 400 mg/kg should be adequate for measles prophylaxis after exposures occurring within 3 weeks of receiving IGIV. For people routinely receiving immune globulin subcutaneous (IGSC) therapy, consult the prescribing information for specific dosing related to measles, because it may vary based on other product characteristics. IG is not indicated for household or other close contacts who have received 1 dose of vaccine at 12 months or older unless they are severely immunocompromised (as defined previously).

For children who receive IGIM for modification or prevention of measles after exposure, measles vaccine (if not contraindicated) should be administered 6 months after IGIM administration and 8 months after IGIV administration, provided the child is at least 12 months of age. Intervals vary between administration of other biologic products and measles-containing vaccines (see Table 1.11, p 69).

HIV Infection.¹ Children living with HIV who are exposed to measles require prophylaxis based on immune status and measles vaccine history. Children living with HIV with no to moderate immunosuppression who have evidence of immunity (eg, serologic evidence of immunity to measles or who received 2 doses of measles vaccine after initiation of ART) do not require any additional measures to prevent measles

¹ Centers for Disease Control and Prevention. Prevention of measles, rubella, congenital rubella syndrome, and mumps, 2013 summary: recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR Recomm Rep*. 2013;62(RR-4):1-34

² Rubin LG, Levin MJ, Ljungman P, et al. 2013 IDSA Clinical practice guideline for vaccination of the immunocompromised host. *Clin Infect Dis*. 2014;58(3):e44-e100

following an exposure. Mildly or moderately immunocompromised people living with HIV without evidence of immunity to measles (eg, no serologic evidence of immunity to measles and who have not received 2 doses of measles vaccine after initiation of ART) should receive immune globulin intramuscular (IGIM) at a dose of 0.5 mL/kg (maximum 15 mL). Severely immunocompromised hosts (for people ≤5 years of age, defined as a CD4+ T-lymphocyte percentage <15%; for people >5 years of age, defined as a CD4+ T-lymphocyte percentage <15% **or** a CD4+ T-lymphocyte count <200 lymphocytes/mm³) who are exposed to measles should receive immune globulin intravenous (IGIV) prophylaxis, 400 mg/kg, after exposure to measles, regardless of prior vaccination status, because they may not be protected by the vaccine. Children living with HIV who have received IGIV within 3 weeks of exposure do not require additional passive immunization.

Health Care Personnel. To decrease health care-associated infection, immunization programs should be established to ensure that all people who work or volunteer in health care facilities (including students) have presumptive evidence of immunity to measles (see Immunization in Health Care Personnel, p 115).

Measles Vaccine Recommendations (see Table 3.34 for summary).

Use of MMR Vaccine. The only measles vaccines licensed in the United States are live attenuated strains. Measles-containing vaccines provided through the Expanded

Table 3.34. Recommendations for Measles Immunization^a

Category	Recommendations
Unimmunized, no history of measles (12 through 15 mo of age)	MMR or MMRV vaccine is recommended at 12 through 15 mo of age; a second dose is recommended at least 28 days after the first dose (or 90 days for MMRV) and usually is administered at 4 through 6 y of age.
Children 6 through 11 mo of age in outbreak situations ^b or before international travel	Immunize with MMR vaccine, ideally at least 2 weeks prior to travel, but this dose is not considered valid, and 2 valid doses administered on or after the first birthday are required. MMRV should not be administered to children <12 mo of age.
Students in kindergarten, elementary, middle, and high school who have received 1 dose of measles vaccine at 12 mo of age or older	Administer the second dose.
Students in college and other postsecondary institutions who have received 1 dose of measles vaccine at 12 mo of age or older	Administer the second dose.
History of immunization before the first birthday	Dose not considered valid; immunize (2 doses).

Table 3.34. Recommendations for Measles Immunization,^a continued

Category	Recommendations
History of receipt of inactivated measles vaccine or unknown type of vaccine, 1963–1967	Dose not considered valid; immunize (2 doses).
Further attenuated or unknown vaccine administered with IG	Dose not considered valid; immunize (2 doses).
Allergy to eggs	Immunize; no reactions likely (see text for details).
Neomycin allergy, nonanaphylactic	Immunize; no reactions likely (see text for details).
Severe hypersensitivity (anaphylaxis) to neomycin or gelatin	Avoid immunization.
Tuberculosis	Immunize (see Tuberculosis, p 888); if patient has untreated tuberculosis disease, start antituberculosis therapy before immunizing.
Measles exposure	Immunize or give IG, depending on circumstances (see Care of Exposed People, p 574, Table 3.32, and Table 3.33).
People with HIV	Immunize (2 doses) unless severely immunocompromised (see text, p 577); administration of IG if exposed to measles is based on degree of immunosuppression and measles vaccine history (see text, p 577).
Personal or family history of seizures	Immunize; advise parents of slightly increased risk of seizures.
IG or blood product recipient	Immunize at the appropriate interval (see Table 1.11, p 69).

HIV indicates human immunodeficiency virus; IG, immune globulin; MMR, measles, mumps, and rubella vaccine; MMRV, measles, mumps, rubella, and varicella vaccine.

^aSee text for details and recommendations for use of MMRV vaccine.

^bSee Outbreak Control (p 585).

Programme on Immunization in resource-limited countries meet the WHO standards and usually are comparable with the vaccines available in the United States. Measles vaccine is only available in the United States as combination formulations, which include MMR (M-M-R II, manufactured by Merck; and Priorix, manufactured by GSK) and measles, mumps, rubella, and varicella (MMRV [ProQuad], manufactured by Merck) vaccines; single-antigen measles vaccine no longer is available in the United States. Measles-containing vaccine in a dose of 0.5 mL can be administered subcutaneously or intramuscularly, depending on the specific vaccine formulation used; M-M-R II and MMRV can be given either subcutaneously or intramuscularly, while Priorix can be given only subcutaneously. Measles-containing vaccine can be administered simultaneously with other immunizations in a separate syringe at a separate site (see Simultaneous Administration of Multiple Vaccines, p 63).

Serum antimeasles antibodies develop in approximately 95% of children immunized at 12 months of age and 98% of children immunized at 15 months of age. Protection conferred by a single dose is durable in most people. A small proportion (5% or less) of immunized people may lose protection after several years. For measles elimination, 2 doses of measles-containing vaccine are required. More than 99% of people who receive 2 doses (separated by at least 28 days, and the first dose administered on or after the first birthday) develop serologic evidence of measles immunity. The second dose provides protection to those failing to respond to their primary measles immunization and, therefore, is not a booster dose. Immunization is not deleterious for people who already are immune. Immunized people do not transmit measles vaccine virus.

Improperly stored vaccine may fail to protect against measles. Since 1979, an improved stabilizer has been added to the vaccine that makes it more resistant to heat inactivation. For recommended storage of MMR and MMRV vaccines, see the manufacturers' package labels. MMRV vaccine must be stored frozen between -58°F and $+5^{\circ}\text{F}$.

Age of Routine Immunization. The first dose of MMR vaccine should be administered at 12 through 15 months of age. Delays in administering the first dose contributed to large outbreaks in the United States from 1989 to 1991. The second dose is recommended routinely at school entry (ie, 4 through 6 years of age) but can be administered at an earlier age (eg, during an outbreak or before international travel) provided the interval between the first and second MMR doses is at least 28 days. Catch-up second-dose immunization should occur for all school-aged children (elementary, middle, high school) who have received only 1 dose, including at the adolescent visit at 11 through 12 years of age and older. If a child receives a dose of measles vaccine before 12 months of age, this dose is not counted toward the required number of doses; the universally recommended 2 doses are still required in the United States beginning at 12 through 15 months of age and separated by at least 28 days.

*Use of MMRV Vaccine.*¹

- MMRV vaccine is indicated for simultaneous immunization against measles, mumps, rubella, and varicella among children 12 months through 12 years of age; MMRV vaccine is not indicated for people outside this age group. See Varicella-Zoster Infections, p 938, for recommendations for use of MMRV vaccine for the first dose.
- Children with HIV infection should not receive MMRV vaccine because of lack of safety data of the quadrivalent vaccine in children infected with HIV.
- MMRV vaccine may be administered with other vaccines recommended at 12 through 15 months of age or at 4 through 6 years of age (**https://redbook.solutions.aap.org/SS/Immunization_Schedules.aspx**).
- At least 28 days should elapse between a dose of measles-containing vaccine, such as MMR vaccine, and a dose of MMRV vaccine. However, the recommended minimal interval between 2 separate MMRV vaccine doses is 90 days.

Colleges and Other Institutions for Education Beyond High School. Colleges and other post-secondary educational institutions should require that all entering students have documentation of evidence of measles immunity (see Evidence of Immunity to Measles, p 574). Students without documentation of measles immunity should receive MMR vaccine on entry, followed by a second dose 28 days later, if not contraindicated.

¹ Centers for Disease Control and Prevention. Use of combination measles, mumps, rubella, and varicella vaccine: recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR Recomm Rep.* 2010;59(RR-3):1–12

Immunization During an Outbreak. During an outbreak, MMR vaccine should be offered to all vaccine-eligible people exposed or in the outbreak setting who lack evidence of measles immunity. During a community-wide outbreak that affects infants, MMR vaccine has been shown to be efficacious and may be recommended for infants 6 through 11 months of age (see Outbreak Control, p 585). Doses received prior to the first birthday do not count toward the recommended 2-dose series.

International Travel. People traveling internationally (any country outside of the United States) should be immune to measles prior to travel. Infants 6 through 11 months of age should receive 1 dose of MMR vaccine at least 2 weeks before departure if possible, and then should receive a second dose of measles-containing vaccine at 12 through 15 months of age (at least 28 days after the initial measles immunization) and a third dose at 4 through 6 years of age. Children 12 months or older as well as adults who have received 1 dose and are traveling to areas where measles is endemic or epidemic should receive their second dose before departure, provided the interval between doses is 28 days or more.

International Adoptees. The US Department of State requires that internationally adopted children 10 years and older receive MMR vaccine before entry into the United States. Internationally adopted children who are younger than 10 years are exempt from Immigration and Nationality Act regulations pertaining to immunization of immigrants before arrival in the United States (see Children Who Received Immunizations Outside the United States or Whose Immunization Status is Unknown or Uncertain, p 119); adoptive parents are required to sign a waiver indicating their intention to comply with US immunization recommendations after their child's arrival in the United States.

Health Care Personnel.¹ Adequate presumptive evidence of immunity to measles for people who work in health care facilities is: (1) documented administration of 2 doses of live-virus measles vaccine with the first dose administered at ≥ 12 months of age and the second dose at least 28 days after the first; (2) laboratory evidence of immunity or laboratory confirmation of disease; or (3) birth before 1957. Birth before 1957 is not a guarantee of measles immunity, and therefore, facilities should consider vaccinating unimmunized personnel born before 1957 who lack laboratory evidence of immunity with 2 doses of MMR vaccine at the appropriate interval (see Immunization in Health Care Personnel, p 115). For recommendations during an outbreak, see Outbreak Control (p 585).

Adverse Events. A body temperature of 39.4°C (103°F) or higher develops in approximately 5% to 15% of vaccine recipients, usually between 5 and 12 days after receipt of MMR vaccine; fever generally lasts 1 to 2 days but may last as long as 5 days. Most people with fever do not have other symptoms. Transient rashes have been reported in approximately 5% of vaccine recipients. Although recipients who develop fever and/or rash are not considered contagious and are not at risk for long-term sequelae of measles, suspicion for wild-type measles may be high, especially if vaccine was administered as part of an outbreak response. Therefore, rapid differentiation of vaccine reactions from infections with wild-type virus is critical for guiding the public health response to outbreaks. Vaccine reactions can be laboratory confirmed by detecting

¹ Centers for Disease Control and Prevention. Immunization of health-care personnel: recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR Recomm Rep*. 2011;60(RR-07):1–45

measles vaccine virus in respiratory secretions or urine followed by sequencing to determine genotype or by use of a NAAT for specific detection of measles vaccine strains (MeVa) that is available at the CDC and through state health departments.

Febrile seizures 5 to 12 days after immunization occur in 1 in 3000 to 4000 people immunized with MMR vaccine. Transient thrombocytopenia occurs in 1 in 22 000 to 40 000 people after administration of measles-containing vaccines, specifically MMR (see Thrombocytopenia, p 583). There is no evidence that reimmunization increases the risk of adverse events in people already immune to these diseases. Data indicate that only people who are not immune to the viruses in MMR tend to have adverse effects. Thus, events following a second dose of MMR vaccine would be expected to be substantially lower than after a first dose because most people who received a first dose would be immune.

Rates of most local and systemic adverse events for children immunized with MMRV vaccine are comparable with rates for children immunized with MMR and varicella vaccines administered concomitantly. However, recipients of a first dose of MMRV vaccine have a greater rate of fever 102°F (38.9°C) or higher than do recipients of MMR and varicella vaccine administered concomitantly (22% vs 15%, respectively). Febrile seizures occur in 1 in 1100 to 1400 children immunized with a first dose of MMRV vaccine at 12 through 23 months of age and in 1 in 2500 to 3000 children immunized with a first dose of MMR and varicella vaccines administered separately at the same visit. The period of risk for febrile seizures is from 5 to 12 days following receipt of the vaccine. The benefit of using MMRV instead of MMR and monovalent varicella vaccines separately is that the quadrivalent product results in 1 fewer injection. Either MMRV or separate MMR and varicella vaccines are an acceptable option for dose 1 at 12 through 15 months of age and pediatricians should discuss risks and benefits of the vaccine choices with the parents or caregivers. For the first dose of measles, mumps, rubella, and varicella vaccines at ages 48 months and older and for dose 2 at any age (15 months through 12 years), use of MMRV vaccine generally is preferred over separate injections of MMR and varicella vaccines to minimize the number of injections.

The reported frequency of central nervous system conditions, such as encephalitis and encephalopathy, after measles immunization is less than 1 per million doses administered in the United States. Because the incidence of encephalitis or encephalopathy after measles immunization in the United States is lower than the observed incidence of encephalitis of unknown cause, some or most of the rare reported severe neurologic disorders may be related temporally, rather than causally, to measles immunization. Multiple studies, as well as the National Academy of Medicine Vaccine Safety Review, refute a causal relationship between autism and MMR vaccine or between inflammatory bowel disease and MMR vaccine.

Precautions and Contraindications.

Febrile Illnesses. Children with minor illnesses, such as upper respiratory tract infections, may be immunized. Fever is not a contraindication to immunization. However, if other manifestations suggest a more serious illness, immunization should be deferred until the illness has resolved.

Allergic Reactions. Hypersensitivity reactions occur rarely and usually are minor, consisting of wheal-and-flare reactions or urticaria at the injection site. Reactions have been attributed to trace amounts of neomycin or gelatin or some other component in

the vaccine formulation. Anaphylaxis is rare. Measles vaccine is produced in chicken embryo cell culture and does not contain significant amounts of egg white (ovalbumin) cross-reacting proteins. Children with egg allergy are at low risk of anaphylactic reactions to measles-containing vaccine (including MMR and MMRV). Skin testing of children for egg allergy is not predictive of reactions to MMR vaccine and is not recommended before administering MMR or other measles-containing vaccine. People with allergies to chickens or feathers are not at increased risk of reaction to the vaccine.

Measles-containing vaccine should not be administered to people who have had a severe allergic reaction to a previous dose of measles-containing vaccine or to a vaccine component.

Thrombocytopenia. Rarely, MMR vaccine can be associated with mild thrombocytopenia within 2 months of immunization, with a temporal clustering 2 to 3 weeks after immunization. Most cases of thrombocytopenia resolve within 1 week. Based on case reports, the risk of vaccine-associated thrombocytopenia may be higher for people who previously experienced thrombocytopenia, especially if it occurred in temporal association with earlier MMR immunization. The decision to immunize these children should be based on assessment of immunity after the first dose and the benefits of protection against measles, mumps, and rubella in comparison with the risks of recurrence of thrombocytopenia after immunization. The risk of thrombocytopenia is higher after the first dose of vaccine than after the second dose. There have been no reported cases of thrombocytopenia associated with receipt of MMR vaccine that have resulted in hemorrhagic complications or death in otherwise healthy people.

Recent Administration of IG or Other Blood Products. IG preparations interfere with the serologic response to measles vaccine for variable periods, depending on the dose of IG administered. Suggested intervals between IG or blood-product administration and measles immunization are provided in Table 1.11 (p 69). If vaccine is administered at intervals shorter than those indicated, as may be warranted if the risk of exposure to measles is imminent, the child should be reimmunized at or after the appropriate interval for immunization (and at least 28 days after the earlier immunization).

MMR vaccine should be administered at least 2 weeks before planned administration of IG, blood transfusion, or other blood products because of the theoretical possibility that antibody in those products could neutralize vaccine virus and interfere with successful immunization. If IG must be administered within 14 days after administration of MMR or MMRV, these vaccines should be administered again after the interval specified in Table 1.11 (p 69).

Tuberculosis. Tuberculin skin testing or interferon gamma release assay (IGRA) testing is not a prerequisite for MMR immunization. Antituberculosis therapy should be initiated before administering MMR vaccine to people with untreated tuberculosis infection or disease. Tuberculin skin or IGRA testing, if otherwise indicated, can be performed on the day of immunization with MMR vaccine. Otherwise, tuberculin skin or IGRA testing should be postponed for 4 to 6 weeks, because measles immunization temporarily may suppress tuberculin skin test reactivity and possibly affect IGRA testing.

Altered Immunity. Immunocompromised patients with disorders associated with increased severity of viral infections should not receive live-virus measles vaccine (the

exception is people with HIV infection, unless they have evidence of severe immunosuppression; see Immunization and Other Considerations in Immunocompromised Children, p 93, and HIV Infection, below). The risk of exposure to measles for immunocompromised patients can be decreased by immunizing their close susceptible contacts. Immunized people do not shed or transmit infectious measles vaccine virus. Management of immunodeficient and immunosuppressed patients exposed to measles can be facilitated by previous knowledge of their immune status. If possible, children should receive measles vaccine before initiating treatment with biologic response modifiers, such as tumor necrosis factor antagonists, and before transplantation, ideally with 2 doses. Severely immunocompromised patients should receive IG after measles exposure regardless of immunologic or vaccination status (see Care of Exposed People, p 574, Table 3.32, and Table 3.33).

Corticosteroids. For patients who have received high doses of corticosteroids (≥ 2 mg/kg of body weight or ≥ 20 mg/day of prednisone or its equivalent for people who weigh ≥ 10 kg) for 14 days or more and who otherwise are not immunocompromised, the recommended interval between stopping the corticosteroids and immunization is at least 4 weeks (see Immunization and Other Considerations in Immunocompromised Children, p 93). In general, inhaled steroids do not cause immunosuppression and are not a contraindication to measles immunization.

HIV Infection.¹ Measles immunization (administered as MMR vaccine) is recommended for all people ≥ 12 months of age with HIV who do not have evidence of measles immunity and who do not have evidence of severe immunosuppression, because measles can be severe and sometimes is fatal in patients with HIV (see Human Immunodeficiency Virus Infection, p 489). For vaccination purposes, severe immunosuppression for people ≤ 5 years of age is defined as a CD4+ T-lymphocyte percentage $< 15\%$, and for people > 5 years of age is defined as a CD4+ T-lymphocyte percentage $< 15\%$ **or** a CD4+ T-lymphocyte count < 200 lymphocytes/mm³. Severely immunocompromised HIV-infected infants, children, adolescents, and young adults should not receive measles virus-containing vaccine. MMRV vaccine should not be administered to any infant or child with HIV, regardless of degree of immunosuppression, because of lack of safety data in this population. Children, adolescents, and adults with newly diagnosed HIV and without evidence of measles immunity should complete a 2-dose schedule with MMR vaccine as soon as possible after diagnosis, unless they have evidence of severe immunosuppression. People with perinatally acquired HIV who were vaccinated against measles prior to the establishment of effective ART should be considered unvaccinated and should be revaccinated with 2 doses of MMR vaccine once effective ART has been administered, unless they have other acceptable current evidence of measles immunity or unless they are severely immunocompromised. All members of the household of an HIV-infected person who lack evidence of measles immunity should receive 2 doses of MMR.

Personal or Family History of Seizures. Children with a personal or family history of seizures should be immunized after parents or guardians are advised that the risk of seizures after measles immunization is increased slightly. Children receiving anticonvulsants should continue such therapy after measles immunization.

¹ Rubin LG, Levin MJ, Ljungman P, et al. 2013 IDSA clinical practice guideline for vaccination of the immunocompromised host. *Clin Infect Dis.* 2014;58(3):309-318

Pregnancy. Measles-containing vaccine should not be administered to people known to be pregnant. People who receive MMR vaccine should not become pregnant for at least 28 days. This precaution is based on the theoretical risk of fetal infection, which applies to administration of any live-virus vaccine to people who might be pregnant or who might become pregnant shortly after immunization. No data from people who were inadvertently vaccinated while pregnant substantiate this theoretical risk. When immunizing adolescents and young adults against measles, recommended precautions include asking if they are pregnant, excluding people who are pregnant, and explaining the theoretical risks to others who may become pregnant. Pregnancy testing prior to immunization is not required.

Outbreak Control. Every suspected measles case should be reported immediately to the local health department, and every effort must be made to obtain laboratory evidence that would confirm that the illness is measles, especially if the illness may be the first case in the community. Subsequent prevention of spread of measles depends on prompt immunization of people at risk of exposure or people already exposed. People who have not been immunized, including those who have been exempted from measles immunization for medical reasons, should be excluded from school, child care, and health care settings until at least 21 days after the onset of rash in the last case of measles involved in the outbreak.

Schools and Child Care Facilities. During measles outbreaks in child care facilities, schools, and colleges and other institutions of higher education, all students, their siblings, and personnel born in 1957 or after who cannot provide evidence of measles immunity should be immunized. People receiving their second dose, as well as unimmunized people receiving their first dose as part of the outbreak-control program, may be readmitted immediately to the school or child care facility.

Health Care Facilities. If an outbreak occurs in an area served by a hospital or within a hospital, all employees and volunteers who cannot provide evidence of immunity to measles should receive 2 doses of MMR vaccine. Because some health care personnel born before 1957 have acquired measles in health care facilities, immunization with 2 doses of MMR vaccine is recommended for health care personnel without serologic evidence of immunity in this age category during outbreaks. Serologic testing before immunization is not recommended during an outbreak because rapid immunization is required to halt disease transmission. Health care personnel without evidence of immunity who have been exposed should be relieved of direct patient contact from the fifth day after the first exposure to the 21st day after the last exposure, regardless of whether they received vaccine or IG after the exposure. Health care personnel who become ill should be relieved of patient contact until 4 days after rash develops.

Meningococcal Infections

CLINICAL MANIFESTATIONS: Invasive meningococcal infection usually results in septicemia (35%–40% of cases), meningitis (~50% of cases), or both. Bacteremic pneumonia is less common (10% of cases). Rarely, *Neisseria meningitidis* is identified as a cause of occult bacteremia. The onset of invasive infections can be insidious and nonspecific, but the onset of septicemia (meningococcemia) typically is abrupt, with fever, chills, malaise, myalgia, limb pain, prostration, and a rash that initially can be macular or maculopapular but typically becomes petechial or purpuric within hours.

A similar rash can occur with viral infections or with severe sepsis attributable to other bacterial pathogens. In fulminant cases, purpura, limb ischemia, coagulopathy, pulmonary edema, shock, coma, and death can ensue within hours despite appropriate management. Signs and symptoms of meningococcal meningitis are indistinguishable from those associated with pneumococcal meningitis. In severe and fatal cases of meningococcal meningitis, increased intracranial pressure is a predominant presenting feature. Invasive infections can be complicated by arthritis, myocarditis, pericarditis, and endophthalmitis. Noninvasive meningococcal infections, such as conjunctivitis and urethritis, also occur. Chronic meningococcemia is a rare syndrome, mostly seen in young adults, that is characterized by a more prolonged course (>7 days) with intermittent fever, migratory arthralgia, and cutaneous lesions (erythematous macules, papules, nodules, petechiae, or purpura).

The overall case fatality rate for invasive meningococcal disease is 15% and is somewhat higher in older adults. Clinical predictors of mortality include coma, hypotension, leukopenia, and thrombocytopenia. A self-limiting postinfectious inflammatory syndrome occurs in fewer than 10% of cases, begins a minimum 4 days after onset of meningococcal infection, and most commonly presents as fever and arthritis or vasculitis with less common manifestations including iritis, scleritis, conjunctivitis, pericarditis, and polyserositis.

Sequelae associated with meningococcal disease occur in up to 20% of survivors and include hearing loss, neurologic disability, digit or limb amputations, and skin scarring. In addition, patients may experience subtle long-term neurologic deficits, such as impaired school performance, behavioral problems, and attention-deficit/hyperactivity disorder.

ETIOLOGY: *Neisseria meningitidis* is a gram-negative diplococcus with 12 confirmed serogroups based on capsular type.

EPIDEMIOLOGY: *N meningitidis* disease rates are highest in infants <1 year of age, followed by children 1 to 4 years of age, the very elderly (≥ 85 years), and adolescents and young adults 16 to 23 years of age. Household contacts of cases have 500 to 800 times the rate of disease of the general population. A predominance of US cases is observed in the winter, often noted 2 to 3 weeks following onset of influenza outbreaks, with a peak of cases in January, February, and March. Patients with persistent complement-component deficiencies (eg, C3, C5–C9, properdin, or factor D or factor H deficiencies), with anatomic or functional asplenia or human immunodeficiency virus infection (HIV), or treated with eculizumab or similar complement inhibitors are at increased risk of invasive and recurrent meningococcal disease. Asymptomatic colonization of the upper respiratory tract is most common in older adolescents and young adults and is the reservoir from which the organism is spread. Transmission occurs from person to person through droplets from the respiratory tract and requires close contact. Patients should be considered capable of transmitting the organism for up to 24 hours after initiation of effective antimicrobial treatment.

Distribution of meningococcal serogroups in the United States has shifted in the past 2 decades. Serogroups B accounts for most cases currently, followed by serogroups C, W, and Y and nongroupable (nonencapsulated) meningococci. Serogroup distribution varies by age, location, and time. In infants and children younger than 60 months, approximately two thirds of cases are caused by serogroup B. More than 75% of cases

among adolescents and young adults are caused by serogroups B, C, Y, or W and, therefore, potentially are preventable with available vaccines.

Since the early 2000s, annual incidence rates for invasive meningococcal disease have decreased, and during 2019 approximately 375 cases occurred (incidence of 0.11 per 100 000 population) in the United States. The decrease in cases in the United States started before the 2005 introduction of ACWY meningococcal conjugate vaccine into the routine immunization schedule at age 11 through 12 years and the 2010 recommendation for a booster vaccine at age 16 years. Reasons for this decrease in incidence are postulated to be related to the increased use of influenza vaccine, reduction in the carriage rates, the use of meningococcal conjugate vaccines in preadolescents and adolescents, and changes in behavioral risk factors (eg, decreases in smoking and exposure to secondhand smoke among adolescents and young adults).

Strains belonging to groups A, B, C, W, X, and Y are implicated most commonly in invasive disease worldwide. Serogroup A has historically been associated with epidemics outside the United States, primarily in sub-Saharan Africa. A serogroup A meningococcal conjugate vaccine was introduced in the “meningitis belt” of sub-Saharan Africa starting in December 2010, and its widespread use has been associated with a marked reduction in serogroup A disease rates; recent outbreaks in the meningitis belt have been associated with serogroups C, W, and X. In Europe, Australia, and South America, the incidence of meningococcal disease ranged from 0.3 to 2 cases per 100 000 population in recent years. Serogroups B, C, W, and Y are most commonly reported in these regions. Rates of meningococcal disease declined globally (~70%) in 2020 during the COVID-19 pandemic; these declines may have been the result of masking, social distancing, and other measures controlling respiratory droplet spread.

Most cases of meningococcal disease are sporadic, with fewer than 10% associated with outbreaks. Outbreaks occur in communities and institutions, including child care centers, schools, colleges, and military recruit camps. Multiple outbreaks of serogroup B meningococcal disease have occurred on college campuses, and outbreaks of serogroup C meningococcal disease have been reported among men who have sex with men and among people lacking housing.

The **incubation period** for invasive disease is 1 to 10 days, usually less than 4 days.

DIAGNOSTIC TESTS: Cultures of blood and cerebrospinal fluid (CSF) are indicated for patients with suspected invasive meningococcal disease. Cultures of a petechial or purpuric lesion scraping, synovial fluid, and other usually sterile body fluid specimens sometimes are positive. Specimens for culture should be plated onto both sheep blood and chocolate agar and incubated at 35°C to 37°C with 5% carbon dioxide in a moist atmosphere. The organism is readily identified with standard biochemical tests as well as by the newer method of mass spectrometry of bacterial cell components. Antimicrobial susceptibility testing of invasive isolates is useful because of the occurrence of beta-lactamase producing strains and fluoroquinolone-resistant strains (ciprofloxacin is one of the agents used for prophylaxis of close contacts; antimicrobial testing should not delay administration of prophylaxis). A Gram stain of a petechial or purpuric scraping, CSF, or buffy coat smear of blood may reveal gram negative diplococci. Because *N meningitidis* can be a component of the nasopharyngeal flora, isolation of *N meningitidis* from this site is not helpful diagnostically. A serogroup-specific nucleic acid amplification test (NAAT) to detect *N meningitidis* from clinical specimens from

Table 3.35. Surveillance Case Definitions for Invasive Meningococcal Disease^a

Confirmed case

- Detection of *Neisseria meningitidis*-specific nucleic acid in a specimen obtained from a normally sterile body site (eg, blood or cerebrospinal fluid [CSF]) using a validated polymerase chain reaction assay; or
- Isolation of *N meningitidis*
 - ♦ From a normally sterile body site (eg, blood or CSF, or less commonly, synovial, pleural, or pericardial fluid); or
 - ♦ From purpuric lesions

Probable case

- Detection of *N meningitidis* antigen
 - ♦ In formalin-fixed tissue by immunohistochemistry; or
 - ♦ In CSF by latex agglutination

Suspect case

- Clinical purpura fulminans in the absence of a positive blood culture; or
- Gram-negative diplococci, not yet identified, isolated from a normally sterile body site (eg, blood or CSF)

^a<https://ndc.services.cdc.gov/case-definitions/meningococcal-disease-2015/>

usually sterile sites (eg, CSF) is useful particularly in patients who receive antimicrobial therapy before cultures are obtained. In the United States, commercially available multiplex polymerase chain reaction (PCR) assays have excellent sensitivity and specificity for detection of serogroups A, B, C, W, X, and Y. Antigen detection tests, primarily by latex agglutination, to detect select meningococcal polysaccharide types in CSF were developed more than 3 decades ago. These assays no longer are commonly used in the United States because of concerns about test sensitivity and specificity.

Surveillance case definitions for invasive meningococcal disease are provided in Table 3.35. Serologic typing and other characterization such as whole genome sequencing and genomic typing can be useful epidemiologic tools during a suspected outbreak to detect concordance among invasive strains.

TREATMENT: The priority in management of meningococcal disease is treatment of shock in meningococcemia and of raised intracranial pressure in severe meningitis. Empirical therapy for suspected meningococcal disease should include cefotaxime or ceftriaxone. Once the microbiologic diagnosis is established, treatment options include cefotaxime, ceftriaxone, penicillin G, or ampicillin. A course of 5 to 7 days of antimicrobial therapy is adequate. Because of recent detections of β -lactamase-producing *N meningitidis* in the United States, meningococcal isolate susceptibility to penicillin should be determined before switching to penicillin or ampicillin.¹ Ceftriaxone clears nasopharyngeal carriage effectively after 1 dose. For patients with a life-threatening penicillin allergy characterized by anaphylaxis, meropenem can be used with caution as the rate of cross-reactivity in penicillin-allergic adults is very low. In meningococcemia, early and rapid fluid resuscitation and early use of inotropic and ventilatory

¹ McNamara LA, Potts C, Blain AE, et al. Detection of ciprofloxacin-resistant, β -lactamase-producing *Neisseria meningitidis* serogroup Y isolates—United States, 2019–2020. *MMWR Morb Mortal Wkly Rep.* 2020;69(24):735–739

support may reduce mortality. The postinfectious inflammatory syndromes associated with meningococcal disease often respond to nonsteroidal anti-inflammatory drugs. Treating physicians should consider evaluating for conditions that increase risk of disease, such as underlying complement component deficiencies. In some studies, underlying complement deficiency has been identified in up to 10% to 50% of patients with meningococcal disease, although no recent data are available on complement deficiency prevalence among US patients with meningococcal disease.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, droplet precautions are recommended until 24 hours after initiation of effective antimicrobial therapy.

CONTROL MEASURES:

Care of Exposed People.

Postexposure Chemoprophylaxis. Regardless of immunization status, close contacts including household contacts of all people with invasive meningococcal disease (see Table 3.36), whether endemic or in an outbreak situation, are at high risk of infection and should promptly receive chemoprophylaxis. Chemoprophylaxis should be provided even if the close contact has received a meningococcal vaccine. The decision to administer chemoprophylaxis to other contacts is based on risk of contracting invasive disease related to specific exposure to the secretions from the infected patient. Throat and nasopharyngeal cultures are not recommended, because these cultures are of no value in deciding who should receive chemoprophylaxis.

Table 3.36. Disease Risk for Contacts of People With Invasive Meningococcal Disease

High risk: chemoprophylaxis recommended (close contacts)

- Household contact
- Child care or preschool contact at any time during 7 days before onset of illness
- Direct exposure to index patient's secretions through kissing or through sharing toothbrushes or eating utensils, markers of close social contact, at any time during 7 days before onset of illness
- Mouth-to-mouth resuscitation, unprotected contact during endotracheal intubation at any time from 7 days before onset of illness to 24 h after initiation of effective antimicrobial therapy
- Frequently slept in same dwelling as index patient during 7 days before onset of illness
- Passengers seated directly next to the index case during airline flights lasting more than 8 hours (gate to gate), or passengers seated within one seat in any direction from an index case on a flight of any duration if the index case was coughing or vomiting during the flight

Low risk: chemoprophylaxis not recommended

- Casual contact: no history of direct exposure to index patient's oral secretions (eg, school or work)
- Indirect contact: only contact is with a high-risk contact, no direct contact with the index patient
- Health care personnel without direct exposure to patient's oral secretions

In outbreak or cluster

- Chemoprophylaxis for people other than people at high risk (close contacts) should be administered only after consultation with local public health authorities

Table 3.35 provides the surveillance case definition for invasive meningococcal disease. Table 3.36 provides prophylaxis recommendations for contacts of a person with invasive meningococcal disease, and Table 3.37 provides recommended prophylaxis regimens. Routine prophylaxis is not recommended for health care personnel unless they have had intimate exposure to respiratory tract secretions, such as occurs with unprotected mouth-to-mouth resuscitation, intubation, or suctioning before or

Table 3.37. Recommended Chemoprophylaxis Regimens for High-Risk Contacts and People With Invasive Meningococcal Disease

Age of Infants, Children, and Adults	Dose	Duration	Efficacy, %	Cautions
Rifampin ^a				
<1 mo	5 mg/kg per dose, orally, every 12 h	2 days		Discussion with an expert for infants <1 mo
≥1 mo	10 mg/kg per dose (maximum 600 mg), orally, every 12 h	2 days	90–95	Can interfere with efficacy of oral contraceptives and some seizure and anticoagulant medications; can stain soft contact lenses
Ceftriaxone				
<15 y	125 mg, intramuscularly	Single dose	90–95	To decrease pain at injection site, dilute with 1% lidocaine
≥15 y	250 mg, intramuscularly	Single dose	90–95	To decrease pain at injection site, dilute with 1% lidocaine
Ciprofloxacin ^{a,b}				
≥1 mo	20 mg/kg (maximum 500 mg), orally	Single dose	90–95	
Azithromycin	10 mg/kg (maximum 500 mg)	Single dose	90	<u>Not</u> recommended routinely; equivalent to rifampin for eradication of <i>Neisseria meningitidis</i> from nasopharynx in one study of young adults

^aNot recommended for use in pregnant people.
^bIf fluoroquinolone-resistant strains of *N meningitidis* have been identified in a community, refer to Table 3.38.

Table 3.38. Recommended Approach to Chemoprophylaxis When Ciprofloxacin-Resistant Invasive Isolates Have Been Detected^a

- Consult local or state public health officials on whether ciprofloxacin-resistant isolates have been detected and discuss approach (which may be refined depending on local epidemiology)
- Discontinue use of ciprofloxacin for prophylaxis of close contacts when both of the following threshold criteria have been met in the catchment area during a rolling 12-month period:
 - Two or more invasive meningococcal disease cases caused by ciprofloxacin-resistant strains have been reported, and
 - Cases caused by ciprofloxacin-resistant strains make up at least 20% of all reported invasive meningococcal disease cases
- Prescribe rifampin, ceftriaxone, or azithromycin instead of ciprofloxacin as prophylaxis when the threshold criteria have been reached
- Implement updated prophylaxis guidance in all counties within the catchment area (or other geographic area as determined by local or state public health officials)
- Maintain updated prophylaxis guidance until a full 24 months have passed without any invasive meningococcal disease cases caused by ciprofloxacin-resistant strains having been reported in the catchment area

^aAdapted from www.cdc.gov/meningococcal/outbreaks/changing-prophylaxis-antibiotics.html.

less than 24 hours after antimicrobial therapy was initiated. Chemoprophylaxis ideally should be initiated within 24 hours after the index patient is identified; prophylaxis is not indicated if more than 2 weeks have passed since the last exposure. If antimicrobial agents other than ceftriaxone or cefotaxime (each of which will eradicate nasopharyngeal carriage) are used for treatment of invasive meningococcal disease, the index patient should receive chemoprophylaxis before hospital discharge to eradicate nasopharyngeal carriage of *N meningitidis*.

Ciprofloxacin-resistant strains of *N meningitidis* have been detected over the past 17 years.^{1,2} Prophylaxis failures and antimicrobial resistance among meningococcal isolates should be monitored and reported to the local or state public health department to inform meningococcal prophylaxis recommendations. The Centers for Disease Control and Prevention (CDC) has provided guidance on meningococcal disease prophylaxis in areas with ciprofloxacin resistance (see Table 3.38 and www.cdc.gov/meningococcal/outbreaks/changing-prophylaxis-antibiotics.html).

Meningococcal Vaccines. In the United States, 3 meningococcal vaccines are licensed and available for use in children and adults against serogroups A, C, W, and Y (MenACWY), and 2 vaccines are licensed for people 10 through 25 years of age against serogroup B (MenB). All 3 MenACWY vaccines are protein-polysaccharide conjugate vaccines, while the 2 MenB vaccines are protein-based vaccines using 2 different technologies. In addition, the US Food and Drug Administration licensed a MenABCWY pentavalent meningococcal vaccine on October 20, 2023, for persons 10 through

Table 3.39. Recommended Meningococcal Vaccines for Immunocompetent Children and Adults^a

Age	Vaccine	Status
Meningococcal ACWY Vaccines		
2 mo through 10 y	MenACWY-D ^b (Menactra) or MenACWY-CRM ^c (Menveo) or MenACWY-TT ^d (MenQuadfi)	Not routinely recommended; see Table 3.40 (p 594) for recommendations for people at increased risk
11 through 21 y	MenACWY-D or MenACWY-CRM or MenACWY-TT	• 11 through 18 y of age, with first dose at age 11–12 y and booster dose at age 16 y (give booster only if first dose administered prior to 16th birthday) • 19 through 21 y of age, not routinely recommended but may be administered as catch-up immunization for those who have not received a dose after their 16th birthday or who become at increased risk for meningococcal disease
Meningococcal B Vaccines		
10 y through 15 y	MenB-FHbp ^e (Trumenba) or MenB-4C ^f (Bexsero)	Not routinely recommended see Table 3.40 (p 594) for recommendations for people at increased risk
16 y through 23 y	MenB-FHbp or MenB-4C	• Administer based on shared clinical decision-making with preferred age of 16 y through 18 y and 2-dose series recommended • For MenB-4C (Bexsero), dose 1 administered initially, then followed by dose 2 administered ≥1 month later • For MenB-FHbp (Trumenba), dose 1 administered initially, then followed by dose 2 administered 6 months later; in setting of serogroup B meningococcal outbreak, a 3-dose vaccine series administered at 0, 1–2, and 6 months See Table 3.40 (p 594) for recommendations for people at increased risk

Table 3.39. Recommended Meningococcal Vaccines for Immunocompetent Children and Adults,^a continued

Age	Vaccine	Status
Meningococcal ABCWY Vaccine		
10 through 25 y	MenABCWY ^g	May be used when both MenACWY and MenB are indicated at the same visit ^h

^aPlease see full recommendations on Meningococcal Vaccination: Recommendations of the Advisory Committee on Immunization Practices, United States, 2020 at www.cdc.gov/mmwr/volumes/69/rr/rr6909a1.htm

^bLicensed for people 9 months through 55 years of age but should not be used before 2 y of age in patients with asplenia or HIV to avoid interference with the immune response to the pneumococcal conjugate vaccine. In all patients (not just those with asplenia or HIV infection), administration of MenACWY-D 30 days after diphtheria and tetanus toxoids and acellular pertussis (DTaP) vaccine interferes with the immune response for all four meningococcal serogroups; therefore, MenACWY-D should be administered either before or at the same time as DTaP, or alternatively one of two other MenACWY vaccines could be used.

^cLicensed for people 2 months through 55 years of age.

^dLicensed for people 2 years of age and older.

^eLicensed for people 10 years through 25 years of age.

^fLicensed for people 10 years through 25 years of age.

^gComposed of MenACWY-TT (Nimenrix) and MenB-FHbp (Trumenba).

^h1) Healthy individuals aged 16–23 years of age (routine schedule) when shared clinical decision making favors administration of MenB vaccination; or 2) individuals aged 10 years and older at increased risk of meningococcal disease (eg, because of persistent complement deficiencies, complement inhibitor use, or functional or anatomic asplenia) for whom both vaccines are due.

25 years of age; it is composed of Pfizer's Trumenba (serogroup B) and Nimenrix (serogroups ACWY) vaccines. Tables 3.39 and 3.40 provide recommendations on meningococcal vaccines.

Serogroup A, C, W, and Y Vaccines. Meningococcal groups A, C, W, and Y polysaccharide diphtheria toxoid conjugate vaccine (MenACWY-D [Menactra]) is licensed for use in people 9 months through 55 years of age. Meningococcal groups A, C, W, and Y oligosaccharide diphtheria CRM₁₉₇ conjugate vaccine (MenACWY-CRM [Menveo]) is licensed for use in people 2 months through 55 years of age. Meningococcal groups A, C, W, and Y polysaccharide tetanus toxoid conjugate vaccine (MenACWY-TT [MenQuadfi]) is licensed for use in people 2 years and older. Each is administered intramuscularly as a 0.5-mL dose. Dosing during the primary series varies by product, age, and underlying risk for disease.

Recommendations for use of MenACWY vaccine are as follows¹ (Tables 3.39 and 3.40):

- Adolescents should be immunized routinely with 1 dose at the 11- through 12-year health care visit (see https://redbook.solutions.aap.org/SS/Immunization_Schedules.aspx), when immunization status and other preventive health services can be addressed. A booster dose at 16 years of age is recommended for adolescents immunized at 11 through 12 years of age.
- Adolescents who receive their first dose at age 13 to 15 years should receive a booster dose at age 16 to 18 years; the booster dose can be administered at any time, as long as a minimum interval of 8 weeks between doses is maintained.
- Adolescents who receive a first dose after their 16th birthday do not need a booster dose unless they become at increased risk for meningococcal disease.

¹Mbaeyi SA, Bozio CH, Duffy J, et al. Meningococcal vaccination: recommendations of the Advisory Committee on Immunization Practices, United States, 2020. *MMWR Recomm Rep.* 2020;69(RR-9):1–41

Table 3.40. Recommended Immunization Schedule and Intervals for People at Increased Risk of Invasive Meningococcal Disease^{a,b,c}

Age	Subgroup	Primary Immunization	Booster Dose
Meningococcal ACWY Vaccines			
2 through 23 mo of age	Children who: • have persistent complement deficiencies (including complement inhibitor use) • have functional or anatomic asplenia • have human immunodeficiency virus (HIV) infection • travel to or are residents of countries where meningococcal disease is hyperendemic or epidemic • are at risk during a community outbreak attributable to an A,C,W,Y vaccine serogroup	MenACWY-CRM (Menveo): 4 doses at 2, 4, 6, and 12 mo In children initiating vaccination at 7 through 23 mo of age, MenACWY-CRM is to be administered as a 2-dose series, with the second dose administered in the second year of life and at least 3 mo after the first dose MenACWY-D (Menactra): MenACWY-D SHOULD NOT BE USED before 2 y of age in children with asplenia or HIV to avoid interference with the immune response to the pneumococcal conjugate vaccine (PCV) series For children aged ≥9 mo who are at increased risk because of complement deficiency, travel or an outbreak, MenACWY-D can be administered as a 2-dose series at 9 and 12 months (3 months apart; may be administered ≥8 weeks apart in travelers) MenACWY-TT (MenQuadfi): SHOULD NOT BE USED before 2 y of age because not approved in this age group	Person remains at increased risk and first dose received at age: • 2 mo through 6 y of age: Should receive additional dose of MenACWY 3 y after primary immunization. Boosters should be repeated every 5 y.^d

Table 3.40. Recommended Immunization Schedule and Intervals for People at Increased Risk of Invasive Meningococcal Disease,^{a,b,c} continued

Age	Subgroup	Primary Immunization	Booster Dose
≥2 y ^f	People who: • have persistent complement deficiencies • have functional or anatomic asplenia • have HIV infection	2 doses of either MenACWY-CRM or MenACWY-D^e or MenACWY-TT , 8–12 wk apart MenACWY-D (Menactra) may be used if at least 4 wk after completion of PCV doses	• 2 y through 6 y of age: Should receive additional dose of MenACWY 3 y after primary immunization. Boosters should be repeated every 5 y.^d
≥2 y ^f	People who: • are at risk during a community outbreak attributable to an A,C,W,Y vaccine serogroup • travel to or are residents of countries where meningococcal disease is hyperendemic or epidemic • college freshmen living in residence halls and military recruits • are laboratory workers routinely exposed to isolates of <i>Neisseria meningitidis</i>	1 dose of MenACWY-CRM or MenACWY-D^e or MenACWY-TT	• ≥7 y of age: should receive an additional dose of MenACWY 5 y after primary immunization. Boosters should be repeated every 5 y.^d
Meningococcal B Vaccines			
≥10 y ^g	People who: • have persistent complement deficiencies (including complement inhibitor use) • have functional or anatomic asplenia	2-dose series of MenB-4C , ≥1 mo apart OR 3-dose series of MenB-FHbp , with 2 nd and 3 rd doses administered 1–2 and 6 mo after initial doses	For subgroup at increased risk: • Other than outbreak: booster^g 1 year following completion of a MenB primary series followed by MenB booster every 2–3 years thereafter.^d

Table 3.40. Recommended Immunization Schedule and Intervals for People at Increased Risk of Invasive Meningococcal Disease,^{a,b,c} continued

Age	Subgroup	Primary Immunization	Booster Dose
	- are laboratory workers routinely exposed to isolates of <i>N meningitidis</i> - are at increased risk, as determined by public health officials, because of a serogroup B meningococcal disease outbreak		For outbreak: booster^h if it has been ≥ 1 year since completion of a MenB primary series (≥ 6 months interval might also be considered by public health officials).

^aPlease see full recommendations on Meningococcal Vaccination: Recommendations of the Advisory Committee on Immunization Practices, United States, 2020 at www.cdc.gov/mmwr/volumes/69/rr/rr6909a1.htm

^bIncludes children who have persistent complement deficiencies (eg, C3, C5-C9, properdin, or factor D or factor H or receiving eculizumab or ravulizumab) or anatomic or functional asplenia; travelers to or residents of countries in which meningococcal disease is hyperendemic or epidemic; and children who are part of a community outbreak of a vaccine-preventable serogroup.

^cThe pentavalent MenACWY vaccine may be used when both MenACWY and MenB are indicated at the same visit: 1) healthy individuals aged 16–23 years of age (routine schedule) when shared clinical decision making favors administration of MenB vaccination; or 2) individuals aged 10 years and older at increased risk of meningococcal disease (eg, because of persistent complement deficiencies, complement inhibitor use, or functional or anatomic asplenia) for whom both vaccines are due.

^dIf person remains at increased risk of meningococcal disease.

^eWhen MenACWY-D and DTaP are being administered to children 4 through 6 years of age, preference should be given to simultaneous administration of the 2 vaccines or administration of MenACWY-D before administration of DTaP, because administration of MenACWY-D 1 month after Daptacel has been shown to reduce meningococcal antibody response to MenACWY-D. Alternatively, one of two other MenACWY vaccines could be used.

^fMeningococcal polysaccharide vaccine is no longer available in the United States.

^gAccording to the Advisory Committee on Immunization Practices, people >25 years who are at increased risk for meningococcal B disease can receive MenB vaccine (no preference for MenB vaccine, but the same vaccine should be used for full series).

^hThe same MenB vaccine should be used for boosters as was used in the primary series.

- People 19 to 21 years of age who have not received a dose after their 16th birthday can receive a single MenACWY dose as part of catch-up vaccination.
- Routine childhood immunization with meningococcal conjugate vaccines is not recommended for children 2 months through 10 years of age because of the low proportion of infections that are preventable with MenACWY vaccine.
- People at increased risk of invasive meningococcal disease (defined, by age, in the subgroup column of Table 3.40) should be immunized with a meningococcal conjugate vaccine beginning at 2 months of age. Table 3.40 also details dosing recommendations for each of the 3 MenACWY vaccines in these increased-risk populations.
- Because of their high risk for invasive pneumococcal disease, children with functional or anatomic asplenia or HIV infection should not be vaccinated with MenACWY-D (Menactra) before age 2 years to avoid interference with the immune response to pneumococcal conjugate vaccine; only MenACWY-CRM (Menveo) should be used in this group. MenACWY-TT (MenQuadfi) should not be used in this situation because it is only approved in children ≥ 2 years of age.

- When MenACWY-D (Menactra) is administered 30 days after diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP), it interferes with the immune response to all four meningococcal serogroups. Therefore, MenACWY-D (Menactra) should be administered either before or at the same time as DTaP. Alternatively, Menveo or MenQuadfi (if ≥ 2 years of age) may be administered instead of Menactra.

Serogroup B Meningococcal Vaccines. MenB-FHbp (Trumenba) is based on a surface-exposed lipoprotein named factor H binding protein (FHbp). MenB-FHbp can be administered as either a 2- or 3-dose series (0 and 6 months; or 0, 1–2, and 6 months), depending on risk factors for disease and on outbreak conditions (see Tables 3.39 and 3.40).

MenB-4C (Bexsero, GSK) contains 4 antigenic components: 1 FHbp fusion protein, NadA, NHBA fusion protein, and outer membrane vesicles. It is administered as a 2-dose series (0, ≥ 1 month [see Tables 3.39 and 3.40]).

Data on effectiveness against clinical disease endpoints and duration of protection for either vaccine in the age groups for which they are licensed in the United States are limited. Recommendations for use of a MenB vaccine are as follows¹ (Tables 3.39 and 3.40):

- People 10 years and older at increased risk for meningococcal disease should receive a MenB vaccine, using the same vaccine product for all doses in the vaccination series. Vaccination may further activate complement, and as a result, patients with complement-mediated diseases may experience increased symptoms of their underlying disease, such as hemolysis, following vaccination.
- A MenB vaccine series may be considered for people 16 through 23 years of age on the basis of shared clinical decision making (decided in the context of the provider-patient relationship and joint decision making), with a preferred age at vaccination of 16 through 18 years. If MenB vaccine is elected to be administered, the same vaccine product should be used for all doses. MenB vaccine may be administered with other vaccines at the same visit but at a different injection site.

Serogroup A, B, C, W, and Y Meningococcal Vaccine. A pentavalent meningococcal vaccine composed of Pfizer's Trumenba (serogroup B) and Nimenrix (serogroups ACWY) vaccines was licensed by the FDA on October 20, 2023, for persons 10 through 25 years of age. It may be used when both MenACWY and MenB are indicated at the same visit for: 1) healthy individuals aged 16 through 23 years of age (routine schedule) when shared clinical decision making favors administration of MenB vaccination; or 2) individuals aged 10 years and older at increased risk of meningococcal disease (eg, because of persistent complement deficiencies, complement inhibitor use, or functional or anatomic asplenia) for whom both vaccines are due. The licensed B component vaccines are not interchangeable by manufacturer. Administration of a B component vaccine (MenB or MenABCWY) requires that subsequent B component vaccine doses be from the same manufacturer. The minimum interval for Pfizer's MenABCWY vaccine is 6 months. Individuals at increased risk of meningococcal disease who are recommended to receive additional doses of MenACWY and MenB less than 6 months after a dose of pentavalent meningococcal vaccine should instead receive separate MenACWY and MenB-FHbp vaccines.

Immunization During Eculizumab Therapy.¹ Use of complement inhibitors (eg, eculizumab [Soliris] and its long-acting derivative ravulizumab [Ultomiris]; monoclonal antibody therapies that block C5) is associated with a substantially increased risk for

¹ Mbaeyi SA, Bozio CH, Duffy J, et al. Meningococcal vaccination: recommendations of the Advisory Committee on Immunization Practices, United States, 2020. *MMWR Recomm Rep.* 2020;69(RR-9):1–41

meningococcal disease. Eculizumab use is associated with an approximately 2000-fold increased incidence of meningococcal disease. Eculizumab and ravulizumab recipients should receive both MenACWY and MenB vaccines. Because these monoclonal antibodies inhibit terminal complement activation and opsonophagocytic killing of meningococci, patients receiving them are still at risk for invasive meningococcal disease even if they develop antibodies following vaccination. Providers, therefore, should also consider antimicrobial prophylaxis (usually penicillin prophylaxis) for the duration of eculizumab or ravulizumab treatment and until immunocompetence is restored once the monoclonal antibody therapy is stopped, to potentially reduce the risk for meningococcal disease.

Reimmunization/Booster Doses. Children previously immunized with a meningococcal conjugate vaccine (ACWY or B) who are at ongoing increased risk for meningococcal disease should receive booster immunizations (see Table 3.40). If a child was vaccinated with MenACWY vaccine because of an outbreak or travel at <10 years of age, the adolescent doses are still needed. For MenB vaccine, the same vaccine product used in the primary series should be used for booster doses.

Immunization During Outbreaks. During an outbreak, additional cases can occur several weeks or more after onset of disease in the index case; therefore, meningococcal vaccine is recommended when an outbreak is caused by a serogroup prevented by a meningococcal vaccine.

Adverse Events. Common adverse events after quadrivalent meningococcal conjugate vaccines include pain, erythema, and swelling at the injection site; headache; fatigue; and irritability. Similar adverse effects are observed after MenB vaccines, although effects are more common and may be more severe, and often include myalgia. Syncope can occur after any vaccination and is most common among adolescents and young adults. Adolescents should be seated or lying down during vaccination and ideally remain that way for at least 15 minutes after immunization to avert syncopal episodes and secondary injuries. If syncope develops, patients should be observed until symptoms resolve.¹ Syncope following receipt of a vaccine is not a contraindication to subsequent doses.

Pregnant People.² Pregnant and lactating people should receive MenACWY vaccine if indicated. Because limited data are available for MenB vaccination during pregnancy, vaccination with MenB should be deferred unless the person is at increased risk and, after consultation with their health care provider, the benefits of vaccination are considered to outweigh the potential risks.

Counseling and Public Education. When a case of invasive meningococcal disease is detected, the physician should provide accurate and timely information about meningococcal disease and the risk of transmission to families and contacts of the infected person and provide or arrange for chemoprophylaxis (which may be accomplished together with the public health department). Some experts recommend that all patients with invasive meningococcal disease be evaluated for a complement component deficiency; screening can be accomplished with inexpensive CH50 and AH50 testing. If a specific complement component deficiency is detected, patients should receive a MenACWY vaccine series if 2 months or older and a MenB series if 10 years or older. Patients and parents should be counseled about the risk of recurrent invasive

¹ Centers for Disease Control and Prevention. Syncope after vaccination—United States, January 2005–July 2007. *MMWR Morb Mortal Wkly Rep.* 2008;57(17):457–460

² Mbaeyi SA, Bozio CH, Duffy J, et al. Meningococcal vaccination: recommendations of the Advisory Committee on Immunization Practices, United States, 2020. *MMWR Recomm Rep.* 2020;69(No. RR-9):1–41

meningococcal disease and the need for immediate medical evaluation when fever develops. Patients on eculizumab or ravulizumab or with other complement deficiencies should be counseled about the risk of invasive infection. Public health questions, such as whether a mass immunization program or an expanded chemoprophylaxis program is needed, should be referred to the local or state public health department. In appropriate situations, early provision of information in collaboration with the health department to schools or affected groups, and to the media may help minimize public anxiety and unrealistic or inappropriate demands for intervention.

Public Health Reporting. All confirmed, suspected, and probable cases of invasive meningococcal disease (see Table 3.35) must be immediately reported to the appropriate public health department. Meningococcal disease is a nationally notifiable condition. Timely reporting can facilitate early administration of chemoprophylaxis to close contacts, recognition and containment of outbreaks, and characterization of isolates so that appropriate prevention recommendations can be implemented rapidly.

Human Metapneumovirus

CLINICAL MANIFESTATIONS: Human metapneumovirus (hMPV) causes acute respiratory tract illness in people of all ages but is most common in children, especially those younger than 5 years. In infants, hMPV is a common cause of bronchiolitis. In children, hMPV also causes asthma exacerbations, croup, pneumonia, upper respiratory tract infections, and acute otitis media; these may be accompanied by fever. Healthy, young children generally have mild or moderate symptoms when infected with hMPV, but some can develop severe disease requiring hospitalization. Encephalitis has been reported rarely. As with other respiratory viral infections, secondary bacterial pneumonia can occur. Children with underlying cardiopulmonary disease and those born preterm, especially at a gestational age <32 weeks, are at higher risk for hospitalization, suffer more severe disease, and require longer stays and supplementary oxygen administration. hMPV infection in immunocompromised patients can result in severe disease, and fatalities have been reported in hematopoietic cell or lung transplant recipients. Among adults, hMPV is associated with acute exacerbations of chronic obstructive pulmonary disease (COPD) and pneumonia. Recurrent infections can occur throughout life and, in people without medical conditions, are usually mild or asymptomatic.

ETIOLOGY: hMPV is an enveloped single-stranded nonsegmented negative-sense RNA virus in the genus *Metapneumovirus* of the family *Pneumoviridae*. Phylogenetic analyses, based on sequence differences in the fusion (F) and attachment (G) surface glycoproteins, have identified 2 major hMPV antigenic lineages further subdivided into 2 clades within each lineage for a total of 5 genotypes (designated A1, A2a, A2b, B1, and B2). Viruses from these different clades cocirculate each year in varying proportions.

EPIDEMIOLOGY: Humans are the only host. Transmission occurs by direct or close contact with contaminated secretions via large particle aerosols, droplets, or fomites. Health care-associated infections have been reported.

In temperate climates, hMPV circulation usually occurs during late winter and early spring, overlapping with the latter part of the respiratory syncytial virus (RSV) season, but typically peaks 1 to 2 months later than RSV. Sporadic infections may occur throughout the year, and summer outbreaks have occasionally been described in closed settings. In otherwise healthy infants, the duration of viral shedding is 1 to 2 weeks. Prolonged shedding (weeks to months) has been reported in severely immunocompromised individuals.

Serologic studies suggest that nearly all children are infected at least once by 5 years of age. The incidence of hospitalizations attributed to hMPV is lower than that attributed to RSV but comparable to influenza and parainfluenza 3 in children younger than 5 years. Large studies have shown that hMPV is detected among 5% to 15% of children with medically attended lower respiratory tract illnesses. Worldwide, models have estimated >14 million annual cases of lower respiratory tract infections secondary to hMPV in children younger than 5 years. Overall annual rates of hospitalization associated with hMPV infection are highest in the first year of life but occur throughout childhood. In infants, the peak age of hospitalization is 6 to 12 months (compared with 2 to 3 months for RSV). Coinfection with other respiratory viruses occurs.

The **incubation period** is 3 to 9 days.

DIAGNOSTIC TESTS: Nucleic acid amplification tests (NAATs) are the diagnostic method of choice for hMPV. Several NAATs for hMPV are available commercially and have been approved for use by the US Food and Drug Administration. These include reverse transcriptase polymerase chain reaction (RT-PCR) tests for hMPV alone or in multiplex RT-PCR respiratory pathogen panels. hMPV is difficult to isolate in cell culture. Direct fluorescent antibody (DFA) testing for hMPV detection in respiratory specimens is available in some reference laboratories, with reported sensitivity of 85%. Serologic testing is only used in research settings.

TREATMENT: Treatment is supportive. In vitro studies and animal models have shown that ribavirin and some preparations of immune globulin intravenous have activity against hMPV. There are anecdotal reports using these therapies in humans, but there are no controlled clinical data available to assess whether these have therapeutic benefit, and their use is not routinely recommended. Antimicrobial agents are not indicated in the treatment of infants hospitalized with uncomplicated hMPV bronchiolitis or pneumonia unless evidence exists for the presence of a concurrent bacterial infection. Additional management recommendations for infants with bronchiolitis can be found in the bronchiolitis guidelines from the American Academy of Pediatrics.¹

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, contact and droplet precautions are recommended for the duration of hMPV-associated illness. In immunocompromised patients, the duration of precautions should be extended because of possible prolonged shedding.

CONTROL MEASURES: Appropriate respiratory and hand hygiene and cough etiquette should be followed. Control of health care-associated hMPV infection depends on adherence to contact and droplet precautions, and routine cleaning and sanitizing of potentially contaminated surfaces. Exposure to hMPV-infected people, including other patients, staff, and family members, may not be recognized because illness may be mild.

Preventive measures outside the health care setting include emphasizing hand and respiratory hygiene in all settings. Commonly used surfaces should be cleaned and sanitized routinely.

Microsporidia Infections

(Microsporidiosis)

CLINICAL MANIFESTATIONS: Clinical presentations of microsporidia infections are diverse and vary according to the causal species and route of infection. They can be grouped broadly into intestinal, ocular, and disseminated infections. Infection may also be asymptomatic. Patients with symptomatic intestinal infection have watery, non-bloody diarrhea; nausea; and diffuse abdominal pain. Abdominal cramping can occur. Symptomatic intestinal infection, often manifested by protracted diarrhea, is most common in immunocompromised people, especially in organ transplant recipients and people with human immunodeficiency virus (HIV) infection with low CD4+ T-lymphocyte counts (<100 cells/μL). Complications include malnutrition, progressive weight loss, and failure to thrive. Ocular infections most often affect the cornea, and disseminated infections can lead to biliary tract, cerebral, respiratory, muscle, and genitourinary involvement (see Table 3.41). Chronic infection in immunocompetent people is rare.

ETIOLOGY: Microsporidia are obligate intracellular, spore-forming organisms historically classified as parasites but closely related to fungi; their taxonomic position continues to

Table 3.41. Clinical Manifestations of Microsporidia Infections

Microsporidia	Clinical Manifestation
<i>Anncaliia algerae</i>	Myositis, ocular infection, cellulitis, myositis, disseminated disease
<i>Anncaliia connori</i>	Disseminated disease, ocular infection
<i>Anncaliia vesicularum</i>	Myositis
<i>Encephalitozoon cuniculi</i>	Encephalitis, hepatitis, peritonitis, ocular infection, sinusitis, osteomyelitis, pulmonary disease, disseminated disease
<i>Encephalitozoon hellem</i>	Ocular infection, disseminated disease, sinusitis, pneumonitis, nephritis, urethritis, cystitis
<i>Encephalitozoon intestinalis</i>	Diarrhea, cholangitis, disseminated infection, skin infection, ocular infection
<i>Enterocytozoon bienersi</i>	Diarrhea, acalculous cholecystitis, pulmonary disease
<i>Microsporidium africanum</i>	Ocular infection
<i>Microsporidium ceylonensis</i>	Ocular infection
<i>Nosema ocularum</i>	Ocular infection
<i>Pleistophora</i> species	Myositis, disseminated disease, sinusitis
<i>Trachipleistophora anthropophthera</i>	Disseminated infection, encephalitis, ocular infection
<i>Trachipleistophora hominis</i>	Myositis, sinusitis, encephalitis, ocular infection, disseminated disease
<i>Tubulinosema acridophagus</i>	Disseminated infection, myositis
<i>Vittaforma corneae</i>	Ocular infection, urinary tract infection, diarrhea

Adapted from: Han B, Weiss LM. Microsporidia: obligate intracellular pathogens within the fungal kingdom. *Microbiol Spectr.* 2017;5(2).

See also: www.cdc.gov/dpdx/microsporidiosis/

be debated. More than 1400 species belonging to about 200 genera have been identified with at least 15 reported in human infection (Table 3.41). *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis* are the pathogens reported most commonly in humans and are associated most often with chronic diarrhea in people with HIV infection.

EPIDEMIOLOGY: Most microsporidia infections are transmitted by oral ingestion of spores. Microsporidia spores commonly are found in surface water, and strains responsible for human infection have been identified in municipal water supplies and ground water. Spores can survive for extended periods in the environment. Several studies indicate that waterborne transmission occurs. Donor-derived infections in organ transplant recipients have been documented. Person-to-person spread by the fecal-oral route also occurs. Spores also have been detected in other body fluids, but their role in transmission is unknown. Data suggest the possibility of zoonotic and vector-borne transmission.

The **incubation period** is unknown.

DIAGNOSTIC TESTS: Infection with gastrointestinal tract microsporidia can be documented by microscopic identification of spores in stool or biopsy specimens. The laboratory should be alerted and specific stains for microsporidia requested, because routine ova and parasite examination usually does not detect microsporidia spores. Microsporidia spores can be detected in formalin-fixed or unfixed stool, other fluid, or tissue specimens stained with a chromotrope-based stain (a modification of the trichrome stain) and examined by an experienced microscopist. Fluorescent techniques including calcofluor or Fungi-Fluor also can be used to detect organisms in stool or tissue sections. Identification and diagnostic confirmation of species requires transmission electron microscopy or molecular methods (nucleic acid amplification test [NAAT]), which are available for *E bieneusi*, *E intestinalis*, *Encephalitozoon hellem*, and *Encephalitozoon cuniculi*. The value of serologic testing, when available, has not been substantiated.

TREATMENT: Restoration of immune function is critical for control of microsporidia infection in immunocompromised individuals. Effective antiretroviral therapy is the primary initial treatment for these infections in people with HIV infection and can result in resolution of symptoms even without specific therapy against microsporidia. Albendazole is the drug of choice for systemic infections caused by microsporidia other than *E bieneusi* infection, which may respond to fumagillin (see Table 4.11, Drugs for Parasitic Infections, p 1068). Fumagillin for systemic use is not available in the United States; it is associated with bone marrow toxicity, and recurrence of diarrhea is common after therapy is discontinued. Limited data suggest that nitazoxanide may be effective for treatment of *E bieneusi* gastroenteritis in patients with acquired immunodeficiency syndrome (AIDS). Topical fumagillin is used to treat ocular microsporidial infection. Topical voriconazole (1%) and topical fluoroquinolones have been reported effective for treatment of microsporidial ocular infection, but more study is needed. Supportive care for malnutrition and dehydration may be necessary. Antimotility agents may be useful to control chronic diarrhea.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, contact precautions are recommended for diapered and incontinent children for the duration of illness.

CONTROL MEASURES: In patients with HIV infection and other immunocompromised people, attention to hand hygiene, drinking bottled or boiled water, and avoiding unpeeled fruits and vegetables may decrease exposure. No chemoprophylactic

regimens are known to be effective in preventing microsporidiosis, although continuation of treatment regimens is recommended as secondary prophylaxis in individuals with HIV infection until immune reconstitution.

Molluscum Contagiosum

CLINICAL MANIFESTATIONS: Molluscum contagiosum is a benign viral infection of the skin with no systemic manifestations. It usually is characterized by 1 to 20 discrete, 2- to 5-mm-diameter, flesh-colored to translucent, dome-shaped papules, some with central umbilication. Lesions commonly occur on the trunk, face, and extremities but rarely are generalized. Molluscum contagiosum is a self-limited epidermal infection with individual lesions often spontaneously resolving in 6 to 12 months but some taking as long as 3 to 4 years to disappear completely. An eczematous reaction (molluscum dermatitis) encircling the lesions is common. People with atopic dermatitis and immunocompromising conditions, including human immunodeficiency virus infection and patients with congenital DOCK8 deficiency or CARD11 mutations, tend to have more widespread and prolonged eruptions, which often are recalcitrant to therapy.

ETIOLOGY: Molluscum contagiosum virus is the sole member of the genus *Molluscipoxvirus*, family *Poxviridae*. DNA subtypes of molluscum contagiosum virus can be differentiated, but the specific subtype probably is insignificant in pathogenesis. Other poxviruses include the agents of smallpox, mpox, vaccinia, and cowpox.

EPIDEMIOLOGY: Humans are the only known source of the virus, which is spread by direct contact with lesions, including scratching, shaving, sexual contact, or fomites. Vertical transmission has been linked with neonatal molluscum contagiosum infection. Lesions can be disseminated by autoinoculation. Infectivity generally is low, but occasional outbreaks may occur in facilities such as child care centers. The period of communicability is unknown.

The **incubation period** is generally between 2 and 7 weeks but may be as long as 6 months.

DIAGNOSTIC TESTS: The diagnosis usually can be made clinically from the characteristic appearance of umbilicated papules. Side lighting of the individual lesions may enhance the visibility of the umbilication. Handheld dermoscopy can be useful in identifying orifices (umbilications) along with white amorphous structures with a surrounding crown of vessels. Wright or Giemsa staining of cells expressed from the central core of a lesion reveals characteristic intracytoplasmic inclusions. Electron microscopic examination of these cells identifies typical poxvirus particles. The virus does not grow readily in culture. Serologic testing is not available routinely for clinical practice. If uncertainty persists in the differential diagnosis (eg, warts, trichoepithelioma, tuberous sclerosis), nucleic acid amplification tests (NAATs) are available at certain reference centers. Adolescents and young adults with genital molluscum contagiosum should prompt a screening for other sexually transmitted infections.

TREATMENT: There is no consensus on management of molluscum contagiosum in children and adolescents. Genital lesions in sexually active patients should be treated to prevent spread to sexual contacts. Nongenital lesions in healthy people are typically self-limited, so treatment may be unnecessary. However, therapy may be warranted to (1) alleviate discomfort, including itching; (2) reduce autoinoculation; (3) limit

transmission of the virus to close contacts; (4) reduce cosmetic concerns; and (5) prevent secondary infection.

Physical destruction of the lesions is the most rapid and effective means of curing molluscum contagiosum. Modalities available include curettage, cryodestruction with liquid nitrogen, electrodesiccation, and chemical agents designed to initiate a local inflammatory response (podophyllin, tretinoin, cantharidin, 25%–50% trichloroacetic acid, liquefied phenol, silver nitrate, tincture of iodine, or potassium hydroxide). Although randomized controlled trials have been conducted for the use of cantharidin, the evidence for most of these other modalities remains anecdotal. Cantharidin was approved by the US Food and Drug Administration (FDA) on July 21, 2023, for treatment of molluscum. In addition, berdazimer gel was approved by the FDA for treatment of molluscum on January 5, 2024. When treatment is desired, the most support exists for cryotherapy, curettage, or cantharidin. These treatments require an experienced health care professional, as they can result in postprocedural pain, irritation, dyspigmentation, and scarring. Because physical destruction of the lesions is painful, appropriate local anesthesia may be required, particularly in young children.

Cidofovir is a cytosine nucleotide analogue with in vitro activity against molluscum contagiosum; successful intravenous treatment of immunocompromised adults with severe involvement has been reported. However, use of cidofovir should be reserved for extreme cases because of potential carcinogenicity and known toxicities (neutropenia and potentially permanent nephrotoxicity) associated with systemic administration of cidofovir. Successful treatment using compounded formulations of topical cidofovir has been reported in both adult and pediatric cases, most of whom were immunocompromised. Solitary genital lesions in children usually are not acquired by sexual transmission and do not necessarily denote sexual abuse, as other modes of direct contact with the virus, including autoinoculation, may result in genital infection.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: No control measures are known for isolated cases. For outbreaks, which are common in the tropics, restricting direct person-to-person contact and sharing of potentially contaminated fomites, such as towels and bedding, may decrease spread. Molluscum contagiosum should not prevent a child from attending child care or school or from swimming in public pools. Covering lesions is not necessary for child care, but when possible, localized lesions not covered by clothing may be covered with a gas-permeable dressing followed by under wrap and tape when participating in sports activities.¹ When children will be entering swimming pools, a watertight bandage can be placed on visible lesions. Bandages should be changed daily or when soiled.

***Moraxella catarrhalis* Infections**

CLINICAL MANIFESTATIONS: *Moraxella catarrhalis* is commonly implicated in acute otitis media (AOM), otitis media with effusion, and sinusitis. AOM caused by *M catarrhalis* occurs predominantly in younger infants and frequently is recovered from middle ear and sinuses as part of mixed infections. Since introduction of the conjugate pneumococcal vaccine, *M catarrhalis* appears to be recovered in a greater proportion of children

¹ Davies HH, Jackson MA, Rice SG; American Academy of Pediatrics, Committee on Infectious Diseases. Infectious diseases associated with organized sports and outbreak control. *Pediatrics*. 2017;140(4):e20172477

undergoing tympanocentesis. *M catarrhalis* was recovered from 15% of children with AOM undergoing tympanocentesis between 2015 and 2019; however, it is unclear whether this represents an increase in cases attributable to *M catarrhalis* or a decrease in pneumococcal disease. *M catarrhalis* can cause pneumonia with or without bacteremia in immunocompetent infants and has been recovered from children with aspirated foreign body complicated by secondary infection. It is more commonly recovered from children with chronic lung disease or impaired host defenses, such as leukemia with neutropenia or congenital immunodeficiency. In immunocompromised children, often no focus of infection is identified. Other clinical manifestations include hypotension with or without a rash that is indistinguishable from that observed in meningococemia; neonatal meningitis; and focal infections, such as preseptal cellulitis, bacterial tracheitis, urethritis, osteomyelitis, or septic arthritis. Rare manifestations include endocarditis, peritonitis, shunt-associated ventriculitis, meningitis, and mastoiditis. Health care-acquired *M catarrhalis* bacteremia has been reported in hospitalized children with transnasal devices (nasogastric tube, elemental diet tube, or nasotracheal tube); foci of infection in these cases have included pneumonia or bronchitis. Other health care-associated outbreaks of *M catarrhalis* have been described.

ETIOLOGY: *M catarrhalis* is a gram-negative aerobic diplococcus.

EPIDEMIOLOGY: *M catarrhalis* is part of the normal microbiota of the upper respiratory tract of humans. At least two thirds of children are colonized within the first year of life. The mode of transmission is presumed to be direct contact with contaminated respiratory tract secretions or droplet spread. Infection is most common in infants and young children but also occurs in immunocompromised people of all ages. The duration of carriage by children with infection or colonization and the period of communicability are unknown. Recent studies suggest early colonization with *M catarrhalis* is associated with a stable microbiome and low risk for recurrent respiratory tract infection.

DIAGNOSTIC TESTS: The organism can be isolated on blood or chocolate agar culture media after incubation in air or with increased carbon dioxide. On Gram stain, *Moraxella* species are short and plump gram-negative cocci, usually occurring in pairs or short chains and are mostly catalase and cytochrome oxidase positive. Nucleic acid amplification tests (NAATs) for *M catarrhalis* have been developed but currently are used for research purposes only. The significance of *M catarrhalis* detection from clinical specimens requires clinical correlation; isolation of *M catarrhalis* from respiratory cultures may often represent colonization rather than infection.

TREATMENT: Almost all strains of *Moraxella* species produce beta-lactamase and are resistant to amoxicillin, unlike other common pathogens causing acute otitis media. *M catarrhalis* are typically susceptible to ampicillin-sulbactam (and amoxicillin-clavulanate), second- or third-generation cephalosporins, trimethoprim sulfamethoxazole, macrolides, and fluoroquinolones. Empiric and definitive therapy will depend on the severity of illness and type of infection, immunocompetence of the patient, and susceptibility of the isolate. The organism is resistant to clindamycin, vancomycin, and oxacillin. Macrolide-resistant isolates have been reported from Asia, but resistant strains only rarely have been identified in the United States or Western Europe.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS: Standard precautions are recommended.

CONTROL MEASURES: None.

Mpox

CLINICAL MANIFESTATIONS: The presentation of mpox (formerly known as monkeypox) is similar to but milder than that of smallpox, prior to its eradication.

Clinical Presentation Associated With Classic Mpox Infections. Classic mpox infection generally involves a prodromal illness that may last several days and is characterized by fever, lymphadenopathy, malaise, sore throat, and headache, followed by the development of a characteristic diffuse rash. The rash typically involves many lesions, begins on the face, and spreads to other parts of the body including the extremities (often with involvement of palms and soles) and trunk. Generally, there are more lesions on the face and extremities than the trunk (centrifugal distribution). Classically, lesions begin as macules that progress to papules, firm vesicles, and deep-seated pustules, which can develop central umbilication and be painful until the healing phase begins. The lesions are typically in the same stage of evolution in a particular area on the body. Crusting and resolution occur over a period of 2 to 4 weeks. Lymphadenopathy in the submandibular, cervical, axillary, or inguinal regions usually occurs during the prodromal period or, rarely, with rash onset. An enanthem characterized by oral lesions on the tongue and other areas of the mouth may develop shortly before the appearance of cutaneous lesions. Ocular involvement can lead to keratitis, corneal scarring, and blindness. Other complications can include vomiting and diarrhea leading to severe dehydration, pneumonia, encephalitis, sepsis, hemorrhagic lesions, bacterial skin infection, pregnancy loss, congenital infection, and preterm delivery. Deaths have occurred. Coinfections, including with varicella zoster virus, have been reported.

Clinical Presentation Associated With 2022 Global Mpox Outbreak. In May 2022, a global outbreak of mpox began, primarily infecting men who have sex with men. Most people infected with mpox virus in this outbreak had mild or absent prodromal symptoms. Occasionally, one or more prodromal symptoms (eg, fever, lymphadenopathy, malaise, sore throat, headache) developed concurrently with the onset of skin lesions. Lesions varied in size, and for some patients were much smaller than those associated with classic mpox and were fewer in number (ie, a single lesion or a few scattered lesions). In many cases, the rash was prominent in the anogenital region and associated with proctitis and rectal complaints (eg, severe rectal pain, tenesmus). Lesions in differing stages of rash progression occurred side-by-side. Fulminant and fatal infection occurred in persons with severe immunocompromise, including uncontrolled human immunodeficiency virus (HIV) infection.

Mpox is typically self-limited and resolves over 2 to 4 weeks. It can be confused with other illnesses, particularly varicella. Generally, varicella in children is not associated with a febrile prodrome or prominent lymphadenopathy, both of which can occur with mpox, particularly the classic clinical presentation of mpox. Mpox lesions develop into firm pustules, and historically (although not always) are in the same stage in the same area of the body, whereas varicella is in multiple stages of rash in the same area. Classic mpox lesions are typically more prominent on the face and extremities, versus varicella, which typically has a higher number of lesions on the trunk. Other common pediatric conditions that can be confused with mpox include hand, foot, and mouth disease; molluscum contagiosum; scabies; insect bites; allergic reactions; and drug eruptions. Genital or perianal lesions can look similar to a variety of sexually

transmitted infections (STIs) (eg, syphilis, herpes simplex virus, lymphogranuloma venereum), and people have been coinfecting with mpox virus and other STIs.

ETIOLOGY: Monkeypox virus, which causes mpox disease, is a member of the *Poxviridae* family (genus *Orthopoxvirus*). Other members of this genus that can infect humans include cowpox virus, vaccinia virus, and smallpox (variola).

EPIDEMIOLOGY: Mpox virus has 2 clades. Clade I (previously called the Congo Basin clade of mpox virus) is associated with a 11% case fatality rate in Africa in individuals without prior smallpox vaccination. Clade II (previously called the West African clade of mpox virus) is associated with a 1% case fatality rate in Africa. Clade IIb was associated with the 2022 global mpox outbreak. Disease severity, regardless of clade, is believed to be increased in pregnant people, young children, people who have atopic dermatitis and other exfoliative skin conditions, and people who are immunocompromised. The classic presentation of mpox has occurred after exposures to either clade in central and west African countries where mpox virus is endemic.

Mpox virus is spread most commonly by direct contact with lesion material, body fluids, or indirectly via fomites, such as contaminated clothing and bedding. It can also be spread by respiratory secretions, occurring when there is exposure to saliva and possibly prolonged face to face contact. A person is considered infectious from prodromal illness onset until all skin lesion crusts have fallen off and a new layer of skin has formed. The animal reservoir for classic mpox has not yet been determined, although small mammals, including rodents, are suspected; humans and other nonhuman primates can be infected and present with disease. Mpox can be acquired by the scratch or bite of an infected animal, through exposure to contaminated animal products, or through fomites (eg, shared towels and bedding).

During the 2022 global mpox outbreak, cases in adolescents were reported resulting from sexual contact; nonsexual transmission also occurred. Cases in children younger than 12 years occurred in the setting of skin-to-skin contact with a household member with mpox during routine caregiving activities (an instance of fomite transmission through shared towels was also reported). No anogenital lesions were reported among the 28 children younger than 12 years of age.¹

The **incubation period** for mpox is 3 to 17 days (average, 5–13 days).

DIAGNOSTIC TESTS: Mpox virus can be detected in a swab of a lesion or a lesion crust or exudate (unroofing or aspirating a lesion is not recommended) by *Orthopoxvirus* or mpox-specific nucleic acid amplification tests (NAATs). Diagnostic testing is available through the US Laboratory Response Network (LRN), through consultation with state or local public health departments, and through some commercial laboratories. A positive NAAT result for *Orthopoxvirus* in the epidemiologic setting of a known mpox outbreak may be treated as a presumptive case, if collected from a patient with a compatible clinical presentation and epidemiologic risk factors. Specimens can also be sent to the Centers for Disease Control and Prevention (CDC) for mpox virus-specific characterization, including a NAAT assay specific for mpox virus, immunohistochemistry in tissue for *Orthopoxvirus*, serology for *Orthopoxvirus*, and genetic sequencing. Anti-*Orthopoxvirus* immunoglobulin M may be useful to diagnose mpox in a patient 4 to

¹ Hennessee I, Shelus V, McArdle CE, et al. Epidemiologic and clinical features of children and adolescents aged <18 years with monkeypox—United States, May 17–September 24, 2022. *MMWR Morb Mortal Wkly Rep.* 2022;71(44):1407–1411

56 days after rash onset who has not been vaccinated with a smallpox or mpox vaccine within the past 60 days.

Testing for other STIs and HIV should be performed for patients with anogenital lesions as coinfections occur.

TREATMENT: Most patients with mpox have self-limited disease. Patients should be counseled not to touch their eyes. Patients with ocular or periorbital lesions should be treated promptly because of the risk of developing keratitis and potentially permanent visual problems; these patients should have a consultation with an ophthalmologist regarding management and discussion of ocular therapy, such as topical trifluridine. Patients with severe disease (eg, hemorrhagic disease, confluent lesions, secondary bacterial infections, sepsis, encephalitis, lesions on the penile foreskin or strictures involving the urethral meatus, or severe involvement of other anatomic areas including anorectal lesions interfering with bowel movements, oral lesions associated with severe dysphagia, or other complicated or severe conditions, including conditions requiring hospitalization) and those at risk for severe disease (eg, patients with immunocompromising conditions, patients who are pregnant or breastfeeding, children younger than 1 year, patients with a condition affecting skin integrity) should also be considered for antiviral treatment. Management of patients with severe or complicated disease or those at risk for severe disease should be discussed with an expert in infectious diseases.

Pain can be severe, particularly when there are genital, rectal, or anal lesions. A variety of over-the-counter treatment modalities, including sitz baths, can be helpful. Information on pain management in mpox infections is described at www.cdc.gov/poxvirus/mpox/clinicians/pain-management.html.

Antiviral Agents. Guidance is available from the CDC (www.cdc.gov/poxvirus/mpox/clinicians/treatment.html and www.cdc.gov/poxvirus/monkeypox/clinicians/people-with-HIV.html). Tecovirimat (TPOXX or ST-246) was approved by the US Food and Drug Administration (FDA) for the treatment of smallpox and has been shown to be active against mpox virus in animal models; it is the preferred treatment for mpox patients who would benefit from antivirals. As of August 2023, tecovirimat is available through an expanded access investigational new drug (EA-IND) protocol for intravenous treatment of mpox for those who weigh at least 3 kg and for oral administration for those who weigh at least 13 kg (see www.accessdata.fda.gov/drugsatfda_docs/label/2022/214518s000lbl.pdf; www.cdc.gov/poxvirus/monkeypox/clinicians/treatment.html#anchor_1655488137245; and Table 4.10, p 1044). At least weekly monitoring of renal function is indicated in children and adolescents receiving intravenous tecovirimat.

Vaccinia immune globulin intravenous (VIGIV) is licensed for the treatment of complications of vaccinia vaccination; effectiveness for mpox is unknown. The CDC has an EA-IND for use in mpox (www.fda.gov/media/78174/download). To discuss use of VIGIV, the CDC clinical consultation team can be accessed by email (eocevent482@cdc.gov) or if urgent, through the CDC Emergency Operations Center (770-488-7100).

Brincidofovir (a lipophilic derivative of cidofovir that can be given orally and does not appear to have renal toxicity) has been approved for smallpox treatment. There is an FDA-authorized single patient emergency use IND for brincidofovir for mpox (www.cdc.gov/poxvirus/monkeypox/clinicians/treatment.html#anchor_1655488353796 and www.accessdata.fda.gov/

drugsatfda_docs/label/2021/214460s000,214461s000lbl.pdf). It can be used in patients who have significant progression on tecovirimat, develop recrudescence of disease after initial improvement on tecovirimat, or have a contraindication for tecovirimat (see Table 4.10, p 1044).

Cidofovir is licensed for treatment of cytomegalovirus retinitis in patients with AIDS, is commercially available, and has activity against orthopoxviruses in studies, but the effectiveness for treating people with severe mpox is unknown. It has dose-dependent nephrotoxicity (**www.accessdata.fda.gov/drugsatfda_docs/label/1999/020638s003lbl.pdf**).

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

A patient suspected of having mpox should be placed in a private room, and a health care professional should use a National Institute for Occupational Safety and Health-approved particulate respirator equipped with an N95 or higher respirator, gown, gloves, and eye protection. If an aerosol-generating procedure is performed, the patient should be placed in a private room equipped with negative-pressure ventilation with high-efficiency particulate air filtration. Good hand hygiene should be practiced, and extreme care should be taken with materials that may have been contaminated by the patient's lesions, crusts, or body fluids, so as not to create aerosols or contaminate additional items. Hospital infection control personnel and the state (and/or local) health department should be notified about the patient.

Mpox patients who do not require hospitalization can be isolated at home. General guidance on isolation and mpox is available on the CDC website (**www.cdc.gov/poxvirus/mpox/clinicians/infection-control-home.html** and **www.cdc.gov/poxvirus/mpox/clinicians/isolation-procedures.html**). During the infectious period, an infected patient should avoid contact with others when possible, and with pets. Ideally, one person should provide care to an infected child. The caregiver should wear a respirator or well-fitting mask when caring for the patient, cover areas of broken skin with bandages and clothing to the extent possible, and avoid direct skin-to-skin contact with the rash. The caregiver should wear gloves when changing bandages or when skin contact may occur. Gloves should be disposed of after each use, followed by handwashing. If any clothing (whether on the caregiver or the child) comes into contact with the rash, it should be laundered. Patients 2 years and older should wear a well-fitting mask, and lesions should be covered when interacting with the caregiver (or other in the household). Skin lesions should be covered when possible. Additional information, including information on laundering and cleaning is available on the CDC website (**www.cdc.gov/poxvirus/mpox/clinicians/pediatric.html** and **www.cdc.gov/poxvirus/mpox/if-sick/cleaning-disinfecting.html**).

CONTROL MEASURES:

Preexposure Immunization. Laboratory workers handling mpox specimens or a member of a high-risk group, as identified by public health, may be eligible for vaccination and for booster doses. Recommendations from the CDC Advisory Committee on Immunization Practices (ACIP) are available.¹

¹ Rao AK, Petersen BW, Whitehill F, et al. Use of JYNNEOS (smallpox and monkeypox vaccine, live, non-replicating) for preexposure vaccination of persons at risk for occupational exposure to orthopoxviruses: recommendations of the Advisory Committee on Immunization Practices—United States, 2022. *MMWR Morb Mortal Wkly Rep.* 2022;71(22):734–742

JYNNEOS is a live, **nonreplicating** vaccinia vaccine that was approved by the FDA in 2019 for the prevention of mpox and smallpox in persons 18 years or older who are at high risk for mpox. It is given as a 2-dose series, separated by 28 days. It has an emergency use authorization (EUA) for use in children younger than 18 years (www.fda.gov/media/160774/download). There is also an EUA for intradermal dosing and administration in patients 18 years or older. In October 2023, the ACIP voted to recommend vaccination with the 2-dose JYNNEOS vaccine series for persons aged 18 years and older at risk for mpox, defined as: 1) gay, bisexual, and other men who have sex with men, transgender, or nonbinary people who in the past 6 months have had a new diagnosis of ≥ 1 sexually transmitted infection, more than one sex partner, sex at a commercial sex venue, or sex in association with a large public event in a geographic area where mpox transmission is occurring; 2) sexual partners of persons with the risks described in above; or 3) persons who anticipate experiencing any of the above.

ACAM2000 is a licensed live, **replicating** vaccinia virus vaccine to prevent smallpox and may be used to protect against mpox under FDA's EA-IND mechanism. It is a lyophilized, single-dose vaccine (for primary administration) that requires a bifurcated needle for administration. Inadvertent transmission of the vaccine virus from ACAM2000 may occur from vaccine recipients to their household contacts. Children who are immunocompromised or have atopic skin disease are at increased risk of serious complications following contact transmission, including progressive vaccinia and eczema vaccinatum. Information on these vaccines can be found on the CDC website (www.cdc.gov/poxvirus/monkeypox/clinicians/smallpox-vaccine.html). Detailed information about contraindications to preexposure smallpox immunization and adverse reactions to vaccination can be found in the ACAM2000 package insert and medication guide (www.fda.gov/BiologicsBloodVaccines/Vaccines/ApprovedProducts/ucm180810.htm). VIGIV, available through the CDC, is licensed for certain complications of ACAM2000 vaccination (www.cdc.gov/smallpox/clinicians/vaccine-medical-management6.html). CDC medical staff can be reached through the CDC emergency operations center at 770-488-7100.

Care of Exposed People. Cases of febrile rash illness for which mpox is considered should be reported to state or local health departments, who will investigate potential contacts and provide recommendations that may include symptom monitoring for 21 days and postexposure prophylaxis. Asymptomatic exposed persons do not need to quarantine but should monitor for symptoms.

Use of Vaccine. Postexposure immunization within 4 days of exposure with JYNNEOS or ACAM2000 vaccines may prevent mpox. If unable to vaccinate within that time, vaccinating up 14 days after exposure may still provide protection against severe disease. State and local health officials should be consulted on the use of vaccine for exposed individuals.

Care of Exposed Neonates. Infants born to people with suspected or confirmed mpox should undergo early bathing and postexposure prophylaxis. Although the optimal strategy for postexposure prophylaxis of newborn infants born to infected persons has not been defined, VIGIV should be considered, and consultation with an expert in pediatric infectious diseases is recommended. Infants should stay in a separate room and not have direct contact with parent(s) or caregivers infected with mpox.

virus. Breastfeeding should be delayed during the isolation period of the breastfeeding parent, and human milk should be pumped and discarded. Neonates should be monitored closely for signs of mpox (eg, fever, lymphadenopathy, rash, symptoms of illness) for 21 days following birth/contact with the infected person. Monitoring should include daily temperature checks and full skin examinations. This monitoring can be performed by a health care professional or the person taking care of the neonate. Additional recommendations are available at www.cdc.gov/poxvirus/mpox/clinicians/pediatric.html.

Public Health Reporting. Mpox is a nationally notifiable disease and should be reported immediately to the state or local health department.

Mumps

CLINICAL MANIFESTATIONS: Mumps is a systemic disease typically characterized by pain and swelling of one or more of the salivary glands, usually the parotid glands. Nonspecific symptoms may precede parotitis, including fever, myalgia, anorexia, malaise, and headache. Approximately one fifth of infections in unvaccinated people may be asymptomatic. The frequency of asymptomatic infection in vaccinated persons is unknown, but mumps symptoms are usually milder and complications less common among vaccinated people. Parotitis occurs in 95% of symptomatic individuals and may be unilateral initially with involvement of the contralateral parotid gland in 70% of cases. Emergence of contralateral parotitis within weeks to months after apparent recovery has been described. Orchitis is the most frequently reported postpubertal complication and occurs in approximately 30% of those who are unvaccinated and 6% of those who are vaccinated. Unilateral testicular involvement is common. Approximately half of patients with mumps orchitis develop testicular atrophy of affected testicles. More than 50% of people with mumps have cerebrospinal fluid pleocytosis, but fewer than 1% have symptoms of viral meningitis. Uncommon complications include oophoritis, pancreatitis, encephalitis, hearing loss (either transient or permanent), arthritis, thyroiditis, mastitis, glomerulonephritis, myocarditis, endocardial fibroelastosis, thrombocytopenia, cerebellar ataxia, and transverse myelitis. In the absence of an immunization program, mumps typically occurs during childhood. Infection in adults is more likely to result in complications. Although mumps virus can cross the placenta, no evidence exists that this transmission results in congenital malformation.

ETIOLOGY: Mumps is an enveloped RNA virus with 12 genotypes in the genus *Rubulavirus* in the family *Paramyxoviridae*. The genus also includes human parainfluenza virus types 2 and 4. Other common infectious causes of parotitis include Epstein-Barr virus, adenovirus, human herpes virus 6, parainfluenza virus types 1 and 3, influenza A virus, enteroviruses, human immunodeficiency virus (HIV), nontuberculous mycobacterium, and gram-positive (eg, *Staphylococcus aureus*) and gram-negative bacteria.

EPIDEMIOLOGY: Mumps occurs worldwide, and humans are the only known natural hosts. The virus is spread by contact with infectious respiratory tract secretions and saliva. Mumps virus is the only known cause of epidemic parotitis. Historically, the peak incidence of mumps was between January and May and among children younger than 10 years. Mumps vaccine was licensed in the United States in 1967 and recommended for routine childhood immunization in 1977. After implementation of the

2-dose measles, mumps, and rubella vaccine (MMR) recommendation in 1989 for measles control in the United States, mumps declined by 99%. From 2000 to 2005, there were fewer than 300 reported cases per year. However, there has been an increase in the number of reported mumps cases with peak years in 2006, 2016-2017 (more than 6000 cases each year), and 2019 (more than 3500 cases). Most cases during these peak years occurred in high-density, close-contact settings (eg, university campuses, military barracks) among young adults and persons who previously received 2 doses of MMR. Complications (eg, orchitis) have occurred following mumps outbreaks in college populations. Transmission of mumps has been reported to occur from asymptomatic, fully vaccinated individuals in close-contact social settings, leading to widespread outbreaks. Although secondary vaccine failure attributable to waning vaccine-derived immunity is believed to be an important contributing factor for mumps outbreaks among vaccinated individuals, antigenic differences between currently circulating wild-type strains and the vaccine strain, or lower incidence of subclinical immunologic boosting because of lack of exposure to wild-type virus may also play a role.

The **incubation period** usually is 16 to 18 days, but cases may occur from 12 to 25 days after exposure. The period of maximum communicability begins 2 days before parotitis onset. The recommended isolation period is 5 days after onset of parotid swelling. However, virus has been detected in patients' saliva as early as 7 days before and until 9 days after onset of swelling. Mumps virus has been isolated from urine and seminal fluids up to 14 days after onset of parotitis.

DIAGNOSTIC TESTS: Unvaccinated and vaccinated people with parotitis, orchitis, or oophoritis without other apparent cause should undergo diagnostic testing for mumps virus. Mumps can be confirmed by detection of mumps virus nucleic acid by nucleic acid amplification tests (NAATs) in buccal swab specimens (Stenson duct exudates), throat or oral swab specimens, urine, or cerebrospinal fluid. The parotid gland should be massaged for 30 seconds prior to buccal swab specimen collection. The mumps NAAT, developed by the Centers for Disease Control and Prevention (CDC) and available at the CDC, many state public health departments, and the Vaccine Preventable Disease Reference Centers (VPD-RC), is highly sensitive and specific. Other NAATs for mumps may be available at clinical or commercial laboratories, but the performance measures of these tests are not well characterized. Mumps virus may be isolated in cell culture using a variety of cell types, using either standard or rapid isolation and identification techniques. However, molecular detection of viral RNA by NAAT is the preferred test for confirmation of mumps infection.

Samples for mumps virus detection should be obtained soon after clinical diagnosis of mumps, preferably within 1 to 3 days after symptom onset. Vaccinated individuals may shed virus for a shorter period (less than 1 week) and may shed smaller amounts of virus. Failure to detect mumps virus RNA by NAAT in samples from a person with clinically compatible mumps symptoms does not rule out mumps as a diagnosis.

Testing for mumps-specific immunoglobulin (Ig) M antibody, IgG seroconversion, or a significant increase between acute and convalescent IgG antibody titer can also aid in the diagnosis of mumps, but these serologic assays do not confirm a diagnosis of mumps. In previously vaccinated patients who acquire mumps, IgM response may be transient, delayed, or not detected. Collection of serum 3 to 10 days after parotitis onset improves the ability to detect IgM. A negative IgM in a person with clinically compatible mumps symptoms does not rule out mumps as a diagnosis. In vaccinated

patients, collection of acute and convalescent phase serum samples to demonstrate a fourfold increase in IgG titer is not recommended, because by the time of onset of symptoms, IgG titers may already be elevated such that detection of a fourfold increase in titer is not possible.

To distinguish wild-type mumps virus from vaccine virus in a person with clinically compatible mumps symptoms who was recently vaccinated, it is necessary to obtain a buccal/oral swab specimen for genotyping. Serologic tests cannot differentiate between an exposure to vaccine and an exposure to wild-type mumps virus.

TREATMENT: Management is supportive.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, droplet precautions are recommended until 5 days after onset of parotid swelling.

CONTROL MEASURES:

Evidence of Immunity to Mumps. Presumptive evidence of immunity to mumps includes any of the following:

1. Documentation of age-appropriate vaccination with a live mumps virus-containing vaccine:
 - Preschool-aged children: 1 dose after their first birthday;
 - School-aged children (grades K–12) and adults at high risk (ie, health care personnel, international travelers, and students at postsecondary educational institutions): 2 doses after their first birthday, with the second dose administered at least 28 days after the first dose;
 - Adults not at high risk: 1 dose;
2. Laboratory evidence of immunity (Note: although the presence of mumps-specific IgG is considered evidence of prior exposure to mumps vaccine or mumps virus and is considered evidence of immunity for most situations [eg, employment], it does not necessarily predict protection against mumps disease, and equivocal tests should be considered negative);
3. Laboratory confirmation of disease; or
4. Born before 1957 (note: health care workers of any age are not considered immune unless they have had 2 immunizations separated by at least 28 days or have serologic evidence of immunity).

School and Child Care. Children and young adults should be excluded for 5 days from onset of parotid gland swelling. When determining means to control outbreaks, exclusion of students without evidence of immunity from affected schools and schools judged by local public health authorities to be at risk of transmission should be considered. If implemented, unimmunized students should be excluded until at least 26 days after onset of parotitis in the last person with mumps. Excluded students can be readmitted after receipt of a dose of MMR vaccine at the discretion of local or state health department.

Care of Exposed People. Mumps vaccine has not been demonstrated to be effective in preventing infection or decreasing the severity of infection if administered after exposure.

However, people without evidence of immunity who are exposed to mumps still should receive MMR vaccine (or measles, mumps, rubella, and varicella vaccine

[MMRV]), because immunization will provide protection against subsequent exposures. Immunization during the incubation period presents no increased risk of adverse events. Immune globulin (IG) preparations are not effective as postexposure prophylaxis for mumps.

During an outbreak, all people should be brought up-to-date on age-appropriate vaccinations (1 dose or 2 doses, depending on age; see below).

Mumps Vaccine. The only mumps vaccines licensed in the United States are live attenuated strains. Mumps vaccine is only available in the United States as combination formulations, which include MMR (M-M-R II, manufactured by Merck; and Priorix, manufactured by GSK) and MMRV vaccines. Vaccine is administered by subcutaneous injection of 0.5 mL of MMR vaccine (licensed for people 12 months or older) or MMRV vaccine (licensed for children 12 months through 12 years of age). Monovalent mumps vaccine is no longer available in the United States.

Vaccine Recommendations.

- The first dose of MMR or MMRV (see MMRV-specific recommendations in Varicella-Zoster Infections, p 938) should be administered routinely to children at 12 through 15 months of age, with a second dose of MMR or MMRV administered at 4 through 6 years of age. The second dose of MMR or MMRV may be administered before 4 years of age, provided at least 28 days have elapsed since the first dose. MMR or MMRV is not harmful if administered to a person already immune to one or more of the viruses from previous infection or immunization.
- People should be immunized unless they have evidence of mumps immunity (p 613). Adequate immunization is 2 doses of mumps-containing vaccine (≥ 28 days apart) for school-aged children and adults at high risk (ie, health care personnel, students at postsecondary educational institutions, and international travelers). Because mumps is endemic throughout most of the world, unless they have evidence of immunity, people 12 months or older should be offered 2 doses of MMR before beginning travel. Children younger than 12 months need not receive mumps vaccine before travel, but they may receive it as MMR starting at 6 months of age if measles immunization is indicated. If a child receives a dose of mumps vaccine before 12 months of age, this dose is not counted toward the recommended number of doses, and 2 additional doses are recommended beginning at 12 through 15 months of age and separated by at least 28 days.
- During a mumps outbreak, people previously vaccinated with 2 doses who are identified by public health authorities as being part of a group or population at increased risk for acquiring mumps should receive a third dose of MMR (or MMRV if age appropriate). Active and passive surveillance have not identified any new or unexpected short-term safety concerns following receipt of a third dose of mumps-containing vaccine. People who have evidence of presumptive immunity for mumps other than receipt of 2 doses also should receive a dose of MMR (or MMRV if age appropriate) if they are part of the group at increased risk. No additional dose is recommended for people who already received 3 or more doses before the outbreak.
- Health care personnel born before 1957 should receive 2 doses of MMR unless they have laboratory evidence of immunity or disease.
- A mumps-containing vaccine may be administered with other vaccines at different injection sites and with separate syringes (see Simultaneous Administration of Multiple Vaccines, p 63).

- Vaccine documentation is required in multiple states for attendance in lower and higher educational institutions and is an effective public health tool to maximize immunization rates.

Adverse Reactions. Adverse reactions associated with the mumps component of US-licensed MMR or MMRV vaccines are rare. Orchitis, parotitis, and low-grade fever may occur. Causality has not been established for nerve deafness, aseptic meningitis, encephalitis, rash, pruritus, and purpura. Allergic reactions also are rare. Other reactions that occur after immunization with MMR or MMRV may be attributable to other components of the vaccines (see Adverse Event sections in Measles, p 581, Rubella, p 740, and Varicella-Zoster Infections, p 948).

A second dose of MMR or MMRV is not associated with an increased incidence of reactions relative to the first dose.

Precautions and Contraindications. See Measles, p 582, Rubella, p 740, and, if MMRV is used, Varicella-Zoster Infections, p 949.

Febrile Illness. Children with minor illnesses, such as upper respiratory tract infections, should be immunized. Fever is not a contraindication to immunization. However, if other manifestations suggest a more serious illness, the child should not be immunized until recovered.

Allergies. Hypersensitivity reactions occur rarely and usually are minor, consisting of wheal-and-flare reactions or urticaria at the injection site. Reactions have been attributed to trace amounts of neomycin or gelatin or some other component in the vaccine formulation.

Anaphylaxis is rare. MMR and MMRV are produced in chicken embryo cell culture and do not contain significant amounts of egg white (ovalbumin) cross-reacting proteins, so children with egg allergy are at low risk of anaphylactic reactions. Skin testing of children for egg allergy is not predictive of reactions to MMR or MMRV and, therefore, is not required before administering vaccine. People with allergies to chickens or feathers are not at increased risk of reaction to the vaccine. People who have experienced anaphylactic reactions to gelatin or topically or systemically administered neomycin should receive mumps vaccine only in settings where such reactions could be managed and after consultation with an allergist or immunologist. Most often, however, neomycin allergy manifests as contact dermatitis, which is not a contraindication to receiving mumps vaccine (see Measles, p 570).

Recent Administration of IG. Administration of MMR or MMRV should be delayed from 3 to 11 months following receipt of specific blood products or IG (see Table 1.11, p 69). When possible, MMR should be administered at least 2 weeks before planned administration of IG, blood transfusion, or other blood products because of the theoretical possibility that antibody will neutralize vaccine virus and interfere with successful immunization. If IG must be administered within 14 days after administration of MMR or MMRV, these vaccines should be readministered after the interval specified in Table 1.11 (p 69).

Altered Immunity. Patients with immunodeficiency diseases and those receiving immunosuppressive therapy or expected to receive such therapy within 4 weeks, including high doses of systemically administered corticosteroids, alkylating agents, antineoplastic agents, or radiation, or people who are otherwise immunocompromised should not receive live attenuated vaccines including MMR or MMRV (see Immunization and Other Considerations in Immunocompromised Children, p 93).

Exceptions are patients with human immunodeficiency virus (HIV) infection who are not severely immunocompromised. MMR vaccine is recommended for all people ≥ 12 months of age with HIV who do not have evidence of severe immunosuppression (see Human Immunodeficiency Virus Infection, p 489). For vaccination purposes, severe immunosuppression for people ≤ 5 years of age is defined as a CD4+ T-lymphocyte percentage $< 15\%$, and for people > 5 years of age is defined as a CD4+ T-lymphocyte percentage $< 15\%$ **or** a CD4+ T-lymphocyte count < 200 lymphocytes/mm³. Severely immunocompromised HIV-infected infants, children, adolescents, and young adults should not receive MMR. MMRV vaccine should not be administered to any infant or child with HIV, regardless of degree of immunosuppression, because of lack of safety data in this population.

The risk of mumps exposure for patients with altered immunity can be decreased by immunizing their close susceptible (ie, household) contacts. Vaccine recipients cannot transmit mumps vaccine virus.

After cessation of immunosuppressive therapy, MMR immunization should be deferred for at least 3 months (except for corticosteroid recipients [see next paragraph]). This interval is based on the assumptions that immunologic responsiveness will have been restored in 3 months and the underlying disease for which immunosuppressive therapy was given is in remission or under control. However, because the interval can vary with the intensity and type of immunosuppressive therapy, radiation therapy, underlying disease, and other factors, a definitive recommendation for an interval after cessation of immunosuppressive therapy when mumps vaccine (as MMR) can be administered safely and effectively often is not possible.

Corticosteroids. Children receiving ≥ 2 mg/kg per day of prednisone or its equivalent, or ≥ 20 mg/day if they weigh 10 kg or more, for 14 days or more and who otherwise are not immunocompromised should not receive live-virus vaccines until 4 weeks after discontinuation (see Immunization and Other Considerations in Immunocompromised Children, p 93).

Pregnancy. Conception should be avoided for 4 weeks after mumps immunization because of the theoretical risk associated with live-virus vaccine. Susceptible postpubertal people should not be immunized if they are known to be pregnant. However, mumps immunization during pregnancy has not been associated with congenital malformations (see Immunization in Pregnancy, p 89).

Tuberculosis. Tuberculin skin testing or interferon gamma release assay (IGRA) testing is not a prerequisite for MMR immunization. Antituberculosis therapy should be initiated before administering MMR vaccine to people with untreated tuberculosis infection or disease. Tuberculin skin or IGRA testing, if otherwise indicated, can be performed on the day of immunization with MMR vaccine. Otherwise, tuberculin skin or IGRA testing should be postponed for 4 to 6 weeks, because measles immunization temporarily may suppress tuberculin skin test reactivity and possibly affect IGRA testing.

Public Health Reporting. Mumps is a nationally notifiable disease in the United States.

***Mycoplasma pneumoniae* and Other *Mycoplasma* Species Infections**

CLINICAL MANIFESTATIONS: *Mycoplasma pneumoniae* is a frequent cause of upper and lower respiratory tract infections in children, including pharyngitis, acute bronchitis, and pneumonia. Acute otitis media is uncommon. Bullous myringitis, once considered

pathognomonic for mycoplasma, now is known to occur with other pathogens as well. Sinusitis and croup are rare. Symptoms are variable and include cough, malaise, fever, and occasionally headache. Acute bronchitis and upper respiratory tract illness caused by *M pneumoniae* generally are mild and self-limited. Approximately 25% of infected school-aged children will develop pneumonia with cough and rales on physical examination within days after onset of constitutional symptoms. Cough, initially nonproductive, can become productive, persist for 3 to 4 weeks, and be accompanied by wheezing. Approximately 10% of children with *M pneumoniae* infection will exhibit a rash, which most often is maculopapular. Radiographic abnormalities are variable; bilateral diffuse infiltrates or focal abnormalities, such as consolidation, pleural effusion, or hilar adenopathy, can occur.

Unusual manifestations include nervous system disease (eg, aseptic meningitis, encephalitis, acute disseminated encephalomyelitis, cerebellar ataxia, transverse myelitis, and peripheral neuropathy) as well as myocarditis, pericarditis, arthritis (particularly in immunocompromised hosts), erythema nodosum, polymorphous mucocutaneous eruptions (eg, Stevens-Johnson syndrome or reactive infection mucocutaneous eruption [RIME], formerly referred to as *Mycoplasma*-induced rash and mucositis [MIRM] syndrome), hemolytic anemia, thrombocytopenic purpura, hemophagocytic syndromes, and postinfectious glomerulonephritis. Severe pneumonia with pleural effusion can occur, particularly in patients with sickle cell disease, Down syndrome, immunodeficiencies, and chronic cardiorespiratory disease. Acute chest syndrome and pneumonia have been associated with *M pneumoniae* in patients with sickle cell disease. Infection also has been associated with exacerbations of asthma.

Several other *Mycoplasma* species colonize mucosal surfaces of humans and can produce disease in children. *Mycoplasma hominis* infection has been reported in neonates and children (both immunocompetent and immunocompromised). Intra-abdominal abscess, septic arthritis, endocarditis, pneumonia, meningoencephalitis, brain abscess, and surgical wound infection have been attributed to *M hominis*. *Mycoplasma genitalium* causes urethritis among male individuals and is the etiology of approximately 15% to 20% of nongonococcal urethritis (NGU), 20% to 25% of nonchlamydial NGU, and 40% of persistent or recurrent urethritis.¹ Among female individuals, *M genitalium* has been associated with cervicitis, pelvic inflammatory disease, preterm delivery, spontaneous abortion, and infertility, with an approximately twofold increase in the risk for these outcomes among women with *M genitalium*. Female individuals with *M genitalium* are also frequently asymptomatic, and the consequences associated with asymptomatic *M genitalium* infection are unknown.

ETIOLOGY: Mycoplasmas are pleomorphic bacteria that lack a cell wall. They are classified in the family *Mycoplasmataceae*, which includes the *Mycoplasma* and *Ureaplasma* genera.

EPIDEMIOLOGY: Mycoplasmas are ubiquitous in animals and plants, but *M pneumoniae* causes disease only in humans. *M pneumoniae* is transmissible by respiratory droplets during close contact. Outbreaks have been described in hospitals, military bases, colleges, and summer camps. Occasionally, *M pneumoniae* causes ventilator-associated pneumonia. *M pneumoniae* is a leading cause of pneumonia in school-aged children and young adults but is an infrequent cause of community-acquired pneumonia (CAP) in

¹ The terms male, female, men, and women refer to sex assigned at birth.

children younger than 5 years. In the United States, an estimated 2 million infections are caused by *M pneumoniae* each year. Overall, approximately 10% to 20% of cases of CAP in hospitalized patients are believed to be caused by *M pneumoniae*. Infections occur throughout the world, in any season, and in all geographic settings. In family studies, approximately 30% of household contacts develop pneumonia. Asymptomatic carriage after infection may occur for weeks to months. Immunity after infection is not long lasting.

The **incubation period** usually is 2 to 3 weeks (range, 1–4 weeks), which can contribute to lengthy outbreaks.

DIAGNOSTIC TESTS: Nucleic acid amplification tests (NAATs) for *M pneumoniae* are available commercially and increasingly are replacing other tests, because NAATs performed on respiratory tract specimens (nasal wash, nasopharyngeal swab, oropharyngeal swab, sputum, and bronchoalveolar lavage fluid) are rapid, have sensitivity and specificity between 80% and 100%, and yield positive results earlier in the course of illness. Several assays are cleared by the US Food and Drug Administration (FDA) for diagnostic use, including an assay targeting *M pneumoniae* alone and multiplex assays that simultaneously target other respiratory pathogens as well. Identification of *M pneumoniae* by NAAT or culture in a patient with compatible clinical manifestations suggests causation. However, attributing a nonclassic clinical disorder to *M pneumoniae* is problematic, because the organism can colonize the respiratory tract for several weeks after acute infection (even after appropriate antimicrobial therapy) and has been detected by NAAT in 17% to 25% of asymptomatic children 3 months to 16 years of age. NAAT of body fluids for *M hominis* is available at reference laboratories and may be helpful diagnostically.

Serologic tests using immunofluorescence and enzyme immunoassays that detect *M pneumoniae*-specific immunoglobulin (Ig) M, IgA, and IgG antibodies are available commercially. IgM antibodies generally are not detectable within the first 7 days after onset of symptoms. Although the presence of IgM antibodies may indicate recent *M pneumoniae* infection, false-positive test results occur, and antibodies may persist in serum for several months or even years and, thus, may not indicate acute infection. IgM antibodies may not be elevated in older children and adults who have had recurrent *M pneumoniae* infection. Serologic diagnosis is best accomplished by demonstrating a fourfold or greater increase in IgG antibody titer between acute and convalescent serum specimens. Complement-fixation assay results should be interpreted cautiously, because the assay is both less sensitive and less specific than is immunofluorescent assay or enzyme immunoassay. Measurement of serum cold hemagglutinin titer has limited value, because titers of $\geq 1:64$ are present in only 50% to 75% of patients with pneumonia caused by *M pneumoniae*, and lower titers are nonspecifically present during respiratory viral infections.

Mycoplasma organisms lack cell walls and so are not visible by cell-wall specific stains (eg, Gram stain) using light microscopy. *M pneumoniae* and *M hominis* can be grown in special enriched broth and agar media such as SP4 or on commercially available mixed liquid broth/agar slant media. However, most clinical laboratories lack the capacity to perform culture isolation and culture and identification may take longer than 21 days. *M genitalium* culture can take up to several months, and technical laboratory capacity is limited to research settings. A NAAT for *M genitalium* is FDA cleared for use with urine and urethral, penile meatal, endocervical, and vaginal swab samples.

Molecular tests for macrolide (ie, azithromycin) or quinolone (ie, moxifloxacin) resistance markers are limited in the United States. However, molecular assays that incorporate detection of mutations associated with macrolide resistance are under evaluation.

The diagnosis of mycoplasma-associated central nervous system disease is challenging, both because disease may not be the result of direct invasion and because there is no reliable single test for cerebrospinal fluid to establish a diagnosis.

TREATMENT: Evidence of benefit of antimicrobial therapy for nonhospitalized children with lower respiratory tract disease attributable to *M pneumoniae* is limited. Most children with CAP attributable to *M pneumoniae* have a relatively mild, self-limited illness, but effective antibiotic therapy may be more important with more severe infections. The usual course of antimicrobial therapy for pneumonia is 7 to 10 days, except for azithromycin, for which it usually is 5 days.

Antimicrobial therapy is not routinely recommended for preschool-aged children with CAP, because viral pathogens are responsible for the great majority of cases.¹ There is no evidence that treatment of other possible manifestations of *M pneumoniae* infection (eg, upper respiratory tract infection) with antimicrobial agents alters the course of illness. However, despite limited data, it is reasonable to treat severe extrapulmonary infections such as central nervous system disease or septic arthritis in an immunocompromised patient with an expectation that it may shorten the duration and severity of illness.

Because mycoplasmas lack a cell wall, they inherently are resistant to beta-lactam agents. Macrolides, including azithromycin, clarithromycin, and erythromycin, are the preferred antimicrobial agents for treatment of *Mycoplasma pneumoniae* in school-aged children who have moderate to severe infection and those with underlying conditions, such as sickle cell disease.¹ Fluoroquinolones, tetracyclines (doxycycline), and pleuromutilins (the latter only approved in people 18 years and older) are 3 other classes of antibiotics to which *M pneumoniae* is susceptible.

Although macrolide-resistant strains of *M pneumoniae* have been identified, the majority of strains are susceptible, and the clinical implications of resistance are unclear. Treatment of hospitalized children with CAP attributable to a macrolide-resistant *M pneumoniae* using a fluoroquinolone has been shown in some studies to shorten the duration of fever and the length of hospitalization, but other studies have found no difference. *M hominis* usually is resistant to erythromycin and azithromycin but is variably susceptible to clindamycin, tetracyclines, and fluoroquinolones.

M genitalium is susceptible in vitro to macrolides, tetracyclines, and fluoroquinolones; however, resistance to macrolides has been rapidly increasing and has been confirmed in multiple studies. Prevalence of molecular markers for macrolide resistance, which highly correlates with treatment failure, range from 44% to 90% in the United States, Canada, Western Europe, and Australia. Although the majority of *M genitalium* strains are sensitive to moxifloxacin, resistance has been reported. Resistance-guided therapy has demonstrated cure rates of >90% and should be used whenever possible. As part of this approach, doxycycline is provided as initial empiric therapy,

¹ Bradley JS, Byington CL, Shah SS, et al. The management of community-acquired pneumonia in infants and children older than 3 months of age: clinical practice guidelines by the Pediatric Infectious Diseases Society and the Infectious Diseases Society of America. *Clin Infect Dis*. 2011;53(1):e25-e76

which reduces the organism load and facilitates organism clearance, followed by either azithromycin for macrolide-sensitive strains or moxifloxacin for macrolide-resistant strains. If resistance testing is not available, doxycycline 100 mg twice daily for 7 days is provided followed by moxifloxacin 400 mg once daily for 7 days. Data are limited regarding use of minocycline in instances of treatment failure.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, droplet precautions are recommended for the duration of symptomatic illness with *M pneumoniae*.

CONTROL MEASURES FOR *M PNEUMONIAE* INFECTIONS: Hand hygiene decreases household transmission of respiratory pathogens and should be encouraged.

Tetracycline or azithromycin prophylaxis for close contacts has been shown to limit transmission in family and institutional outbreaks. However, antimicrobial prophylaxis for asymptomatic exposed contacts is not recommended routinely, because most secondary illnesses are generally mild and self-limited. Prophylaxis with a macrolide or a tetracycline (doxycycline) can be considered for people at increased risk of severe illness with *M pneumoniae*, such as children with sickle cell disease who are close contacts of a person who is acutely ill with *M pneumoniae* infection.

Nocardiosis

CLINICAL MANIFESTATIONS: Immunocompetent children typically develop cutaneous or lymphocutaneous disease with pustular or ulcerative lesions following soil contamination of a skin injury. Deep-seated tissue infection may follow traumatic soil-contaminated wounds. Immunocompromised people may develop invasive disease (pulmonary disease, which may disseminate, in particular to the central nervous system). At-risk people include those with chronic granulomatous disease, chronic obstructive pulmonary disease (COPD), impaired cell-mediated immunity including human immunodeficiency virus (HIV) infection, diseases requiring long-term systemic corticosteroid/immunosuppressive therapy, and autoimmune disease; people having received tumor necrosis factor inhibitors; and solid organ or hematopoietic cell transplant recipients, especially if calcineurin inhibitor levels are high. Pulmonary disease commonly manifests as rounded nodular infiltrates that can undergo cavitation; the infection may be acute, subacute, or chronic suppurative. The most common clinical symptoms include fever, cough, pleuritic chest pain, chills, and headache. *Nocardia* has a propensity to spread hematogenously to the brain (single or multiple abscesses) from the lungs. The organism also may spread to the skin (pustules, pyoderma, abscesses, mycetoma), or occasionally to other organs. *Nocardia* organisms can be recovered from respiratory specimens of patients with cystic fibrosis, but the clinical significance of this pathogen in these patients is unclear.

ETIOLOGY: *Nocardia* are gram-positive, aerobic, intracellular, nonmotile, filamentous bacteria in the order *Actinomycetales*. Cell walls of *Nocardia* organisms contain mycolic acid and thus may be described as “acid fast” or “partially acid fast” using the modified Kinyoun or Fite Faraco acid-fast staining and light microscopy.

EPIDEMIOLOGY: *Nocardia* species are ubiquitous environmental saprophytes, living in soil, organic matter, and fresh or sea water. Infections caused by *Nocardia* species typically are the result of environmental exposure through inhalation of soil or

dust particles or through traumatic inoculation with a soil-contaminated object. The most prevalent species reported from human clinical sources in the United States are *Nocardia nova* complex, *Nocardia farcinica*, *Nocardia cyriacigeorgica*, and *Nocardia abscessus* complex; there is geographic variation by infecting species. Primary cutaneous infection and mycetoma most often are associated with *Nocardia brasiliensis*. Other less common pathogenic species include *Nocardia brevicatena* complex, *Nocardia otitidiscaviarum* complex, *Nocardia pseudobrasiliensis*, and *Nocardia transvalensis* complex.

Health care-associated or person-to-person transmission has been reported rarely. Animal-to-human transmission is not known to occur.

The **incubation period** is unknown.

DIAGNOSTIC TESTS: Isolation of *Nocardia* species from clinical specimens can require extended incubation periods, often 2 to 3 weeks. Specimens from sterile sites can be inoculated directly onto enriched solid media such as trypticase soy agar supplemented with 5% sheep blood, chocolate, brain-heart infusion, Sabouraud dextrose agars, and buffered charcoal yeast extract (BCYE) agar. Colonies look like white snowballs because of aerial hyphae. Specimens from nonsterile or contaminated sites, such as tissue or sputum, should be inoculated onto selective media, such as Thayer Martin or BCYE supplemented with vancomycin, with a minimum incubation of 3 weeks. Recovery of *Nocardia* species from tissue can be improved if the laboratory is requested to observe cultures for up to 4 weeks in an appropriate liquid medium at optimal growth temperature (between 25°C and 35°C for most species). Stained smears of sputum, body fluids, or pus demonstrating beaded, branching rods that stain weakly gram positive and partially acid-fast by the modified Kinyoun method suggest the diagnosis. The Brown-Brenn tissue Gram stain method and Grocott-Gomori methenamine silver stains are recommended to demonstrate microorganisms in tissue specimens.

Accurate identification of *Nocardia* isolates paired with antimicrobial susceptibility testing greatly enhances selection of appropriate antimicrobial therapy. Because of variability of phenotypic traits and difficulty growing organisms on commercial biochemical testing media, accurate identification is accomplished through molecular methods. Matrix-assisted laser desorption/ionization–time-of-flight (MALDI-TOF) mass spectrometry is often the first method used to identify the *Nocardia* isolate down to the species level, with other complementary methods used as necessary, such as 16S rRNA gene sequence analysis of full length or nearly full-length (~1440 bp) sequences, or whole genome analysis. Serologic tests for *Nocardia* species are not useful except for an enzyme-linked immunosorbent assay used to determine the presence of antibodies to *N. brasiliensis* mycetoma.

Most experts recommend neuroimaging with or without cerebrospinal fluid examination in patients with pulmonary disease, even with a nonfocal neurologic examination, given the propensity of these organisms to infect the central nervous system.

TREATMENT: Rapid and accurate identification of *Nocardia* isolates and antimicrobial susceptibility testing are essential tools for successful treatment of nocardiosis. *Nocardia* species possess intrinsic resistance to multiple drugs. Antimicrobial susceptibility testing recommended by the Clinical and Laboratory Standards Institute (CLSI) is complex and generally requires a specialty or reference laboratory. Such testing should guide therapy and is recommended for all strains from patients with invasive disease, when patients are unable to tolerate a sulfonamide, or for patients in whom sulfonamide therapy fails.

Trimethoprim-sulfamethoxazole (TMP/SMX) is the drug of choice for mild infections. Certain *Nocardia* species including *N. farcinica*, *N. nova*, and *N. otitidiscaviarum* may demonstrate intrinsic resistance to TMP/SMX. If infection does not respond to TMP/SMX, a fluoroquinolone or a carbapenem may be considered, although most *Nocardia* species are resistant to ertapenem. Linezolid has excellent activity against all *Nocardia* species but is not recommended for long-term administration because of hematologic and possible neurologic toxicity. Other agents with specific *Nocardia* coverage include clarithromycin (*N. nova*) and amoxicillin-clavulanate (*N. brasiliensis* and *N. abscessus* complex). Pediatric data are lacking for many of these agents in the treatment of nocardiosis. Immunocompetent patients with lymphocutaneous disease usually respond after 6 to 12 weeks of monotherapy.

Combination drug therapy is recommended for patients with serious disease (pulmonary infection, disseminated disease, central nervous system involvement) and for infection in immunocompromised hosts. Initial combination treatment should include TMP/SMX, amikacin, and either linezolid, imipenem, or meropenem (resistance noted for some strains of *N. brasiliensis*) until susceptibilities are available. Ceftriaxone is an alternative agent, but resistance is noted for many strains of *N. farcinica*, *N. transvalensis* complex, and *N. otitidiscaviarum* complex. Immunocompromised patients and patients with serious disease should be treated for 6 to 12 months and for at least 3 months after apparent cure because of the propensity for relapse. Patients living with HIV may need even longer therapy, and suppressive therapy should be considered for life in the absence of immune reconstitution. Patients with central nervous system disease should be monitored with serial neuroimaging studies.

Drainage of abscesses is beneficial, and removal of infected foreign bodies (eg, central venous catheters) is recommended.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: People with weakened immune systems should be advised to cover their skin when working with soil. TMP/SMX administered 3 times per week for prophylaxis against *Pneumocystis jirovecii* generally is ineffective in preventing nocardiosis.

Norovirus and Sapovirus Infections

CLINICAL MANIFESTATIONS: Abrupt onset of vomiting and/or watery diarrhea, accompanied by abdominal cramps and nausea, are characteristic of norovirus and sapovirus gastroenteritis. Symptoms typically last from 24 to 72 hours. However, more prolonged courses of illness can occur, particularly among elderly people, young children, and hospitalized patients. Norovirus illness is recognized as a cause of chronic gastroenteritis in immunocompromised patients. Systemic manifestations, including fever, myalgia, malaise, anorexia, and headache, may accompany gastrointestinal tract symptoms.

ETIOLOGY: *Norovirus* and *Sapovirus* are genera in the family *Caliciviridae* and are 23- to 40-nm, nonenveloped, single-stranded RNA viruses. Noroviruses are genetically diverse and are classified into 10 genogroups of which viruses from genogroups (G) I and GII cause most of the infections in humans. Globally, GII genotype 4 viruses have caused the majority of outbreaks in recent decades (although some other genotypes have dominated in parts of Asia). Sapovirus genogroups I, II, IV, and V cause acute

gastroenteritis with symptoms indistinguishable to norovirus in humans. At least 19 different sapovirus genogroups have been recognized.

EPIDEMIOLOGY: Norovirus causes illness in an estimated 1 in 15 Americans each year, resulting in 109 000 hospitalizations and 900 deaths annually. Nearly 1 million children (particularly those younger than 5 years) seek medical care because of norovirus. Deaths occur primarily among the elderly. As a result of the success of rotavirus vaccines, noroviruses have become the predominant cause of medically attended acute gastroenteritis in the United States, causing both sporadic cases and outbreaks. Outbreaks of sapovirus infection are relatively rare, with a prevalence in children younger than 5 years ranging from 3% to 17%.

Outbreaks with high attack rates tend to occur in semi-closed communities, such as long-term care facilities, schools, child care centers, and cruise ships. Transmission occurs via the fecal-oral or vomitus-oral routes, either directly person to person or indirectly by ingesting contaminated food or water or by touching surfaces contaminated with the virus and then touching the mouth. Common-source outbreaks have been described after ingestion of ice, shellfish, and a variety of ready-to-eat foods, including salads, berries, and bakery products, usually contaminated by infected food handlers. Transmission via vomitus has been documented, and exposure to contaminated surfaces and aerosolized vomitus has been implicated in some outbreaks. Asymptomatic shedding of norovirus is common across all age groups, with the highest prevalence in children.

Most norovirus strains bind to histo-blood group antigens, which are expressed on intestinal epithelial cells and are genetically regulated by the fucosyltransferase 2 (FUT2) gene. Individuals with a functional FUT2 gene are referred to as “secretors” whereas nonsecretors have a single point mutation in FUT2 making them nonsusceptible to most norovirus infections.

The **incubation period** for both norovirus and sapovirus is 12 to 48 hours. Viral shedding may start before onset of symptoms, peaks several days after exposure, and in some cases, may persist for ≥ 4 weeks. Prolonged shedding (>6 months) has been reported in immunocompromised hosts. Infection occurs year-round but is more common during the colder months of the year.

DIAGNOSTIC TESTS: Molecular diagnostic methods, such as nucleic acid amplification tests (NAATs) of stool samples, are the most sensitive means to detect norovirus and sapovirus. Several multiplex NAATs for the detection of gastrointestinal tract pathogens are cleared by the US Food and Drug Administration, with the majority including norovirus testing and some also including sapovirus testing. In children, interpretation of multipathogen test results may be complicated by coinfection with other enteric pathogens.

State and local public health laboratories use reverse transcriptase quantitative polymerase chain reaction (RT-qPCR) or multipathogen platforms for detection of norovirus and sapovirus RNA in clinical specimens. Both norovirus and sapovirus can be genotyped by amplification and sequencing of small regions of the capsid regions. Laboratory and epidemiologic support for investigation of suspected viral gastroenteritis outbreaks in the United States is available through local and state health departments.

TREATMENT: Supportive therapy includes oral or intravenous rehydration solutions to replace and maintain fluid and electrolyte balance. In transplant recipients with

chronic diarrhea, some experts consider reduction in immunosuppressive medications, if feasible, and/or use of nitazoxanide.¹

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, contact precautions are recommended for suspected cases of acute gastroenteritis attributable to norovirus infection until 48 hours after symptom resolution.

CONTROL MEASURES: Appropriate hand hygiene is the most important method to prevent norovirus and sapovirus infections and control transmission. This hand hygiene is best accomplished by thorough handwashing with running water and plain or antiseptic soap. Washing hands with soap and water after contact with a patient with norovirus or sapovirus infection is more effective than using alcohol-based hand sanitizers for reducing transmission.

Several factors favor transmission of noroviruses, including low infectious dose, large numbers of virus particles excreted, prolonged shedding, and persistence of the virus in the environment. The risk of infection can be decreased by standard measures for control of vomiting and diarrhea, such as educating child care providers and food handlers about infection control, maintaining cleanliness of surfaces and food preparation areas, using appropriate disinfectants (principally sodium hypochlorite [chlorine bleach]), excluding caregivers or food handlers who are ill and for at least 2 days after symptoms stop, and exercising appropriate hand hygiene, as discussed previously. If a source of transmission can be identified (eg, contaminated food or water) during an outbreak, then specific interventions to interrupt transmission can be effective.

Infants and children should be excluded from child care centers until stools are contained in the diaper or when toilet-trained children no longer have accidents using the toilet and when stool frequency becomes no more than 2 stools above that child's normal frequency for the time the child is in the program, even if the stools remain loose.

Public Health Reporting. Sporadic cases are not nationally notifiable, but outbreaks should be reported to local and state public health authorities as required and to the Centers for Disease Control and Prevention via the National Outbreak Reporting System (NORS) (www.cdc.gov/nors), and laboratory test data including genotype information should be submitted to CaliciNet (www.cdc.gov/norovirus/reporting/calicinet/index.html).

Onchocerciasis

(River Blindness, Filariasis)

CLINICAL MANIFESTATIONS: Onchocerciasis primarily affects skin, subcutaneous tissues, and eyes. Subcutaneous, nontender nodules containing male and female adult worms can be up to several centimeters in diameter and are more common over bony prominences. Nodules tend to be found on the lower torso, pelvis, and lower extremities in patients infected in Africa, whereas in patients infected in South America,

¹ Angarone M, Snyderman D; American Society of Transplantation Infectious Diseases Community of Practice. Diagnosis and management of diarrhea in solid-organ transplant recipients: Guidelines from the American Society of Transplantation Infectious Diseases Community of Practice. *Clin Transplant*. 2019;33(9):e13550

nodules are located more often on the upper body (the head and trunk). After the worms mature, fertilized female worms produce prelarval stages called microfilariae that migrate to the dermis and may cause a papular dermatitis. Pruritus often is intense, resulting in patient-inflicted excoriations over the affected areas. After years, skin can become lichenified and hypo- or hyperpigmented. Microfilariae may invade ocular structures, leading to inflammation of the cornea, iris, ciliary body, retina, choroid, and optic nerve. Loss of visual acuity and blindness can result over time if the disease is left untreated. Infection has also been associated with development of epilepsy.

ETIOLOGY: *Onchocerca volvulus* is a filarial nematode.

EPIDEMIOLOGY: *O. volvulus* has no significant animal or environmental reservoir. Humans are infected when infectious larvae are transmitted through the bites of *Simulium* species flies (black flies). Black flies breed in fast-flowing streams and rivers (hence, the colloquial name for the disease, “river blindness”). Transmission of the parasite occurs primarily in equatorial Africa, but small foci are found in Venezuela, Brazil, and Yemen. Prevalence is greatest among people who live near vector breeding sites. The infection is not transmissible by person-to-person contact, blood transfusion, or breastfeeding; congenital transmission does not occur. Infection in travelers to areas with endemic infection who stay less than 6 to 12 months is uncommon.

The **incubation period** from infective bite to adult worm nodules is 6 to 12 months, and to microfilariae in the skin usually is 12 to 18 months but can be as long as 3 years.

DIAGNOSTIC TESTS: Direct microscopic examination of a 1- to 2-mm biopsy specimen of the epidermis and upper dermis (taken from the posterior iliac crest or other areas with highest suspicion for local microfilariae), incubated in saline, can reveal emerging microfilariae. Multiple skin snips may be needed to make a diagnosis, and in children in whom clinical suspicion of onchocerciasis is high, use of a nucleic acid amplification test (NAAT) may increase diagnostic yield if microscopic examination is negative. Microfilariae are not found in blood. Adult worms may be demonstrated in excised nodules that have been sectioned and stained. A slit-lamp examination of an involved eye may reveal motile microfilariae in the anterior chamber or “snowflake” corneal lesions. Eosinophilia is common. Specific serologic tests and detection of microfilariae in skin by NAAT are available in the United States in research and public health laboratories, including those of the National Institutes of Health and Centers for Disease Control and Prevention. Ultrasonography of nodules may visualize adult worms.

TREATMENT: Ivermectin and moxidectin are approved in the United States for treatment of onchocerciasis, although moxidectin is not yet available commercially (see Drugs for Parasitic Infections, p 1068). Patients from areas with endemic *Loa loa* infection should be screened for *L. loa* and should be referred to an expert if coinfecting with *O. volvulus* and *L. loa*, as treatment of patients with high levels of circulating *L. loa* microfilariaemia with ivermectin rarely can result in fatal encephalopathy. Ivermectin can be used in younger children weighing more than 15 kg. Treatment decreases pruritus and dermatitis as well as the risk of developing severe ocular disease but does not kill the adult worms (which can live for more than a decade) and, thus, is not curative. Treatment with ivermectin is administered every 6 months until asymptomatic. Moxidectin, as a

single oral dose for patients 12 years and older, has superior and more durable efficacy in reducing microfilariae in skin compared with a single dose of ivermectin. Safety and efficacy of repeated doses of moxidectin have not been studied, but on the basis of the duration of microfilarial suppression observed in the available studies, yearly dosing of moxidectin until asymptomatic is reasonable. Adverse reactions to treatment are caused by death of microfilariae and can include rash, edema, fever, myalgia, and rarely, asthma exacerbation and hypotension. Such reactions are more common in people with higher skin loads of microfilariae and decrease with repeated treatment in the absence of reexposure. Precautions to ivermectin/moxidectin treatment include pregnancy (class C drug), central nervous system disorders, and coinfection with *L loa* (see Lymphatic Filariasis, p 557). Ivermectin usually is compatible with breastfeeding, but because low levels of drug are found in human milk after treatment of the lactating person, most experts recommend delaying treatment of a breastfeeding person until the infant is >7 days of age.

A 6-week course of doxycycline can be used in addition to ivermectin or moxidectin to kill adult worms through depletion of their endosymbiotic rickettsia-like bacteria *Wolbachia*, which appear to be required for survival of *O volvulus*. Doxycycline may be used regardless of age in nonpregnant patients to obviate the need for years of ivermectin treatment. Doxycycline treatment may be initiated 1 week after treatment with ivermectin/moxidectin; for patients without symptoms, a 4- to 6-week course of doxycycline may be given, followed by a dose of ivermectin/moxidectin. There are no studies of the safety of simultaneous treatment.

The microfilaricide diethylcarbamazine (DEC) is contraindicated for the treatment of onchocerciasis, because it may cause adverse ocular reactions. Nodules can be removed surgically, but medical treatment still should be offered, because not all nodules may be detectable clinically or accessible surgically.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: Repellents and protective clothing (long sleeves and pants) can decrease exposure to bites from black flies, which bite by day. Treatment of vector breeding sites with larvicides is effective for controlling black fly populations. Vector control, however, largely has been supplanted by community-wide mass ivermectin administration programs. A highly successful global initiative being led by the World Health Organization has distributed hundreds of millions of ivermectin treatments (donated by the drug manufacturer for this purpose) in communities with endemic onchocerciasis. As a result of these programs, morbidity and transmission largely have been eliminated from the Americas (where most mass treatment programs now have halted) and markedly curtailed throughout Africa.

Paracoccidioidomycosis

(Formerly Known as South American Blastomycosis)

CLINICAL MANIFESTATIONS: Most disease occurs in adults (90%–95% of cases). The site of initial infection is the lungs. Clinical patterns include subclinical infection or progressive disease that can be either acute-subacute (juvenile type) or chronic (adult type). Constitutional symptoms, such as fever, malaise, anorexia, and weight loss, are common in both adult and juvenile forms.

In the juvenile form, the initial pulmonary infection usually is asymptomatic, and manifestations are related to dissemination of infection to the reticuloendothelial system, resulting in enlarged lymph nodes and involvement of liver, spleen, and bone marrow. Skin lesions are observed regularly and are located typically on the face, neck, and trunk. Involvement of bones, joints, and mucous membranes is less common. Enlarged lymph nodes occasionally coalesce and form abscesses or fistulas. The chronic form of the illness can be localized to the lungs or can disseminate. Oral mucosal lesions are observed in half of the cases, and skin involvement is common but occurs in a smaller proportion than in patients with the acute-subacute form. Infection can be latent for years before causing illness.

ETIOLOGY: *Paracoccidioides brasiliensis* is a thermally dimorphic fungus with yeast and mycelia (mold) phases. *P brasiliensis* complex contains 5 different phylogenetic lineages (S1a, S1b, PS2, PS3, and PS4). *Paracoccidioides lutzii* also causes paracoccidioidomycosis.

EPIDEMIOLOGY: The infection occurs in Latin America, from Mexico to Argentina, with 80% of cases in Brazil. The natural reservoir is unknown although soil is suspected; most disease is associated with agricultural work. The mode of transmission is unknown but most likely occurs via inhalation of contaminated soil or dust; person-to-person transmission does not occur. The armadillo is a known reservoir of *P brasiliensis*.

The **incubation period** is highly variable, ranging from 1 month to decades. Cases have been diagnosed outside endemic regions, so prior residence in Latin America is an important determinant in raising suspicion of the infection.

DIAGNOSTIC TESTS: Diagnosis is confirmed by visualization of fungal elements. Round, multiple-budding yeast cells with a distinguishing pilot's wheel appearance can be seen in preparations of sputum, bronchoalveolar lavage specimens, scrapings from ulcers, and material from lesions or in tissue biopsy specimens. Specimens can be prepared with several procedures, including wet or KOH wet preparations, or histologic staining with hematoxylin and eosin, silver, or periodic-acid Schiff. The mycelia form of *P brasiliensis* can be cultured on most enriched media, including Mycosel or Sabouraud dextrose agar, at 25°C to 30°C. Cultures should be held at least 8 weeks. The appearance of the mycelia form is not distinctive, and identification requires conversion to the yeast phase or DNA sequence determination. Complement fixation and immunodiffusion serologic tests are available for antibody detection. Semiquantitative immunodiffusion is the preferred test, with sensitivity around 80% and specificity >95%, and is the most widely available test in endemic regions.

TREATMENT¹: Oral therapy with itraconazole is the treatment of choice for less severe or localized infection. Serum trough concentrations of itraconazole should be 1 to 2 µg/mL. A trough level should be checked 10 days or later following initiation to ensure adequate drug exposure. When measured by high-pressure liquid chromatography, both itraconazole and its bioactive hydroxyitraconazole metabolite are reported, the sum of which should be considered in assessing the trough concentration. The itraconazole oral solution formulation is preferred over the capsule formulation because of improved absorption, and should be taken on an empty stomach.

¹ Thompson GR III, Le T, Chindamporn A, et al. Global guideline for the diagnosis and management of the endemic mycoses: an initiative of the European Confederation of Medical Mycology in cooperation with the International Society for Human and Animal Mycology [Erratum in: *Lancet Infect Dis*. 2021;21(11):e341]. *Lancet Infect Dis*. 2021;21(12):e364-e374

However, a super bioavailable (SUBA) itraconazole is now approved by the Food and Drug Administration for the treatment of pulmonary and extrapulmonary blastomycosis in individuals 18 years or older, with pharmacokinetic studies of this formulation demonstrating less variable absorption than conventional itraconazole capsules and a similar side effect profile; data in children are lacking.

Voriconazole may be as effective as itraconazole, including when there is central nervous system involvement, but has not been studied as extensively. Close monitoring of voriconazole serum trough concentrations is critical for both efficacy and safety. Most experts agree that voriconazole trough concentrations should be measured on day 3 or later after initiating treatment and for children, therapeutic trough concentrations are 2 to 6 µg/mL. It is important to individualize dosing in patients following initiation of voriconazole therapy, because there is high interpatient variability in metabolism.

Isavuconazole has been efficacious in adults, but there are limited pediatric data for paracoccidioidomycosis.

Optimal duration of therapy is unknown, but prolonged therapy for 9 to 18 months is necessary to minimize the relapse rate, and children with severe disease can require a longer course. See Table 4.8 (p 1026) for dosing.

Trimethoprim-sulfamethoxazole orally is an inferior alternative to itraconazole, and treatment must be continued for 18 months or longer to lessen risk of relapse, which occurs in 10% to 15% of optimally treated patients. Amphotericin B generally is given only for initial treatment of severe paracoccidioidomycosis for 2 to 4 weeks. Intravenous trimethoprim-sulfamethoxazole is another option. Children treated initially by the intravenous route can transition to orally administered therapy after clinical improvement has been observed, usually after 3 to 6 weeks.

Serial serologic testing by complement fixation or semiquantitative immunodiffusion is useful for monitoring the response to therapy. The expected response is a progressive decline in titers after 1 to 3 months of treatment with stabilization at a low titer for years or even for life.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: None.

Paragonimiasis

CLINICAL MANIFESTATIONS: There are 2 major forms of paragonimiasis: 1) primary pulmonary disease with or without extrapulmonary manifestations caused by adult flukes and their eggs, and 2) extrapulmonary disease caused by aberrant migrating immature flukes, sometimes resulting in a visceral larva migrans syndrome.

Pulmonary infections mostly are asymptomatic or result in mild symptoms but may be associated with chronic cough, chest pain, and dyspnea, often of insidious onset and often misdiagnosed as pulmonary tuberculosis, malignancy, or chronic obstructive pulmonary disease. During worm migration in the lungs, migratory infiltrates may be noted on serial imaging. Heavy infestations cause paroxysms of coughing, which often produce blood-tinged, foul-smelling sputum that is brown because of the presence of the pigmented *Paragonimus* eggs and hemosiderin. Hemoptysis can be severe. Eosinophilic pleural effusion, pneumothorax, bronchiectasis, and pulmonary fibrosis with clubbing can develop.

Extrapulmonary manifestations may involve the liver, spleen, abdominal cavity, intestinal wall, intra-abdominal lymph nodes, skin, pericardium, or central nervous system, with meningoencephalitis, seizures, and space-occupying tumors attributable to invasion of the brain by adult flukes. Cerebral paragonimiasis is the most common extrapulmonary manifestation, is more common in children, and typically presents with seizure, headache, visual disturbance, or motor or sensory dysfunction. Extrapulmonary paragonimiasis also is associated with migratory subcutaneous nodules, which contain juvenile worms. Symptoms tend to subside after approximately 5 years but can persist for as many as 20 years.

ETIOLOGY: Paragonimiasis is caused by the lung fluke (trematode, flat worm) *Paragonimus*. In Asia, pulmonary paragonimiasis with or without extrapulmonary manifestations is caused by adult flukes and eggs of *Paragonimus westermani* and *Paragonimus heterotremus*. In Africa, the adult flukes and eggs of *Paragonimus africanus* and *Paragonimus uterobilateralis* produce the disease. *Paragonimus kellicotti* is the endemic species in North America.

Adult flukes of *P. westermani* are up to 12 mm long and 7 mm wide and occur throughout Asia. A triploid parthenogenetic form of *P. westermani*, which is larger, produces more eggs, and elicits greater disease, has been described in Japan, Korea, Taiwan, and parts of eastern China. *P. heterotremus* occurs in Southeast Asia, adjacent parts of China, and India. *P. africanus* and *P. uterobilateralis* are found in the rainforests of West and Central Africa.

Extrapulmonary paragonimiasis (ie, visceral larva migrans syndrome) can be caused by larval stages of *Paragonimus skrjabini* and *Paragonimus miyazakii*. The worms rarely mature in infected human tissues. *P. skrjabini* occurs in China, whereas *P. miyazakii* occurs in Japan. *Paragonimus mexicanus* and *Paragonimus ecuadoriensis* occur in Mexico, Costa Rica, Ecuador, and Peru.

EPIDEMIOLOGY: Transmission occurs when raw or undercooked freshwater crabs or crayfish, including pickled and soy sauce-marinated products, containing larvae (metacercariae) are ingested. Numerous cases of *P. kellicotti* infection have occurred when people have ingested uncooked or undercooked crayfish while canoeing or camping in the Midwestern United States. In North America, disease also has been caused by *P. westermani* present in imported crab. A less common mode of transmission that also may occur is human infection through ingestion of meat from a paratenic host, most commonly ingestion of raw pork, usually from wild pigs, containing the juvenile stages of *Paragonimus* species (described as occurring in Japan). Humans are accidental (“dead-end”) hosts for *P. skrjabini* and *P. miyazakii* in visceral larva migrans. These flukes cannot mature in humans and do not produce eggs. *Paragonimus* species also infect a variety of other mammals, such as canids, mustelids, felids, and rodents, which serve as animal reservoir hosts.

The **incubation period** is variable. Egg production begins approximately 9 to 13 weeks after ingestion of *P. westermani* metacercariae.

DIAGNOSIS: Paragonimiasis should be considered in patients with unexplained fever, cough, eosinophilia, and pleural effusion or other chest radiographic abnormalities who have eaten raw or undercooked crab or crayfish. Microscopic examination of stool, sputum, pleural fluid, cerebrospinal fluid, and other tissue specimens may reveal operculate eggs. A Western blot serologic antibody test based on *P. westermani* antigen,

available at the Centers for Disease Control and Prevention (CDC), is sensitive and specific; antibody concentrations detected by immunoblot decrease slowly after the infection is cured by treatment. Charcot-Leyden crystals and eosinophils in sputum are useful diagnostic elements. Peripheral blood eosinophilia also is characteristic. Chest radiographs may appear normal or may resemble radiographs from patients with tuberculosis or malignancy.

TREATMENT: Praziquantel is the treatment of choice (see Drugs for Parasitic Infections, p 1068) and typically is associated with high cure rates, as demonstrated by cessation of egg production and resolution of radiographic lesions in the lungs. The drug also is effective for some extrapulmonary manifestations. An alternative drug for patients unable to take praziquantel (eg, because of previous allergic reaction) is triclabendazole. Triclabendazole is a narrow-spectrum anthelmintic with activity against *Fasciola* and *Paragonimus*; it is approved by the US Food and Drug Administration (FDA) only for fascioliasis. In patients with central nervous system paragonimiasis, a short course of steroids may be beneficial, in addition to praziquantel, to reduce the inflammatory response associated with dying flukes. Other supportive care, including anti-epileptics and shunt placement, may be needed.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS: Standard precautions are recommended. There is no person-to-person transmission.

CONTROL MEASURES: Crabs and crayfish should be cooked for several minutes to at least 145°F [63°C]. Meat from wild pigs should be cooked to an internal temperature of at least 160°F [71°C] before eating. Control of animal reservoirs is not possible.

Parainfluenza Viral Infections

CLINICAL MANIFESTATIONS: Human parainfluenza viruses (hPIVs) are the major cause of laryngotracheobronchitis (croup) and also cause bronchiolitis and pneumonia as well as upper respiratory tract infection.¹ hPIV type 1 (hPIV1) and, to a lesser extent, hPIV type 2 (hPIV2) are the most common pathogens associated with croup. hPIV type 3 (hPIV3) most commonly is associated with bronchiolitis and pneumonia in infants and young children. Infections with hPIV type 4 (hPIV4) are less well characterized but have been associated with both upper and lower respiratory tract infections. Longitudinal studies have demonstrated that upper respiratory infections caused by viruses, including hPIVs, can be associated with acute otitis media, which is frequently a mixed viral-bacterial infection. Rarely, hPIVs have been isolated from patients with parotitis, myopericarditis, aseptic meningitis, encephalitis, febrile seizures, and Guillain-Barré syndrome. hPIV infections can exacerbate symptoms of chronic lung disease and asthma in children and adults. In children with immunodeficiency and recipients of hematopoietic cell transplants, hPIVs, most commonly hPIV3, can cause refractory infections with persistent shedding, severe pneumonia with extrapulmonary dissemination, and even fatal disease. hPIV infections do not confer complete protective immunity; therefore, reinfections can occur with all serotypes and at any age, but reinfections usually are mild and limited to the upper respiratory tract.

¹ American Academy of Pediatrics, Subcommittee on Diagnosis and Management of Bronchiolitis. Clinical practice guideline: the diagnosis, management, and prevention of bronchiolitis. *Pediatrics*. 2014;134(5):e1474-e1502

ETIOLOGY: hPIVs are enveloped single-stranded negative-sense RNA viruses classified in the family *Paramyxoviridae*. Four antigenically distinct types—1, 2, 3, and 4 (with 2 subtypes, 4A and 4B)—that infect humans have been identified. hPIV1 and hPIV3 are in the genus *Respirovirus*, and hPIV2 and hPIV4 are classified in the genus *Rubulavirus*.

EPIDEMIOLOGY: hPIVs are transmitted from person to person by direct contact with contaminated nasopharyngeal secretions through large respiratory tract droplets and fomites. hPIV infections can be sporadic or associated with outbreaks of acute respiratory tract disease. Seasonal patterns of infection are distinct, predictable, and cyclic in temperate regions. Different serotypes have distinct epidemiologic patterns. hPIV1 tends to produce outbreaks of respiratory tract illness, usually croup, in the autumn of every other year. A major increase in the number of cases of croup in the autumn usually indicates a hPIV1 outbreak. hPIV2 also can cause outbreaks of respiratory tract illness in the autumn, but hPIV2 outbreaks tend to be less severe, irregular, and less common. hPIV3 is endemic and usually is prominent during spring and summer in temperate climates but often continues into autumn, especially in years when autumn outbreaks of hPIV1 or hPIV2 are absent. hPIV4 seasonal patterns are not as well characterized, but studies have shown that infections with hPIV4 had year-round prevalence with peaks during the fall and winter.

The age of primary infection varies with serotype. Primary infection with all types usually occurs by 5 years of age. Infection with hPIV3 more often occurs in infants and is a frequent cause of bronchiolitis and pneumonia in this age group. By 12 months of age, 50% of infants have acquired hPIV3 infection. Infections with hPIV1 and, to a lesser extent, hPIV2 are more likely to occur between 1 and 5 years of age. Acquisition of hPIV4 also occurs more often during preschool years.

Immunocompetent children with primary hPIV infection may shed virus for up to 1 week before onset of clinical symptoms and for 1 to 3 weeks after symptoms have disappeared, depending on serotype. Severe lower respiratory tract disease with prolonged shedding of the virus can occur in immunocompromised individuals. In these patients, infection may disseminate, with reports of extrapulmonary dissemination to brain, myocardium, and pericardium.

The **incubation period** ranges from 2 to 6 days. Symptoms can develop from 2 to 10 days after exposure and typically last up to 7 to 10 days, although viral shedding can persist for several weeks.

DIAGNOSTIC TESTS: Nucleic acid amplification tests (NAATs) are the preferred diagnostic method for detection and differentiation of hPIVs and have become the standard method in clinical practice. hPIVs are included in many multiplex polymerase chain reaction (PCR)-based respiratory pathogen panels, although hPIV4 is less commonly included. hPIVs may be isolated from nasopharyngeal secretions in cell culture, usually within 4 to 7 days of culture inoculation. Serologic diagnosis, made by a significant increase in antibody titer between acute and convalescent serum specimens, is less useful, because results are delayed and infection may not always be accompanied by a significant homotypic antibody response.

TREATMENT: Specific antiviral therapy is not available. Pharmacologic therapy focuses on decreasing airway edema via corticosteroids and nebulized epinephrine, which are mainstays of treatment. Patients with mild croup can often be managed with supportive care at home, although data have shown benefit for outpatients with mild

croup who receive steroids. Oral, intramuscular, and nebulized corticosteroids (ie, budesonide) have been demonstrated to decrease the severity and duration of symptoms and hospitalization in patients with moderate to severe laryngotracheobronchitis. Nebulized epinephrine is typically used in conjunction with corticosteroids for moderate to severe croup, and repeated doses may be needed for patients with severe croup. Antimicrobial agents should be reserved for documented secondary bacterial infections. Use of ribavirin (usually inhaled), with or without concomitant administration of immune globulin intravenous (IGIV), has been reported anecdotally in immunocompromised patients with severe pneumonia; however, controlled studies are lacking and this use is not routinely recommended.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, contact and droplet precautions are recommended for the duration of hPIV-associated illness. In immunocompromised patients, the duration of precautions should be extended because of possible prolonged shedding.

CONTROL MEASURES: Appropriate respiratory hygiene and cough etiquette should be followed. Exposure to hPIV-infected people, including other patients, staff, and family members, may not be recognized, both because illness may be mild and because infected people may shed virus for up to 1 week before onset of clinical symptoms. Additional infection control measures should be considered in certain settings (eg, child care centers, nursing homes) when respiratory infections have been identified.

Parasitic Diseases

Parasites are among the most common causes of morbidity and mortality in children worldwide. Outside the tropics and subtropics, parasitic diseases occur among travelers and immigrants. Toxocariasis occurs in the United States, most commonly in the South. Malaria infections in the United States occur among people who have traveled to regions with ongoing malaria transmission, and the diagnosis should be considered when evaluating fever in a returned traveler. Local transmission of malaria has recently been detected as well in the United States (<https://emergency.cdc.gov/han/2023/han00494.asp>). Certain parasitic infections have long latency periods, and the diseases they cause, such as Chagas disease, neurocysticercosis, schistosomiasis, and strongyloidiasis, are encountered in immigrants from or travelers to regions with endemic infection. Clinicians need to be aware of where these infections may be acquired, their clinical presentations, methods of diagnosis, and how to prevent infection. A number of human parasitic infections are discussed in individual chapters in Section 3; diseases are arranged alphabetically. Table 3.42 provides details on some infrequently encountered parasitic diseases not discussed elsewhere.

Consultation and assistance in diagnosis and management of parasitic diseases are available from the Centers for Disease Control and Prevention (CDC), state health departments, and university departments or hospitals that have divisions of travel medicine, tropical medicine, infectious diseases, international or global health, and public health.

Drugs for Parasitic Infections can be found beginning on p 1068; information in the table is compiled from recommendations from the CDC and other sources. Treatment recommendations may vary based on expert opinion, and because some commonly used drugs do not have approved indications for a specific parasitic

Table 3.42. Selected Parasitic Diseases Not Covered Elsewhere^a

Disease and/or Agent	Where Infection May Be Acquired	Definitive Host	Intermediate Host	Modes of Human Infection	Diagnostic Laboratory Tests in Humans	Parasitic Form Causing Human Disease	Common Manifestations in Humans
<i>Angiostrongylus cantonensis</i> (neurotropic disease)	Widespread in the tropics, particularly Pacific Islands and Southeast Asia; also in Central and South America, the Caribbean, Africa, and the United States	Rats	Snails and slugs	Eating raw or improperly cooked infected mollusks, including inadvertent ingestion on raw produce; possibly other modes	Eosinophils in CSF; rarely, identification of larvae in CSF; serologic testing and CSF NAAT not commercially available	Larval worms	Eosinophilic meningitis with severe headache, neck stiffness, nausea, vomiting, paresthesias or hyperesthesias, peripheral eosinophilia
<i>Angiostrongylus costaricensis</i> (gastrointestinal tract disease)	Central and South America, the Caribbean	Rodents	Snails and slugs	Eating raw or improperly cooked infected mollusks including inadvertent ingestion on raw produce; possibly other modes	Identification of larvae and eggs in tissue (not stool); NAAT and serologic testing not commercially available	Larval worms	Eosinophilic enterocolitis with abdominal pain, fever, nausea, vomiting, diarrhea (may mimic appendicitis), peripheral eosinophilia

Table 3.42. Selected Parasitic Diseases Not Covered Elsewhere,^a continued

Disease and/or Agent	Where Infection May Be Acquired	Definitive Host	Intermediate Host	Modes of Human Infection	Diagnostic Laboratory Tests in Humans	Parasitic Form Causing Human Disease	Common Manifestations in Humans
Anisakiasis (<i>Anisakis</i> and <i>Pseudoterranova</i> species)	Cosmopolitan, most common where eating raw fish is practiced	Marine mammals	Certain saltwater fish, squid, and octopus	Eating raw, pickled, or undercooked infected marine fish or squid or octopus	Identification of recovered larvae on endoscopy or within tissue biopsies; serologic testing and NAAT not available in the United States	Larval worms	Abdominal pain, nausea, vomiting, diarrhea, allergic reactions
Capillariasis-intestinal disease (<i>Capillaria philippinensis</i>)	Philippines, Thailand	Humans, fish-eating birds	Freshwater fish	Ingestion of raw or undercooked infected fish	Eggs and parasite in feces or biopsies of small intestine	Larvae and mature worms	Abdominal pain, diarrhea, vomiting, weight loss
<i>Clonorchis sinensis</i> , <i>Opisthorchis viverrini</i> , <i>Opisthorchis felineus</i> (liver flukes)	East Asia, Southeast Asia, Central and Eastern Europe, Russian Federation	Humans, cats, dogs, other mammals	Certain freshwater snails	Eating raw or undercooked infected freshwater fish, crabs, crayfish	Eggs in stool, bile, or duodenal fluid Serologic testing, antigen tests, and NAAT not commercially available	Larvae and mature flukes	Abdominal pain; nausea, vomiting, diarrhea, hepatobiliary disease; cholangiocarcinoma

Table 3.42. Selected Parasitic Diseases Not Covered Elsewhere,^a continued

Disease and/or Agent	Where Infection May Be Acquired	Definitive Host	Intermediate Host	Modes of Human Infection	Diagnostic Laboratory Tests in Humans	Parasitic Form Causing Human Disease	Common Manifestations in Humans
Dracunculiasis (<i>Dracunculus medinensis</i>) (Guinea worm)	Foci in Africa; global eradication nearly achieved, 13 human cases worldwide in 2022; 2 during the first half of 2023 ^b	Humans, dogs	Crustacea (copepods)	Drinking water infested with infected copepods	Identification of emerging or adult worm in subcutaneous tissues; serology available but not necessary	Adult female worms	Emerging roundworm; inflammatory response; systemic and local blister or ulcer in skin
Fascioliasis (liver flukes; <i>Fasciola hepatica</i>)	Worldwide; predominantly in the tropics	Sheep and cattle most important; other ruminants	Certain freshwater snails	Eating raw freshwater plants (eg, watercress) or drinking water contaminated with larvae	Identifying eggs in stool, duodenal fluid, or bile; serologic testing; examination of surgical specimens	Larvae and mature flukes	Abdominal pain nausea, vomiting; hepatobiliary disease

Table 3.42. Selected Parasitic Diseases Not Covered Elsewhere,^a continued

Disease and/or Agent	Where Infection May Be Acquired	Definitive Host	Intermediate Host	Modes of Human Infection	Diagnostic Laboratory Tests in Humans	Parasitic Form Causing Human Disease	Common Manifestations in Humans
Fasciolopsiasis (intestinal flukes; <i>Fasciolopsis buski</i>)	East Asia, Southeast Asia	Humans, pigs, dogs	Certain freshwater snails	Eating raw plants (eg, bamboo shoots, watercress, water chestnuts) contaminated with larvae	Eggs or worm in feces or duodenal fluid; serologic testing not commercially available	Larvae and mature flukes	Diarrhea, constipation, vomiting, anorexia, edema of face and legs, ascites

CSF indicates cerebrospinal fluid; NAAT, nucleic acid amplification test.

^bFor progress toward global eradication (which will be the second human disease eradicated, after smallpox), see www.cartercenter.org/health/guinea_worm/index.html.

infection or a particular age group. Specific expertise or multiple sources should be consulted especially when there is a lack of familiarity with the parasite or the drugs recommended for treatment. The CDC distributes several drugs that are not available commercially in the United States for treatment of parasitic diseases. To request these drugs, a physician must contact the CDC Parasitic Diseases Inquiries office (see Appendix I, Directory of Resources, p 1134; Monday-Friday 8 am–4 pm: 404-718-4745, and outside these hours 24/7: 770-488-7100; email: parasites@cdc.gov). Consultation with a medical officer from the CDC is required before a drug is released for a patient. For drugs and consultation regarding malaria, a separate CDC hotline is available Monday-Friday 9 am–5 pm (770-488-7788) and outside these hours 24/7 (770-488-7100).

Parechovirus Infections

CLINICAL MANIFESTATIONS: Parechoviruses (PeVs) primarily cause disease in young infants and present in a similar manner to enteroviruses, with febrile illness, exanthems (maculopapular, erythroderma, and/or palmar and plantar erythema), sepsis-like syndrome (frequently with leukopenia), and/or central nervous system disease. The latter includes meningitis (typically with little or no pleocytosis), encephalitis (typically white-matter predominant), seizures, and apnea; long-term neurodevelopmental sequelae may occur. Infections (particularly with HPeV-3) in neonates or very young infants may be severe, with manifestations that include sepsis, hepatitis and coagulopathy, myocarditis, pneumonia, and/or meningoencephalitis; long-term sequelae or death may occur. PeV infections in older infants and toddlers have been associated with generally mild upper and lower respiratory tract disease and gastroenteritis (although causation has not been established consistently) and a variety of other less common manifestations, including acute flaccid paralysis, acute disseminated encephalomyelitis, myalgia and myositis, herpangina, hand-foot-and-mouth disease, sudden infant death syndrome, and hemophagocytic lymphohistiocytosis.

ETIOLOGY: PeVs are small, nonenveloped, single-stranded, positive-sense RNA viruses in the family *Picornaviridae*. The *Parechovirus* genus consists of 6 species, *Parechovirus A* through *F*. *Parechovirus A* (formerly named human *Parechovirus*) includes at least 19 PeV types (designated HPeV1–19) and is the only species known to cause human disease. HPeV-1 and HPeV-2 previously were classified as echoviruses 22 and 23, respectively. HPeV-1 and HPeV-3 have been implicated in disease most frequently.

EPIDEMIOLOGY: Humans are the primary reservoir for PeV-A, although infection in primates has been demonstrated. PeV-A infections have been reported worldwide. Seroepidemiologic studies suggest that PeV-A infections occur commonly during early childhood. In some studies, most school-aged children have serologic evidence of prior infection, but seroprevalence appears to vary by geographic region and specific PeV-A type. PeV infections frequently are asymptomatic. Symptomatic infection is most frequent in children younger than 2 years, with the most severe disease occurring in infants (especially younger than 6 months of age infected with HPeV-6).

Transmission appears to occur via the fecal-oral and respiratory routes, from symptomatic or asymptomatic individuals. On the basis of reports of very early onset neonatal disease, in utero and perinatal transmission also may occur. Certain PeV-A types may circulate throughout the year, while infections by other types (eg, HPeV-3)

occur more commonly during summer and fall months in temperate climates. Multiple PeV-A types may circulate in a community during the same time period. Community outbreaks and health care-associated transmission in neonatal and pediatric hospital units have been observed. Virus is shed from the upper respiratory tract for 1 to 3 weeks and in stool for less than 2 weeks to as long as 6 months. Shedding may occur in the absence of illness or continue after symptoms resolve.

The **incubation period** for PeV infections has not been defined.

DIAGNOSTIC TESTS: Parechovirus-specific molecular tests such as nucleic acid amplification tests (NAATs) represent the best available diagnostic method. Some assays may not detect all PeV-A types. Enterovirus NAATs will not detect PeVs (and vice versa). PeVs can be detected by molecular assays in stool, rectal and throat swab specimens, nasopharyngeal aspirates, tracheal secretions, blood, and cerebrospinal fluid. Certain multiplex NAATs designed to detect multiple bacterial and viral agents of meningitis and encephalitis, including PeVs, in cerebrospinal fluid are available. The PeV type can be identified by partial or complete sequencing of the viral protein 1 region, typically through reverse transcriptase-polymerase chain reaction (RT-PCR) amplification. Serologic assays have been developed for research but are not available commercially for diagnostic purposes.

TREATMENT: No specific therapy is available for PeV infections. Immune globulin intravenous (IGIV) has been used in some published case reports of neonates with severe PeV infections.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, contact precautions are appropriate for infants and young children for the duration of PeV illness. Cohorting of infected neonates may be effective in controlling hospital nursery outbreaks.

CONTROL MEASURES: Hand hygiene and environmental cleaning are important in decreasing spread of PeVs within families and institution.

Parvovirus B19

(Erythema Infectiosum, Fifth Disease)

CLINICAL MANIFESTATIONS: Infection with parvovirus B19 is clinically recognized most often as erythema infectiosum (EI), or fifth disease, which is characterized by a distinctive rash that may be preceded by mild systemic symptoms, including fever in 15% to 30% of patients. Fifth disease is so named because it was fifth in a list of historical classifications of common skin rash illnesses in children. The facial rash can be intensely red with a “slapped cheek” appearance that often is accompanied by circumoral pallor. A symmetric, macular, lace-like, and often pruritic rash occurs on the trunk, moving peripherally to involve the arms, buttocks, and thighs. The rash can fluctuate in intensity and can recur with environmental changes, such as temperature and exposure to sunlight, for weeks to months. A brief, mild, nonspecific illness consisting of fever, malaise, myalgia, and headache often precedes the characteristic exanthem by approximately 7 to 10 days. Arthralgia and arthritis occur in fewer than 10% of infected children but commonly occur among adults, especially women. Knees are involved most commonly in children, but a symmetric polyarthropathy of knees, fingers, and other joints is common in adults.

Table 3.43. Clinical Manifestations of Parvovirus B19 Infection

Conditions	Usual Hosts
Erythema infectiosum (EI, fifth disease)	Immunocompetent children
Polyarthropathy syndrome	Immunocompetent adults (more common in women)
Chronic anemia/pure red cell aplasia	Immunocompromised hosts
Transient aplastic crisis	People with hemolytic anemia (ie, sickle cell disease)
Hydrops fetalis/congenital anemia	Fetus (first 20 weeks of pregnancy)
Petechial, papular-purpuric gloves-and-socks syndrome (PPGSS)	Immunocompetent children and young adults

Parvovirus B19 can cause asymptomatic or subclinical infections. Other manifestations (Table 3.43) include a mild respiratory tract illness with no rash, a rash atypical for EI that may be rubelliform or petechial, papular-purpuric gloves-and-socks syndrome (PPGSS; painful and pruritic papules, petechiae, and purpura of hands and feet, often with fever and an enanthem), polyarthropathy syndrome (arthralgia and arthritis in adults in the absence of other manifestations of EI), chronic erythroid hypoplasia with severe anemia in immunodeficient patients, and transient aplastic crisis lasting 7 to 10 days in patients with hemolytic anemias (eg, sickle cell disease and autoimmune hemolytic anemia). Patients with transient aplastic crisis may have a prodromal illness with fever, malaise, and myalgia, but rash usually is absent. In addition, parvovirus B19 infection sometimes has been associated with decreases in numbers of platelets, lymphocytes, and neutrophils. In rare cases, parvovirus B19 infection has been associated with acute hepatitis, myocarditis, encephalopathies, hemophagocytic lymphohistiocytosis, and nephrotic syndrome in children and young adults. Parvovirus B19 infection occurring during pregnancy can cause fetal hydrops, intrauterine growth restriction, isolated pleural and pericardial effusions, and fetal death, but the virus is not a proven cause of congenital anomalies. The risk of fetal death is between 2% and 6% when infection occurs during pregnancy. The greatest risk appears to occur during the first half of pregnancy.

ETIOLOGY: Parvovirus B19 is a small, nonenveloped, single-stranded DNA virus in the family *Parvoviridae*, genus *Erythroparvovirus*. Three distinct genotypes of the virus have been described that appear to have variable geographic distribution, but there is no evidence of differences of virologic or disease characteristics among the genotypes. Parvovirus B19 replicates in human erythrocyte precursors, which accounts for some of the clinical manifestations following infection. Parvovirus B19-associated red blood cell aplasia is related to cell death of erythrocyte precursors. Other findings are believed to be associated with the immunologic response.

EPIDEMIOLOGY: Parvovirus B19 is distributed worldwide; humans are the only known hosts. Modes of transmission include contact with respiratory tract secretions, percutaneous exposure to blood or blood products, and vertical transmission. The

virus is quite resistant and can survive in the environment at least for days (or longer). Parvovirus B19 infections are ubiquitous, and cases of EI can occur sporadically or in outbreaks in schools, particularly during late winter and early spring. Secondary spread among susceptible household members is common, with infection occurring in approximately 50% of susceptible contacts in some studies. The transmission rate in schools is lower, but infection can be an occupational risk for school and child care personnel, with approximately 20% of susceptible contacts becoming infected. In young children, antibody seroprevalence generally is 5% to 10%. In most communities, approximately 50% of young adults and often more than 90% of elderly people are seropositive.

The **incubation period** from acquisition of parvovirus B19 to onset of initial symptoms (fever, runny nose, fatigue, myalgia) is between 4 and 14 days but can be as long as 21 days. Rash and arthralgias tend to occur at least a few days after initial viral symptoms. Timing of the presence of high levels of parvovirus B19 DNA in serum and respiratory tract secretions indicates that people with EI are likely infectious before rash onset and are unlikely to be infectious after onset of the rash and/or joint symptoms. In contrast, patients with aplastic crises are contagious from before the onset of symptoms through at least the week after onset. Symptoms of PPGSS can occur in association with viremia and before development of antibody response, and affected patients should be considered infectious.

DIAGNOSTIC TESTS: In an immunocompetent host, detection of serum parvovirus B19-specific immunoglobulin (Ig) M antibodies is the preferred diagnostic test for an acute or recent parvovirus B19-associated rash illness. A positive IgM test result indicates that infection probably occurred within the previous 2 to 3 months. IgM antibodies can be detected in 90% or more of patients at the time of the EI rash and by the third day of illness in patients with transient aplastic crisis. Serum IgG antibodies appear by approximately day 2 of EI and persist for life; therefore, presence of parvovirus B19 IgG is not necessarily indicative of acute infection. These assays are available through commercial laboratories and some state public health department laboratories.

Serum IgM and IgG assays are not reliable in immunocompromised patients. The optimal method for detecting transient aplastic crisis or chronic infection in the immunocompromised patient is demonstration of high titer of viral DNA by a quantitative nucleic acid amplification test (NAAT). Such patients generally have $>10^6$ parvovirus B19 DNA copies/mL of plasma. Currently, there are no NAATs cleared by the US Food and Drug Administration for the qualitative or quantitative detection of parvovirus B19 DNA, but such assays are available through select commercial and reference laboratories and sometimes in larger hospital-based laboratories. With the availability of a World Health Organization (WHO) nucleic acid standard for parvovirus B19 DNA, assay results can be reported in international units per mL (IU/mL) to allow for comparison across assays. False-negative results can occur with NAATs that do not detect all 3 genotypes. Because parvovirus B19 DNA can be detected at low levels by NAAT in serum for months and even years after the acute viremic phase when infectious virus no longer appears to be present, detection of low levels of DNA does not necessarily indicate acute infection. Low levels of parvovirus B19 DNA also can be detected by NAAT in tissues (skin, heart, liver, bone marrow), independent of active disease. A qualitative NAAT may be used on amniotic fluid as an aid to diagnosis of hydrops fetalis. Parvovirus B19 cannot be propagated in standard cell culture.

TREATMENT: For most patients, only supportive care is indicated. Patients with aplastic crisis may require transfusions of blood products. Immune globulin intravenous (IGIV) therapy often is effective and should be used for the treatment of parvovirus B19 infection-induced anemia in immunodeficient patients. The optimal dosing regimen and duration of treatment have not been established. Reduction of immune suppression also should be attempted, if possible. There are no approved specific antivirals for the treatment of parvovirus B19. Some cases of parvovirus B19 infection in pregnancy concurrent with hydrops fetalis have been treated successfully with intrauterine blood transfusions of the fetus.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, droplet precautions are recommended for hospitalized children with aplastic crises, children with PPGSS or immunosuppressed patients with chronic infection and anemia for the duration of hospitalization. For patients with transient aplastic or erythrocyte crisis, these precautions should be maintained for 7 days or until the reticulocyte count has recovered from suppression to at least 2%. Neonates who had hydrops attributable to parvovirus B19 in utero do not require isolation if the hydrops is resolved at the time of birth. Pregnant health care workers should be informed of the potential risks to their fetus from parvovirus B19 infections and about preventive measures that may decrease these risks (eg, attention to strict infection control procedures).

CONTROL MEASURES:

- Pregnant people who are exposed to children at home or at work (eg, teachers or child care providers) are at increased risk of infection with parvovirus B19. However, in view of the high prevalence of parvovirus B19 infection, the low incidence of adverse effects on the fetus, and the fact that avoidance of child care or classroom teaching can decrease but not eliminate the risk of exposure, routine exclusion of pregnant people from the workplace where EI is occurring is not required. People capable of becoming pregnant who are concerned can undergo serologic testing for IgG antibody to parvovirus B19 to determine their susceptibility to infection.
- Pregnant people who discover that they have been in contact with children who were in the incubation period of EI or with children who were in aplastic crisis should have the relatively low potential risk of infection explained to them. The American College of Obstetricians and Gynecologists recommends that pregnant people exposed to parvovirus B19 should have serologic testing performed to determine susceptibility and possible evidence of acute parvovirus B19 infection.¹ Pregnant people with evidence of acute parvovirus B19 infection should be monitored closely (eg, serial ultrasonographic examinations) by their obstetric provider. In pregnant people with suspected or proven intrauterine parvovirus B19 infection, amniotic fluid and fetal tissues should be considered infectious, and contact precautions should be used in addition to standard precautions if exposure is likely.
- Children with EI may attend child care or school, because they no longer are contagious once the rash appears.
- Transmission of parvovirus B19 is decreased through use of routine infection control practices, including hand hygiene.

¹ American College of Obstetricians and Gynecologists. Cytomegalovirus, parvovirus B19, varicella zoster, and toxoplasmosis in pregnancy. Practice Bulletin No. 151. *Obstet Gynecol.* 2015;125(6):1510–1525

- Viral DNA may persist in blood and high levels may indicate the presence of infectious virus. The US Food and Drug Administration has issued guidance for use of nucleic acid amplification tests to reduce the possible risk of parvovirus B19 transmission by plasma-derived products (www.fda.gov/ucm/groups/fdagov-public/@fdagov-bio-gen/documents/document/ucm078510.pdf). The goal is to identify and prevent the use of plasma-derived products containing high levels of virus. Parvovirus B19 viral loads in manufacturing pools should not exceed 10^4 IU/mL.

Pasteurella Infections

CLINICAL MANIFESTATIONS: The most common manifestation is cellulitis at the site of a bite or scratch of a cat, dog, or other domestic or wild animal. Cellulitis typically develops within 12 to 24 hours of the injury and includes warmth, swelling, erythema, tenderness, and serosanguinous to purulent drainage at the wound site. Regional lymphadenopathy, chills, and fever can also occur. The most frequent local complications related to deep penetration of the teeth or claws of the biting animal are abscesses and tenosynovitis, but septic arthritis and osteomyelitis also occur. Other less common manifestations include septicemia, central nervous system infections (meningitis is the most common, although brain abscess and subdural empyema have been observed), ocular infections (eg, conjunctivitis, corneal ulcer, endophthalmitis), endocarditis, respiratory tract infections (eg, pneumonia, pulmonary abscesses, pleural empyema, epiglottitis), appendicitis, hepatic abscess, granulomatous hepatitis, peritonitis, ventriculoperitoneal shunt infection, and urinary tract infection. Infection in the neonate is rare but may present as early onset fulminant sepsis with or without meningitis from vertical transmission or later with sepsis and/or meningitis or focal infections after animal exposures (sometimes without known bites, scratches, or licks). People with liver disease, solid organ transplant, or underlying host defense abnormalities are predisposed to bacteremia with *Pasteurella multocida*. Those with chronic pulmonary or renal conditions may be predisposed to lung or kidney infections, respectively.

ETIOLOGY: The genus *Pasteurella* is one of 5 genera of human pathogens classified in the family *Pasteurellaceae*; the other genera are *Actinobacillus*, *Aggregatibacter*, *Haemophilus*, and *Mannheimia*. Members of the genus *Pasteurella* are nonmotile, facultatively anaerobic, mostly catalase and oxidase positive, nitrate reducing, gram-negative coccobacilli that are primarily respiratory tract colonizers and pathogens in animals. The most common human pathogen is *P. multocida*. Most human infections are caused by the following species or subspecies: *P. multocida* subspecies *multocida* (causing more than 50% of infections), followed by *Pasteurella canis*, *P. multocida* subspecies *septica*, *Pasteurella stomatis*, and *Pasteurella dagmatis*.

EPIDEMIOLOGY: *Pasteurella* species have a worldwide distribution. They colonize the upper respiratory tract of 70% to 90% of cats, 25% to 50% of dogs, and many other wild and domestic animals including large cats, lions, tigers, panthers, swine, rats, opossums, rabbits, and fowl. Transmission most frequently occurs from the bite, scratch, or lick of a previous wound by a cat or dog. Infected cat bite wounds contain *Pasteurella* species more often than do dog bite wounds. Rarely, respiratory tract spread occurs from animals to humans, and in 5% to 15% of all cases, no animal exposure can be identified. The highest rates of infection occur in children younger than 5 years and

in adults older than 55 years of age. Human-to-human transmission has been documented vertically, horizontally from colonized people, and through contaminated blood products.

The **incubation period** usually is less than 24 hours.

DIAGNOSTIC TESTS: The isolation of *Pasteurella* species from a normally sterile body site (eg, blood, joint fluid, bone, cerebrospinal fluid, pleural fluid, peritoneal fluid, or suppurative lymph nodes) establishes the diagnosis of systemic infection. Recovery of the organism from a superficial site, such as drainage from a skin lesion subsequent to an animal bite, must be interpreted in the context of other potential pathogens isolated, as mixed infection may occur. *Pasteurella* species are somewhat fastidious but may be cultured on several media generally used in clinical laboratories, including tryptic soybean digest agar with 5% sheep blood and chocolate agars, at 35°C to 37°C without increased carbon dioxide concentration. Although they resemble several other organisms morphologically, laboratory identification to the genus level generally is not difficult, although species and subspecies differentiation is more challenging. Newer laboratory methods, including polymerase chain reaction (PCR) amplification of the 16S rRNA gene followed by sequencing and identification of cellular components by matrix-assisted laser desorption/ionization–time-of-flight (MALDI-TOF) mass spectroscopy, have significantly improved species identification.

TREATMENT: The drug of choice is penicillin. Penicillin resistance is rare, but beta-lactamase–producing strains have been recovered. Other oral agents that usually are effective include ampicillin, amoxicillin, amoxicillin-clavulanate, cefuroxime axetil, cefixime, cefpodoxime, cefdinir, trimethoprim-sulfamethoxazole, azithromycin, doxycycline, and fluoroquinolones. Parenteral third-generation cephalosporins, including ceftriaxone and cefotaxime, demonstrate excellent in vitro activity. Oral and parenteral antistaphylococcal penicillins and first-generation cephalosporins including cephalixin are not as active and therefore not recommended for treatment. *Pasteurella* species usually are resistant to vancomycin, clindamycin, and erythromycin. For patients who are allergic to beta-lactam agents, trimethoprim-sulfamethoxazole, azithromycin, and the fluoroquinolones are alternative choices, but clinical experience with these agents is limited. For suspected polymicrobial infected bite wounds, oral amoxicillin-clavulanate or, for severe infection, intravenous ampicillin-sulbactam or piperacillin-tazobactam can be given. The duration of therapy usually is 7 to 10 days for local infections and 10 to 14 days for more severe infections. Duration of antimicrobial therapy for optimal outcomes for bone and joint infections is unknown but likely 3 to 6 weeks depending on clinical course. Endocarditis may require 4 to 6 weeks. Wound drainage or débridement may be necessary.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: Limiting contact with wild animals and education about appropriate contact with domestic animals can help to prevent *Pasteurella* infections (see Bite Wounds, p 202). Parents should not allow pets to lick infants and children on the face or on pre-existing skin injuries. Wounds from animal bites and scratches should be irrigated, cleansed, and débrided promptly. Following a bite wound, antimicrobial prophylaxis for selected children, depending on host factors and the type of animal bite wound, should be initiated according to the recommendations in Table 2.9, p 203, and the risk of rabies exposure and tetanus immunization status should be assessed.

Pediculosis Capitis¹

(Head Lice)

CLINICAL MANIFESTATIONS: Itching is the most common symptom of head lice infestation, but many children are asymptomatic. Adult lice (2–3 mm long, tan to grayish-white, with claws on all 6 legs) or eggs (match hair color) and nits (empty egg casings, white) are found on the hair and are most readily apparent behind the ears and near the nape of the neck. Excoriations and crusting caused by secondary bacterial infection may occur and often are associated with regional lymphadenopathy. Head lice usually deposit their eggs on a hair shaft 1 to 2 mm from the scalp. Because hair grows at a rate of approximately 1 cm per month, duration of infestation can be estimated by the distance of the nit from the scalp.

ETIOLOGY: *Pediculus humanus capitis* is the head louse. Both nymphs and adult lice feed on human blood.

EPIDEMIOLOGY: Head lice infestation in the United States is most common in children attending child care, preschool, and elementary school. It is not a sign of poor hygiene, and all socioeconomic groups are affected. Head lice infestation is not influenced by hair length, hair texture, or frequency of shampooing or brushing. Head lice are not a health hazard and are not responsible for spread of any disease. Transmission occurs mainly by direct head-to-head contact with hair of infested people. Transmission by contact with personal belongings, such as combs, hair brushes, sporting gear, and hats, is uncommon. Head lice survive <1 day at room temperature away from the scalp, and their eggs cannot hatch at a lower ambient temperature than that near the scalp.

The **incubation period** from the laying of eggs to hatching of the first nymph usually is about 8 to 9 days (range 7 to 12 days). Lice mature to the adult stage approximately 7 days later.

DIAGNOSTIC TESTS: Identification of eggs, nymphs, and adult lice with the naked eye is possible; diagnosis can be confirmed by using a hand lens, dermatoscope (epiluminescence microscope), or traditional microscope. Nymphal and adult lice shun light and move rapidly to conceal themselves. Wetting the hair with water, oil, or a conditioner to “slow down” the movement of the lice and using a fine-tooth comb may improve ability to diagnose infestation and shorten inspection time. It is important to differentiate nits from dandruff, hair casts (a layer of follicular cells that slide easily off the hair shaft), plugs of desquamated cells, external hair debris, and fungal infections of the scalp. Finding nits attached firmly within ¼ inch of the base of the hair shaft suggests that a person has had infestation, but because nits remain affixed firmly to hair even after hatching or when dead, their mere presence (particularly >1 cm from the scalp) is not a conclusive sign of an active infestation.

TREATMENT: Treatment should be initiated only if there is a diagnosis of active head lice infestation. A number of effective pediculicidal agents are available to treat head lice infestation (see Drugs for Parasitic Infections, p 1068, and Table 3.44). Costs and recommended age ranges vary by product. Safety is a major concern with pediculicides, because head lice infestation, itself, presents minimal risk to the host. Instructions

¹ Nolt D, Moore S, Yan AC, Melnick L; American Academy of Pediatrics, Committee on Infectious Diseases, Committee on Practice and Ambulatory Medicine, Section on Dermatology. Head Lice. *Pediatrics*. 2022;150(4):e2022059282

Table 3.44. Pediculicides for the Treatment of Head Lice

Product	Brand Name	Recommended Age Range	Retreatment Interval (If Needed)	Availability
Permethrin 1% lotion	Multiple products	≥2 mo	9–10 days	Over the counter
Pyrethrins + piperonyl butoxide shampoo	Example: Rid	≥24 mo	9–10 days	Over the counter
Ivermectin 0.5% lotion	Sklice	≥6 mo	Single use	Over the counter
Malathion 0.5%	Ovide	≥6 y (safety not established for ages <6 y)	7–9 days if live lice are seen after initial dose	Prescription
Spinosad 0.9% suspension	Natroba	≥6 mo (safety not established for ages <4 y)	7 days if live lice are seen after initial dose	Prescription
Ivermectin (oral)	Stromectol	Any age, if weight ≥15 kg	7–10 days	Prescription

on proper use of any product should be explained carefully. Extra amounts should not be used, and multiple products should not be used concurrently. If medication gets into a child's eyes, it should be flushed out immediately with water. Skin exposure to pediculicide should be limited. Hair should be rinsed over a sink rather than during a shower or bath after topical pediculicide application, and warm rather than hot water should be used to minimize skin absorption attributable to vasodilation. Hair should not be shampooed as part of the rinse process nor for 24 to 48 hours after product is washed out.

Therapy can be initiated with over-the-counter 1% permethrin lotion or with pyrethrin combined with piperonyl butoxide, both of which have good safety profiles. Prevalence of clinical resistance to these products is highly variable from community to community and country to country. Information about these agents and others are listed below and in Table 3.44 and in *Drugs for Parasitic Infections* (p 1068). Drugs vary in their residual activity and no treatment is 100% ovicidal. Retreatment may be needed after eggs present at the time of initial treatment have hatched but before new eggs are produced; retreatment intervals vary by product.

- **Permethrin (1%) lotion.** Permethrin is available without a prescription in a 1% lotion and is approved for infants 2 months or older. Infested hair and scalp are washed first with a nonconditioning shampoo and towel-dried. Permethrin then is applied to the scalp and entire length of wet hair, left for 10 minutes, and then rinsed off with water. Permethrin has a low potential for toxic effects and can be highly effective. Although residual permethrin is designed to kill emerging nymphs, many experts advise a second treatment 9 to 10 days after the first treatment if live lice

are seen in the interim. An alternate treatment schedule on days 0, 7, and 13-15 has been proposed based on the longest possible life cycle of head lice.

- **Pyrethrin-based shampoo products.** Pyrethrins formulated with piperonyl butoxide are available without a prescription as shampoos or mousse preparations for children 24 months or older. The product is applied to dry hair in sufficient amounts to saturate the scalp and entire length of the hair, left for 10 minutes, and then rinsed off with water. Repeat application 9 to 10 days after the first application is necessary to kill newly hatched lice.
- **Ivermectin (0.5%) lotion.** Ivermectin, a widely used anthelmintic agent, appears to prevent newly hatched lice (nymphs) from surviving. The lotion is applied to dry hair in sufficient amounts to saturate the scalp and entire length of the hair, left for 10 minutes, and then rinsed off with water. It is effective in most patients when given as a single application on dry hair and may be used in children 6 months and older.
- **Oral ivermectin.** Oral ivermectin is not approved by the US Food and Drug Administration (FDA) for treatment of head lice in pediatrics but is FDA approved for treatment of head lice in adults and has pediatric indications for other parasitic infections. It has been administered as a single oral dose of 200 µg/kg or 400 µg/kg, with a second dose given after 7 to 10 days. The 400-µg/kg dose has been shown to be comparable or more effective than 0.5% malathion lotion. Ivermectin should not be used for this indication in children weighing less than 15 kg, because it blocks essential neural transmission if it crosses the blood-brain barrier and young children may be at higher risk of this adverse drug reaction.
 - ♦ Oral and topical forms of ivermectin for veterinary use are available without a prescription. The dose of active ingredients, presence of inactive ingredients, and different production standards render these products inappropriate for treatment of head lice in humans.
- **Malathion (0.5%) lotion.** This organophosphate pesticide is available only by prescription as a lotion. Malathion lotion is applied to dry hair in sufficient amounts to saturate the scalp and entire length of the hair, left to dry naturally, and then washed off after 8 to 12 hours by washing and rinsing the hair. The product should be reapplied 7 to 9 days later if live lice are seen in the interim. The high alcohol content of the lotion makes it highly flammable; during treatment the lotion or lotion-coated hair should not be exposed to lighted cigarettes (no smoking around the individual during hair treatment), open flames, or electric heat sources such as hair dryers or curling irons. Malathion should not be used in children younger than 6 years, because safety and effectiveness have not been assessed by the FDA for those children.
- **Spinosad (0.9%) suspension.** Spinosad has a broad spectrum of activity against insects, including lice. The suspension is applied to dry hair in sufficient amounts to saturate the scalp and entire length of the hair, left for 10 minutes, and then rinsed off with water. A second treatment is applied 7 days later if live lice are seen in the interim. This product contains benzyl alcohol and should not be used in infants younger than 6 months, because systemic absorption may lead to benzyl alcohol toxicity.
- **Abametapir (0.74%) lotion** (not available in the United States). Abametapir inhibits metalloproteinases, which have a role in physiological processes critical to egg development and survival of lice. Abametapir lotion is applied to dry hair in

sufficient amounts to coat the hair and scalp thoroughly, left on for 10 minutes, and then rinsed off. Treatment involves a single application. This product contains benzyl alcohol and should not be used in infants younger than 6 months, because systemic absorption may lead to benzyl alcohol toxicity. For 2 weeks after abametapir application, the treated individual should avoid taking drugs that are substrates of CYP3A4, CYP2B6, or CYP1A2.

- Lindane (marketed as Kwell), although FDA approved for treatment of head lice, no longer is recommended by the American Academy of Pediatrics because of toxicity.

Detection of living lice on scalp inspection 24 hours or more after treatment suggests incorrect use of pediculicide, hatching of lice after treatment, reinfestation, or resistance to therapy, because pediculicides kill lice shortly after application. After excluding incorrect use, retreatment with a different pediculicide followed by a second application (with the exception of single-use topical ivermectin) at the intervals specified above and in *Drugs for Parasitic Infections* (p 1068) is recommended in such situations. See Fig 3.14 for a treatment algorithm.

Data are lacking to determine whether heat therapy or suffocation of lice by application of occlusive agents, such as petroleum jelly, olive oil, butter, fat-containing mayonnaise, or desiccating methods are effective methods of treatment. Vinegar-based products claim to loosen the “glue” that attaches the nits to the hair, although clinical benefit has not been demonstrated.

Itching or mild burning of the scalp caused by inflammation of the skin in response to topical therapeutic agents can persist for many days after lice are killed; this is not a reason for retreatment. Topical corticosteroid and oral antihistamine agents may be beneficial for relieving these signs and symptoms.

Manual removal of nits after successful treatment with a pediculicide is helpful to decrease diagnostic confusion and to decrease the small risk of self-reinfestation and social stigmatization. Fine-toothed nit combs designed for this purpose are available, although the type of comb is less important than the actual action of combing.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions plus contact precautions are recommended until the patient has been treated with an appropriate pediculicide.

CONTROL MEASURES: Household and other close contacts should be examined and treated if infested. Bedmates of infested people should be treated prophylactically at the same time as the infested household members and contacts, even if bedmates do not have identifiable live lice. Children should not be excluded or sent home early from school or child care because of head lice, because head lice have a low contagion in these settings (see Table 2.3, p 149). Parents of children with infestation (ie, at least 1 live, crawling louse) should be notified and informed that their child should be treated. The presence of nits alone does not justify treatment.

“No-nit” policies requiring that children be free of nits before they return to a child care facility or school should be discouraged. Nits farther from the scalp are easier to discover but are of no consequence. Routine classroom or schoolwide screening for lice is discouraged, because it is not an accurate or cost-effective way of lowering the incidence of head lice in the school setting. Parents who are educated on the diagnosis of lice infestation may screen their own children’s heads for lice regularly (perhaps monthly) and if the child is symptomatic.

FIG 3.14. TREATMENT ALGORITHM FOR HEAD LICE ^{a,b}

^aCost and insurance formulary coverage for individual patients should be considered by the prescriber.

^bModified from Nolt D, Moore S, Yan AC, Melnick L; American Academy of Pediatrics, Committee on Infectious Diseases, Committee on Practice and Ambulatory Medicine, Section on Dermatology. Head Lice. *Pediatrics*. 2022;150(4):e2022059282

Supplemental measures generally are not required to eliminate an infestation. Head lice rarely are transferred via fomites from shared headgear, clothing, combs, or bedding. Special handling of such items, therefore, is not likely to be useful; protective headgear should not be refused because of fear of head lice. If desired, hats, bedding, clothing, and towels worn or used by the infested person in the 2-day period just before treatment is started can be machine-washed and dried using the hot water and hot air cycles, respectively, because lice and eggs are killed by exposure for 5 minutes to temperatures greater than 130°F. Clothing and items that are not washable can be dry cleaned or sealed in a plastic bag and stored for 2 weeks. Brushes and combs can be soaked in hot water (at least 130°F) for 5 to 10 minutes. Vacuuming furniture and floors can remove an infested person's hairs that might have viable eggs attached. Pediculicide spray is not necessary and should not be used. Treatment of dogs, cats, or other pets is not indicated, because they do not play a role in transmission of human head lice.

Pediculosis Corporis (Body Lice)

CLINICAL MANIFESTATIONS: Patients affected with pediculosis corporis characteristically seek medical attention because of intense itching, particularly at night. The pruritus is an allergic reaction to bites, which manifest as small erythematous macules, papules, and excoriations, primarily on the trunk. In heavily bitten areas of the body, typically around the mid-section (waist, groin, upper thighs), the skin can become thickened and darkened. Secondary bacterial infection of the skin (pyoderma) caused by scratching is common.

ETIOLOGY: *Pediculus humanus corporis* (or *humanus*) is the body louse. Both nymphs and adult lice feed on human blood.

EPIDEMIOLOGY: Body lice live in clothes or bedding used by infested people, lay their eggs on or near the seams of clothing, and only move to the skin to feed before retreating. Body lice cannot survive away from a blood source for longer than 5 to 7 days at room temperature. Body lice generally are restricted to people living in crowded conditions without access to regular bathing (at least weekly) or changes of clean clothing (refugees, victims of war or natural disasters, people lacking housing). Under these conditions, body lice can spread rapidly through direct contact with others or indirect contact with contaminated clothing or bedding. In contrast with head and pubic lice, body lice are well-recognized vectors of disease (eg, epidemic typhus, trench fever, epidemic relapsing fever, and bacillary angiomatosis).

The **incubation period** from laying eggs to hatching of the first nymph is approximately 1 to 2 weeks, depending on ambient temperature. Lice mature and can reproduce 9 to 19 days after hatching.

DIAGNOSTIC TESTS: Seams of clothing should be examined for eggs (nits), nymphs, and adult lice (2–4 mm) if body louse infestation is suspected. Nits and lice may be seen with the naked eye; diagnosis can be confirmed by using a hand lens, dermatoscope (epiluminescence microscope), or traditional microscope. Adult and nymphal body lice seldom are seen on the body because they generally are sequestered in clothing.

TREATMENT: Treatment consists of improving hygiene, including bathing and regular (at least weekly) changes to clean clothes and bedding. Infested materials can be discarded or decontaminated by machine-washing and drying using the hot water and hot air cycles, respectively; by dry cleaning; by sealing in a plastic bag and storing for 2 weeks; or by pressing with a hot iron. Temperatures exceeding 130°F for 5 minutes are lethal to lice and eggs. Pediculicides for patients usually are not necessary if materials are laundered at sufficiently hot temperatures at least weekly. People with abundant body hair may require full-body treatment with a pediculicide, because lice and eggs occasionally may adhere to body hair. Guidance for the choice and application of pediculicide (if desired for treatment) is the same as for head lice (see *Pediculosis Capitis*, p 644; and *Drugs for Parasitic Infections*, p 1068).

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, contact precautions are recommended and should continue until the patient's clothing and bedding have been cleaned effectively.

CONTROL MEASURES: The most important factor in the control of body lice infestation is the ability to change and wash clothing. Close contacts should be examined and treated appropriately. Clothing, beds, bedding, and towels from infested persons should not be shared until articles are treated. Fumigation or dusting with chemical insecticides sometimes is necessary to control and prevent certain diseases (epidemic typhus) that are spread by body lice.

Pediculosis Pubis

(Pubic Lice, Crab Lice)

CLINICAL MANIFESTATIONS: Pruritus of the anogenital area is a common symptom in pubic lice infestations ("crabs" or "phthiriasis"). Adult lice (1–2 mm long and flattened, tan to grayish-white with 4 of its 6 legs terminating in crab-like claws) or eggs (match hair color) and nits (empty egg casings, white) are found on hair, particularly near the hair-skin junction. The parasite most frequently is found in the pubic region, but infestation can involve other coarse body hair, including the eyelashes, eyebrows, beard, axilla, legs, perianal area, and rarely, the scalp. A characteristic sign of heavy pubic lice infestation is the presence of bluish or slate-colored macules (maculae ceruleae) on the chest, abdomen, or thighs.

ETIOLOGY: *Phthirus pubis* is the pubic or crab louse. Both nymphs and adult lice feed on human blood. Pubic lice are not a health hazard and are not responsible for the spread of any disease.

EPIDEMIOLOGY: Pubic lice infestations are more prevalent in teenagers and young adults and usually are spread through sexual contact. Transmission by contact with contaminated items, such as bed linens, towels, or shared clothing, can occur. Pubic lice on the eyelashes or eyebrows of prepubertal children (likely the only areas of coarse hair) may be evidence of sexual abuse, although rarely it may instead be a manifestation of shared sleeping arrangements with infested individuals or fomites. Animals do not get or spread pubic lice.

The **incubation period** from the laying of eggs to the hatching of the first nymph is 6 to 10 days. Adult lice become capable of reproducing 2 to 3 weeks after

hatching. Adult pubic lice can survive away from a host for up to 48 hours, and their eggs can remain viable for up to 10 days under suitable environmental conditions.

DIAGNOSTIC TESTS: Identification of eggs (nits), nymphs, and lice with the naked eye is possible, although it can be difficult to detect lice unless they have had a recent blood meal. The diagnosis can be confirmed by using a hand lens, traditional microscope, or dermatoscope (epiluminescence microscope) to examine hair shafts. Pubic lice may be difficult to find because of low numbers, and they do not crawl as quickly as head and body lice. If crawling lice are not seen, finding nits in the pubic area strongly suggests infestation and should lead to treatment.

TREATMENT¹: All areas of the body with coarse hair should be examined for evidence of pubic lice infestation. Lice and their eggs can be removed manually (hand-picking or wet-combing with a lice comb), or the hairs can be shaved to eliminate infestation immediately; topical pediculicides should still be used even when the affected area is shaved. Caution should be used when inspecting, removing, or treating lice on or near the eyelashes. No high-quality data exist for treatment of pubic lice, and thus treatment is extrapolated from head lice. Recommended therapies include either permethrin 1% cream rinse (applied to affected areas and washed off after 10 minutes) or pyrethrins with piperonyl butoxide (applied to the affected areas and washed off after 10 minutes). Both treatments should be repeated in 9 to 10 days. Reported clinical resistance of head lice to permethrin and pyrethrins has been increasing and may be extrapolated to pubic lice, although data are lacking. Reevaluation is recommended after 1 week if symptoms persist. Retreatment might be necessary if lice are found or if eggs are observed at the hair-skin junction. If no clinical response is achieved to one of the recommended regimens, treatment with malathion (0.5% lotion applied to affected areas and washed off after 8–12 hours) or oral ivermectin (250 µg/kg orally, repeated in 7–14 days) is recommended.

Infested people should be examined for other sexually transmitted infections (see Sexually Transmitted Infections in Adolescents and Children, p 179). Pubic lice on the eyelashes or eyebrows of prepubertal children should prompt evaluation for sexual abuse (see Sexual Assault and Abuse in Children and Adolescents/Young Adults, p 182).

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, contact precautions are recommended until the patient has been treated with an appropriate pediculicide.

CONTROL MEASURES: Pubic lice are highly contagious; thus, all sexual contacts within the previous month should be treated. Patients should be advised to avoid sexual contact until they and their sex partners have been treated successfully, bedding and clothing have been decontaminated, and reevaluation has been performed to rule out persistent infestation if persons are still symptomatic. Bedding, towels, and clothing used in the preceding 3 days should be decontaminated by machine washing and drying using the hot water and hot air cycles, respectively, because lice and eggs are killed by exposure for 5 minutes at temperatures greater than 130°F. Clothing and items that are not washable can be dry cleaned or sealed in a plastic bag and stored for 2 weeks.

¹ Centers for Disease Control and Prevention. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(RR-4):1-187. Available at: www.cdc.gov/std/treatment-guidelines/

Pelvic Inflammatory Disease

CLINICAL MANIFESTATIONS: Pelvic inflammatory disease (PID) comprises a spectrum of inflammatory disorders of the female upper genital tract, including any combination of endometritis, parametritis, salpingitis, oophoritis, tubo-ovarian abscess, and pelvic peritonitis.¹ Acute PID is difficult to diagnose because of the wide variation in symptoms and signs. Symptoms of acute PID include unilateral or bilateral lower abdominal or pelvic pain, fever, vomiting, abnormal vaginal discharge, irregular vaginal bleeding, and pain with intercourse. The severity of symptoms varies widely and may range from indolent to severe. Patients occasionally present with right upper quadrant abdominal pain resulting from peritoneal adhesions related to perihepatitis (Fitz-Hugh-Curtis syndrome). Many episodes of PID go undiagnosed and untreated because the patient and/or health care professional fails to recognize the implications of mild or nonspecific symptoms and signs. Subclinical PID is defined as inflammation of the upper reproductive tract in the absence of signs and symptoms of acute PID, and there is a growing body of evidence that this represents a large proportion of all PID cases. In both clinically apparent and subclinical PID, inflammation occurs within the reproductive tract, which scars or damages the fallopian tubes or surrounding structures. Clinicians should maintain a high degree of suspicion for PID when female patients of reproductive age present with mild or nonspecific findings.

Examination findings vary but may include oral temperature $>101^{\circ}\text{F}$ ($>38.3^{\circ}\text{C}$), lower abdominal tenderness with or without peritoneal signs, abnormal cervical or vaginal discharge, tenderness with lateral motion of the cervix, cervical friability, uterine tenderness, unilateral or bilateral adnexal tenderness, and adnexal fullness. Pyuria (presence of white blood cells [WBCs] on urine microscopy), abundant WBCs on saline microscopy of vaginal fluid, an elevated erythrocyte sedimentation rate, elevated C-reactive protein, and/or an adnexal mass demonstrated by abdominal or transvaginal ultrasonography are findings that support a diagnosis of PID.

Complications of PID include perihepatitis (Fitz-Hugh-Curtis syndrome) and tubo-ovarian abscess/complex formation. Long-term sequelae include tubal scarring that can cause infertility in an estimated 10% to 20% of affected individuals, ectopic pregnancy in an estimated 9%, and chronic pelvic pain in an estimated 18%. Factors that may increase the likelihood of infertility are delay in diagnosis or in initiation of antimicrobial therapy, younger age at time of infection, chlamydial infection, recurrent PID, and PID determined to be severe by laparoscopic examination.

Any prepubertal child with PID needs to be assessed for sexual abuse (see Sexual Assault and Abuse in Children and Adolescents/Young Adults, p 182). Mandatory reporters should follow their state's regulations for reporting.

ETIOLOGY: *Neisseria gonorrhoeae* and *Chlamydia trachomatis* are the pathogens most commonly associated with PID, although only approximately half of PID cases have evidence of these bacterial pathogens. A number of organisms other than *N gonorrhoeae* and *C trachomatis* that are present in the vaginal flora have been isolated from upper genital tract cultures of people with PID, including anaerobes (such as *Prevotella* species), *Gardnerella vaginalis*, *Haemophilus influenzae*, *Streptococcus agalactiae*, and enteric gram-negative rods. Additionally, cytomegalovirus, *Mycoplasma hominis*, and *Ureaplasma*

¹ The terms female, woman/women, and male refer to sex assigned at birth.

urealyticum might be associated with some instances of PID. Therefore, PID is managed as a polymicrobial infection. In more than half of cases, however, no organism is identified from routine lower genital tract swab specimens (ie, endocervical or vaginal swab specimens). *Mycoplasma genitalium* also has been implicated in the etiology of PID in some studies, although the natural history of *M genitalium* in females remains unclear. PID may also be secondary to other causes of peritonitis, such as ruptured appendicitis.

EPIDEMIOLOGY: Although many of the issues pertaining to high-risk sexual behavior and acquisition of sexually transmitted infections (STIs) are common to both adolescents and adults, they often are intensified among adolescents because of both behavioral and biological predispositions. Female adolescents and young adults can be at higher risk of STIs and PID because of behavioral factors such as inconsistent barrier contraceptive use, douching, greater number of concurrent sex partners, and use of alcohol and other substances that may impair judgment while engaging in sexual activity. Use of condoms may reduce the risk of PID. Female adolescents and young adults also have an increased biologic susceptibility to STIs. Cervical ectopy increases risk of chlamydia and gonorrhea infection by exposing columnar epithelium to a potential infectious inoculum.

An **incubation period** for PID is undefined.

DIAGNOSTIC TESTS¹: Centers for Disease Control and Prevention (CDC) criteria for clinical diagnosis and presumptive treatment of PID are presented in Table 3.45. Many individuals with PID have subtle or nonspecific symptoms or are asymptomatic, and a diagnosis of PID usually is based on imprecise clinical findings. A clinical diagnosis of symptomatic PID has a positive predictive value for salpingitis of 65% to 90% compared with laparoscopy. No single historical, physical, or laboratory finding is both sensitive and specific for the diagnosis of acute PID. Because of the difficulty of diagnosis and the potential for damage to reproductive health, providers should maintain a low threshold for the clinical diagnosis of PID.

A cervical or vaginal swab specimen should be obtained from individuals with suspected PID to perform a nucleic acid amplification test (NAAT) for *C trachomatis* and *N gonorrhoeae*. A swab specimen for culture of *N gonorrhoeae* may be collected from the cervix or vagina to allow susceptibility testing to be performed. The most specific criteria for diagnosing PID include endometrial biopsy with histopathologic evidence of endometritis; transvaginal ultrasonography or magnetic resonance imaging techniques showing thickened, fluid-filled tubes with or without free pelvic fluid or tubo-ovarian complex or Doppler ultrasonography suggesting pelvic infection (eg, tubal hyperemia); or laparoscopic findings consistent with PID. A diagnostic evaluation that includes some of these more extensive procedures might be warranted in some cases. Endometrial biopsy is warranted in patients undergoing laparoscopy who do not have visual evidence of salpingitis, because endometritis may be the only sign of PID.

In addition to determining whether WBCs are present in cervicovaginal secretions, a wet mount or NAAT of vaginal fluid will assist in the identification of trichomoniasis or bacterial vaginosis. Serologic testing for HIV and syphilis also should be performed.

¹ Centers for Disease Control and Prevention. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(RR-4):1-187. Available at: www.cdc.gov/std/treatment-guidelines/pid.htm

Table 3.45. Criteria for Clinical Diagnosis and Presumptive Treatment of Pelvic Inflammatory Disease (PID)^a

Minimum Criteria

Presumptive treatment for PID should be initiated in sexually active female adolescents and young adults at risk for STIs if they are experiencing pelvic or lower abdominal pain, if no cause for the illness other than PID can be identified, or if one or more of the following **minimum clinical criteria** are present on pelvic examination:

- Cervical motion tenderness
- or
- Uterine tenderness
- or
- Adnexal tenderness

One or more of the following **additional criteria** can be used to enhance the specificity of the minimum clinical criteria and support a diagnosis of PID:

- Oral temperature >101°F (>38.3°C);
- Abnormal cervical mucopurulent discharge or cervical friability;
- Presence of abundant numbers of WBC on saline microscopy of vaginal fluid;
- Elevated erythrocyte sedimentation rate;
- Elevated C-reactive protein; and
- Laboratory documentation of cervical infection with *Neisseria gonorrhoeae* or *Chlamydia trachomatis*.

Most people with PID have either mucopurulent cervical discharge or evidence of WBCs on a microscopic evaluation of a saline preparation of vaginal fluid (ie, wet prep). If the cervical discharge appears normal and no WBCs are observed on the wet prep of vaginal fluid, the diagnosis of PID is unlikely, and alternative causes of pain should be considered. A wet prep of vaginal fluid also can detect the presence of concomitant infections (eg, bacterial vaginosis and trichomoniasis).

^aAdapted from Centers for Disease Control and Prevention. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(RR-4):1-187. Available at: www.cdc.gov/std/treatment-guidelines/pid.htm.

The possibility of coexisting early pregnancy must always be assessed in patients who are being evaluated for PID.

TREATMENT¹: A sexually active female adolescent or young adult with lower abdominal pain who exhibits uterine, adnexal, or cervical motion tenderness on bimanual examination should be treated for PID if no other cause is identified. To minimize risks of progressive infection and subsequent infertility, treatment should be initiated at the time of clinical diagnosis, and therapy should be completed, regardless of the STI test results.

Among patients with mild to moderate PID, there is no difference in clinical course, recurrent PID, chronic pelvic pain, or infertility rates between those hospitalized and those treated on an outpatient basis for PID. The decision to hospitalize adolescent or young adult patients with acute PID should be based on

¹Centers for Disease Control and Prevention. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(RR-4):1-187. Available at: www.cdc.gov/std/treatment-guidelines/pid.htm

the provider's judgment and whether any of the following suggested criteria are relevant:

- Surgical emergencies (eg, appendicitis) cannot be excluded;
- The patient has tubo-ovarian abscess;
- The patient is pregnant;
- The patient has severe illness, nausea and vomiting, or high fever;
- The patient is unable to follow or tolerate an outpatient oral regimen; or
- There is no clinical response to oral antimicrobial therapy.

Whether treated on an inpatient or outpatient basis, the antimicrobial regimen chosen should provide empiric, broad-spectrum coverage directed against the most common causative agents, including *N gonorrhoeae* and *C trachomatis*, and anaerobic organisms, even if these pathogens are not identified in lower genital tract specimens. If a *N gonorrhoeae* culture is positive, antimicrobial susceptibility testing should guide subsequent therapy. Addition of metronidazole to the PID regimen can effectively eradicate anaerobic organisms from the upper genital tract.

Table 4.4 (p 1007) lists the parenteral regimens recommended by the CDC for treatment of hospitalized patients and the intramuscular/oral regimens recommended for the treatment of patients in the outpatient setting. For management of females hospitalized and managed initially with the parenteral therapy options listed in Table 4.4, clinical experience should guide decisions regarding transition to oral therapy, which usually can be initiated within 24 to 48 hours of clinical improvement. In patients with tubo-ovarian abscesses, at least 24 hours of inpatient observation is recommended. Because of the pain associated with intravenous (IV) infusion, doxycycline should be administered orally when possible. Oral and IV administration of doxycycline and metronidazole provide similar bioavailability. Intramuscular/oral therapy (Table 4.4, p 1007) can be considered for individuals with mild-to-moderately severe acute PID who can be managed in the outpatient setting from the outset, because the clinical outcomes among patients treated with these regimens are similar to those treated with intravenous therapy. Patients who do not respond to intramuscular/oral therapy within 72 hours should be reevaluated to confirm the diagnosis and be administered intravenous therapy. Patients should demonstrate clinical improvement (eg, defervescence; reduction in direct or rebound abdominal tenderness; and reduction in uterine, adnexal, cervical motion tenderness) within 3 days after initiation of therapy. If no clinical improvement has occurred within 72 hours after outpatient intramuscular/oral therapy, hospitalization, assessment of the antimicrobial regimen, and additional diagnostics (including consideration of diagnostic laparoscopy for alternative diagnoses) are recommended.

If a person with an intrauterine device (IUD) receives a diagnosis of PID, the IUD does not need to be removed. However, the patient should have close clinical follow-up, and if there is no clinical improvement 48 to 72 hours after treatment initiation, removal of the IUD may be considered.

Pregnancy. Pregnant people with suspected PID are at high risk for morbidity and preterm delivery. These patients should be hospitalized and treated with IV antimicrobials in consultation with an infectious disease specialist.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS: Standard precautions are recommended.

CONTROL MEASURES:

- All individuals who have received a diagnosis of chlamydial or gonococcal PID should be retested 3 months after treatment, regardless of whether their sex partners were treated. If retesting at 3 months is not possible, retest whenever the patient next presents for medical care in the 12 months following treatment.
- Male sexual partners of a person with PID during the 60 days preceding the onset of symptoms should be evaluated, tested, and presumptively treated for chlamydia and gonorrhea, regardless of the etiology of PID or pathogens isolated from the patient with PID. If the last sexual intercourse was >60 days before onset of symptoms or diagnosis, the most recent sex partner should be treated.
- To minimize disease transmission, patients should be instructed to abstain from sexual intercourse until therapy is completed, symptoms have resolved, and sex partners have been adequately treated.
- The patient and sexual partner(s) should be encouraged to use condoms consistently and correctly.
- The patient should be screened for other STIs, including human immunodeficiency virus, gonorrhea, chlamydia, and syphilis.
- Unimmunized or incompletely immunized patients should complete the immunization series for human papillomavirus and hepatitis B (https://redbook.solutions.aap.org/SS/Immunization_Schedules.aspx).
- The diagnosis of PID provides an opportunity to educate the adolescent about STI prevention, including abstinence, consistent use of barrier methods of protection, immunization, and the importance of receiving periodic STI screening.

Pertussis (Whooping Cough)

CLINICAL MANIFESTATIONS: Pertussis begins with mild upper respiratory tract symptoms similar to the common cold (catarrhal stage) and progresses to cough, usually paroxysms of cough (paroxysmal stage), characterized by inspiratory whoop (gasping) after repeated cough on the same breath, which commonly is followed by post-tussive emesis. Fever is absent or minimal. Symptoms wane gradually over weeks to months (convalescent stage). Cough illness in immunized children and adults can range from typical to very mild. The duration of classic pertussis is 6 to 10 weeks. Complications among adolescents and adults include syncope, weight loss, sleep disturbance, incontinence, rib fractures, and pneumonia; among adults, complications may increase with age. Pertussis is most severe when it occurs during the first 6 months of life, particularly in preterm and unimmunized infants. Disease in infants younger than 6 months can be atypical with a short catarrhal stage, followed by gagging, gasping, bradycardia, or apnea as prominent early manifestations; absence of whoop; and prolonged convalescence. Complications among infants include pneumonia, pulmonary hypertension, and severe coughing spells with associated conjunctival hemorrhage, hernia, and hypoxia. Seizures (0.9%), encephalopathy (less than 0.5%), apnea, acute respiratory distress syndrome, and death can occur in infants with pertussis. Approximately a third of infants with pertussis in the United States are hospitalized. Case fatality rates are approximately 1.1% in infants younger than 2 months and 0.1 in infants 2 through 11 months of age. Immunization with tetanus and diphtheria toxoids and acellular pertussis vaccine (Tdap) during each pregnancy and an infant's receipt of at least some doses of pertussis vaccine reduce morbidity and mortality in young infants.

ETIOLOGY: Pertussis is caused by a fastidious, gram-negative, pleomorphic bacillus, *Bordetella pertussis*. Other *Bordetella* species can cause sporadic prolonged cough illness in people, including *Bordetella parapertussis*, *Bordetella bronchiseptica* (the cause of canine kennel cough), and *Bordetella holmesii*.

EPIDEMIOLOGY: Humans are the only known hosts of *B. pertussis*. Transmission occurs by close contact with infected individuals via large respiratory droplets generated by coughing or sneezing. Cases occur year-round, typically with a late summer-autumn peak. Neither infection nor immunization provides lifelong immunity. Waning immunity is predominantly responsible for increased cases reported in school-aged children, adolescents, and adults. Additionally, waning immunity in pregnant people who have not received Tdap vaccine during that pregnancy results in low concentrations of transplacentally transmitted antibody and an increased risk of pertussis in very young infants. Reported incidence is cyclic and had been increasing since the early 1990s until the start of the COVID-19 pandemic in 2020. Pertussis is highly contagious. As many as 80% of susceptible household contacts of symptomatic infant cases are infected with *B. pertussis*, with symptoms in these contacts varying from mild to classic pertussis. Siblings and adults with cough illness are important sources of pertussis infection for young infants. Infected people are most contagious during the catarrhal stage through the third week after onset of paroxysms or until 5 days after the start of effective antimicrobial treatment. Factors affecting the length of communicability include age, immunization status or previous infection, and receipt of appropriate antimicrobial therapy.

The **incubation period** is 7 to 10 days, with a range of 5 to 21 days.

DIAGNOSTIC TESTS: Culture previously was considered the “gold standard” for laboratory diagnosis of pertussis but is not optimally sensitive and has largely been replaced by nucleic acid amplification tests (NAATs). Culture requires collection of an appropriate nasopharyngeal swab specimen, obtained either by aspiration or with polyester or flocked rayon swabs. Specimens must not be allowed to dry during prompt transport to the laboratory. Culture results can be negative if obtained from a previously immunized person, if antimicrobial therapy has been started, if more than 2 weeks has elapsed since cough onset, or if the specimen is not collected or handled appropriately. Testing nasopharyngeal swab specimens by rolling on slides and staining with direct fluorescent antibodies (DEA) is not recommended because of nonspecific cross-reactions.

NAATs cleared by the US Food and Drug Administration (FDA), including polymerase chain reaction (PCR) assays, are commercially available as standalone tests or as multiplex assays and are the most commonly used laboratory method for detection of *B. pertussis* because of greater sensitivity and more rapid turnaround time. The PCR test requires collection of an adequate nasopharyngeal specimen using a polyester or flocked swab or nasopharyngeal wash or aspirate. Calcium alginate swabs can be inhibitory to PCR and should not be used. The PCR test has optimal sensitivity during the first 3 weeks of cough and is unlikely to be useful if a patient has been receiving antimicrobial therapy for more than 5 days. The Centers for Disease Control and Prevention (CDC) has released a “best practices” document to guide pertussis PCR assays (www.cdc.gov/pertussis/clinical/diagnostic-testing/diagnosis-pcr-bestpractices.html) as well as a video demonstrating optimal specimen collection.

Most PCR assays target a multicopy insertion gene sequence (IS481) found in *B pertussis* as well as the less commonly encountered *B holmesii* and some strains of *B bronchiseptica*. Several multiplex PCR assays test for both *B pertussis* and *B parapertussis* utilizing differing DNA targets for each pathogen. Multiple DNA target sequences are required to distinguish among clinically relevant *Bordetella* species.

Serologic tests for pertussis infection may be helpful for diagnosis, especially late in illness, but are not commonly used. The CDC and FDA have developed a pertussis serologic test that has been used by state public health laboratories during outbreaks; however, no commercial kit is cleared by the FDA for diagnostic use. In the absence of recent immunization, an elevated serum immunoglobulin (Ig) G antibody to pertussis toxin (PT) present 2 to 8 weeks after onset of cough is suggestive of recent *B pertussis* infection. For single serum specimens, an IgG anti-PT value of approximately 100 IU/mL or greater (using an assay calibrated to standard reference sera) has been recommended. IgA and IgM assays lack adequate sensitivity and specificity and should not be used for the diagnosis of pertussis.

An increased white blood cell count attributable to absolute lymphocytosis is suggestive of pertussis in infants and young children but often is absent in older people with pertussis and may be only mildly abnormal in some infants. A markedly elevated white blood cell count is associated with a poor prognosis in young infants.

TREATMENT: Antimicrobial therapy administered during the catarrhal stage may ameliorate the disease. Antimicrobial therapy is indicated before test results are received if the clinical history is strongly suggestive of pertussis or the patient is at high risk of severe or complicated disease (eg, an infant). A 5-day course of azithromycin is the appropriate first-line choice for treatment and for postexposure prophylaxis (PEP [see Table 3.46]). After the paroxysmal cough is established, antimicrobial agents have no discernible effect on the course of illness but are recommended to limit spread of organisms to others. Resistance of *B pertussis* to macrolide antimicrobial agents has been reported but rarely in the United States. Penicillins and cephalosporins are not effective against *B pertussis*. Trimethoprim-sulfamethoxazole is an alternative for patients older than 2 months who cannot tolerate macrolides or who are infected with a macrolide-resistant strain, but studies evaluating trimethoprim-sulfamethoxazole as treatment for pertussis are limited. When administered in the first 6 weeks of life, oral erythromycin and, to a lesser degree azithromycin, are associated with increased risk of infantile hypertrophic pyloric stenosis (IHPS), but azithromycin remains the drug of choice for treatment or prophylaxis of pertussis in very young infants.

Young infants are at increased risk of respiratory failure attributable to apnea or secondary bacterial pneumonia and are at risk of cardiopulmonary failure and death from severe pulmonary hypertension. Hospitalization is most common in infants younger than 6 months. Characteristics that would suggest the need for hospitalization of infants with pertussis include young age, respiratory distress, inability to feed, cyanosis or apnea, and seizures. Hospitalized young infants with pertussis should be managed in a setting/facility where these complications can be recognized and managed urgently. Exchange transfusions or leukopheresis have been reported to be life-saving in infants with progressive pulmonary hypertension and markedly elevated lymphocyte counts.

Because data on the clinical effectiveness of antibiotic treatment on *B parapertussis* are limited, treatment decisions should be based on clinical judgment, with particular attention to special populations that may be at increased risk for severe *B parapertussis*

Table 3.46. Recommended Antimicrobial Therapy and Postexposure Prophylaxis for Pertussis in Infants, Children, Adolescents, and Adults^a

Age	Recommended Drugs			Alternative
	Azithromycin	Erythromycin	Clarithromycin	TMP-SMX
Younger than 1 mo	10 mg/kg/day as a single dose daily for 5 days ^{b,c}	40 mg/kg/day in 4 divided doses for 14 days	Not recommended	Contraindicated at younger than 2 mo
1 through 5 mo	10 mg/kg/day as a single dose daily for 5 days ^b	40 mg/kg/day in 4 divided doses for 14 days	15 mg/kg/day in 2 divided doses for 7 days	2 mo or older: TMP, 8 mg/kg/day; SMX, 40 mg/kg/day in 2 doses for 14 days
6 mo or older and children	10 mg/kg as a single dose on day 1 (maximum 500 mg), then 5 mg/kg/day as a single dose on days 2 through 5 (maximum 250 mg/day) ^{b,d}	40 mg/kg/day in 4 divided doses for 7–14 days (maximum 2 g/day)	15 mg/kg/day in 2 divided doses for 7 days (maximum 1 g/day)	2 mo or older: TMP, 8 mg/kg/day; SMX, 40 mg/kg/day in 2 doses for 14 days
Adolescents and adults	500 mg as a single dose on day 1, then 250 mg as a single dose on days 2 through 5 ^{b,d}	2 g/day in 4 divided doses for 7–14 days	1 g/day in 2 divided doses for 7 days	TMP, 320 mg/day; SMX, 1600 mg/day in 2 divided doses for 14 days

SMX indicates sulfamethoxazole; TMP, trimethoprim.

^aCenters for Disease Control and Prevention. Recommended antimicrobial agents for the treatment and postexposure prophylaxis of pertussis: 2005 CDC guidelines. *MMWR Recomm Rep*. 2005;54(RR-14):1–16

^bAzithromycin should be used with caution in people with prolonged QT interval and certain proarrhythmic conditions.

^cPreferred macrolide for this age because of risk of idiopathic hypertrophic pyloric stenosis associated with erythromycin.

^dA 3-day course of azithromycin for PEP or treatment has not been validated and is not recommended.

disease, including infants, elderly people, and immunocompromised people. Limited available data suggest that *B parapertussis* is less susceptible to antimicrobial agents than *B pertussis*, although some studies indicate that macrolides, trimethoprim-sulfamethoxazole, and ciprofloxacin generally have activity against *B parapertussis*. *B bronchiseptica* has intrinsic resistance to macrolide antibiotics.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, droplet precautions are recommended for 21 days

from onset of cough if appropriate antimicrobial therapy is not administered or for 5 days after initiation of effective therapy.

CONTROL MEASURES:

Care of Exposed People. Individuals, regardless of immunization status and in all settings, who have been in close contact with a person infected with pertussis should be monitored closely for respiratory tract symptoms for 21 days after last contact with the infected person. Close contacts with cough should be evaluated. People in child care settings (both workers and children), schools (both teachers and students), and health care settings with confirmed pertussis should be excluded from child care, school, or work until completion of 5 days of the recommended course of antimicrobial therapy. Untreated individuals should be excluded until 21 days have elapsed from cough onset.

Household and Other Close Contacts. PEP is recommended for all household contacts of the index case and other close contacts, including children in child care, regardless of immunization status. (www.cdc.gov/pertussis/pep.html). When considering a nonhousehold contact with an uncertain amount of exposure, PEP should be administered if the contact personally is at high risk or will have close contact with a person at high risk of severe pertussis (eg, young infant, pregnant person, person who has contact with infants). If 21 days have elapsed since onset of cough in the index case, PEP has limited value but may be considered for households or in situations with high-risk contacts. The agents, doses, and duration of PEP are the same as for treatment of pertussis (see Table 3.46). Prophylaxis for people exposed to *B parapertussis* is not recommended.

Close contacts who are unimmunized or underimmunized should have pertussis immunization initiated or continued as soon as possible using age-appropriate products according to the recommended schedule; this includes off-label use of tetanus toxoid, reduced-content diphtheria toxoid, and acellular pertussis vaccine (Tdap) in children 7 through 9 years of age who did not complete the diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP) series (see Table 3.47). Because pertussis-containing vaccines are non-live, they can be administered concomitantly with PEP.

Child Care. Pertussis vaccine and PEP should be administered as recommended for household and other close contacts. In the setting of known pertussis exposure, children and child care providers who are symptomatic should be excluded from the child care setting, pending evaluation by a physician.

Schools. Use of PEP for large groups of students usually is not recommended, especially in the setting of widespread community transmission, but exceptions for specific individuals can be considered. This occurs when close contact simulates household exposure or when pertussis in the exposed person may result in severe medical consequences. Public health officials should be consulted for recommendations to control pertussis transmission in schools. The immunization status of close contacts should be reviewed, and appropriate vaccines administered when indicated. Parents and teachers should be notified about possible exposures to pertussis. Exclusion of exposed people with cough illness within 21 days of last exposure should be considered pending evaluation by a physician.

Health Care Settings.¹ Health care facilities should maximize efforts to immunize all health care personnel (HCP) with Tdap. All HCP should observe droplet

¹ Centers for Disease Control and Prevention. Immunization of health-care personnel. Recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR Recomm Rep*. 2011;60(RR-07):1–45

Table 3.47. Composition and Recommended Use of Vaccines With Tetanus Toxoid, Diphtheria Toxoid, and Acellular Pertussis Components Licensed and Available in the United States^a

Pharmaceutical	Manufacturer	Recommended Use
DTaP (Infanrix)	GlaxoSmithKline Biologicals	All 5 doses , children 6 wk through 6 y of age.
DTaP (Daptacel)	Sanofi Pasteur	All 5 doses , children 6 wk through 6 y of age.
DTaP-hepatitis B-IPV (Pediarix)	GlaxoSmithKline Biologicals	First 3 doses, children 6 wk through 6 y of age; usual use at 2, 4, and 6 months of age; then 2 doses of DTaP are needed to complete the 5-dose series before 7 y of age.
DTaP-IPV/Hib (Pentacel)	Sanofi Pasteur	First 4 doses, children 6 wk through 4 y of age; usual use at 2, 4, 6, and 15 through 18 mo of age; then 1 dose of DTaP is needed to complete the 5-dose series before 7 y of age.
DTaP-IPV-hepatitis B-Hib (Vaxelis)	Merck/Sanofi Pasteur	First 3 doses, children 6 wk through 4 y of age; usual use at 2, 4, and 6 months of age; then 2 doses of DTaP are needed to complete the 5-dose series before 7 y of age.
DTaP-IPV (Kinrix)	GlaxoSmithKline Biologicals	Booster dose for fifth dose of DTaP and fourth dose of IPV at 4 through 6 y of age.
DTaP-IPV (Quadracel)	Sanofi Pasteur	Booster dose for fifth dose of DTaP and fourth dose of IPV at 4 through 6 y of age.
Tdap (Boostrix)	GlaxoSmithKline Biologicals	Single dose at 11 y or older. Can be used in place of Td. One dose recommended during EACH pregnancy, optimally between 27 and 36 weeks' gestation.
Tdap (Adacel)	Sanofi Pasteur	Single dose at 11 y or older. Can be used in place of Td. One dose recommended during EACH pregnancy, optimally between 27 and 36 weeks' gestation.

DTaP indicates pediatric formulation of diphtheria and tetanus toxoids and acellular pertussis vaccines; FHA, filamentous hemagglutinin; Hib, *Haemophilus influenzae* type b vaccine; IPV, inactivated (non-live) poliovirus; PT, pertussis toxoid; Td, tetanus and reduced diphtheria toxoids (for children 7 years of age or older and adults); Tdap, adolescent/adult formulation of tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine.

^aDTaP recommended schedule is 2, 4, 6, and 15 through 18 months and 4 through 6 years of age. The fourth dose can be administered as early as 12 months of age, provided 6 months have elapsed since the third dose was administered. The fifth dose is not necessary if the fourth dose was administered on or after the fourth birthday. Refer to manufacturers' product information for comprehensive product information regarding indications and use of the vaccines listed.

precautions when examining a patient with pertussis (see Infection Prevention and Control in Health Care Settings). People exposed to a patient with pertussis should be evaluated by infection control personnel for postexposure management and follow-up.

Recommendations of the CDC are as follows:

- PEP is recommended for all HCP (even if immunized with Tdap) who have been exposed to pertussis and are likely to expose patients at risk of severe pertussis (eg, hospitalized neonates and pregnant women). Other exposed HCP either should receive PEP or should be monitored daily for 21 days after exposure and treated at the onset of signs and symptoms of pertussis.
- Other people (patients, caregivers) defined as close contacts or high-risk contacts of a patient or HCP with pertussis should receive PEP (and immunization when indicated), as recommended for household contacts (see Table 3.46, p 659).
- HCP with symptoms of pertussis (or HCP with any respiratory illness within 21 days of exposure to pertussis who did not receive PEP) should be excluded from work for at least the first 5 days of the recommended antimicrobial therapy. HCP with symptoms of pertussis who do not accept antimicrobial therapy should be excluded from work for 21 days from onset of cough.

Immunization.

Vaccine Products. Acellular-component pertussis vaccines (DTaP) replaced previously used diphtheria, tetanus, and whole-cell pertussis vaccine (DTwP or DTP) exclusively in 1997; see Table 3.47 for products. All pertussis vaccines in the United States are combined with diphtheria and tetanus toxoids; none contains thimerosal as a preservative. DTaP products may be formulated as combination vaccines that contain other vaccine components. Adolescent and adult formulations, known as Tdap vaccines, contain reduced quantities of diphtheria toxoid and some pertussis antigens compared with DTaP.

Dose and Route. Each 0.5-mL dose of DTaP or Tdap is administered intramuscularly. Use of a decreased volume of individual doses of pertussis vaccines or multiple doses of decreased-volume (fractional) doses is not recommended.

Interchangeability of Acellular Pertussis Vaccines. Insufficient data exist on the safety, immunogenicity, and efficacy of DTaP vaccines from different manufacturers when administered interchangeably for the primary series in infants. In circumstances in which the type of DTaP product(s) received previously is unknown or the previously administered product(s) is not readily available, any DTaP vaccine licensed for use in the primary series may be used. There is no need to match Tdap vaccine manufacturer with DTaP vaccine manufacturer used for earlier doses.

Recommendations for Routine Childhood Immunization With DTaP. Five doses of pertussis-containing vaccine are recommended prior to entering school. The first dose of DTaP may be administered as early as 6 weeks of age, followed by 2 additional doses at intervals of approximately 2 months. The fourth dose of DTaP is recommended at 15 through 18 months of age, and the fifth dose of DTaP is administered at 4 through 6 years of age. The fourth dose can be administered as early as 12 months of age, provided 6 months have elapsed since the third dose was administered. If the fourth dose of pertussis vaccine is delayed until after the fourth birthday, the fifth dose is not recommended.

Other recommendations are as follows:

- Simultaneous administration of DTaP and all other recommended vaccines is acceptable. Vaccines should not be mixed in the same syringe unless the specific combination is licensed by the FDA (see Simultaneous Administration of Multiple Vaccines, p 63, and *Haemophilus influenzae* Infections, p 400).

- Inadvertent administration of Tdap instead of DTaP to a child younger than 7 years as either dose 1, 2, or 3 of the DTaP series does not count as a valid dose; DTaP should be administered as soon as is feasible.
- Inadvertent administration of Tdap instead of DTaP to a child younger than 7 years of age as either dose 4 or 5 can be counted as valid for DTaP dose 4 or 5.
- During a pertussis outbreak in the community, public health authorities may recommend starting DTaP immunization as early as 6 weeks of age, with doses 2 and 3 in the primary series administered at intervals as short as 4 weeks.
- Children younger than 7 years who have begun but not completed their primary immunization schedule with DTwP outside the United States should receive DTaP to complete the pertussis immunization schedule.
- DTaP is not licensed or recommended for people 7 years or older.

Combined Vaccines. Several pertussis-containing combination vaccines are licensed for use (see Table 3.47, p 661) and may be used when feasible and when any components are indicated and none is contraindicated.

Recommendations for Scheduling Pertussis Immunization for Children Younger Than 7 Years in Special Circumstances.

- For children who have received fewer than the recommended number of doses of pertussis vaccine but who have received the recommended number of diphtheria and tetanus toxoid vaccine doses for their age, DTaP should be administered to complete the recommended pertussis immunization schedule.
- The total number of doses of diphtheria and tetanus toxoids (as DTaP or DTwP) should not exceed 6 before the seventh birthday.
- Although *B pertussis* infection confers protection against recurrent infection, the duration of protection is unknown. Age-appropriate DTaP dose(s) or a Tdap dose should be administered to complete the standard or catch-up immunization series on schedule in people who have had pertussis infection. No minimum interval between disease and immunization is needed.

Adverse Events After DTaP Immunization in Children Younger Than 7 Years.

- **Local and febrile reactions.** Reactions to DTaP can occur within several hours of immunization and subside spontaneously within 48 hours without sequelae. Most commonly, these include redness, swelling, induration, and tenderness at the injection site as well as drowsiness and irritability. Less common reactions include anorexia, vomiting, crying, and slight to moderate fever.
- **Limb swelling** involving the entire thigh or upper arm has been reported in 2% to 3% of vaccine recipients after administration of the fourth and fifth doses of DTaP in that extremity. Although thigh swelling may interfere with walking, most children have no limitation of activity; the condition resolves spontaneously and has no sequelae. Entire limb swelling is not a contraindication to further DTaP, Tdap, or Td immunization.
- A review by the National Academy of Medicine (NAM) based on case-series reports found evidence of a rare yet likely causal relationship between receipt of tetanus toxoid-containing vaccines and **brachial neuritis**. However, the frequency of this event has not been determined.
- **Seizures.** In contrast to DTwP, no increased risk of seizures has been observed after DTaP administration. A small increased risk for febrile seizures after DTaP when administered simultaneously with inactivated (non-live) influenza vaccine was observed in a study by the CDC Vaccine Safety Datalink project. However, neither

the CDC Advisory Committee on Immunization Practices (ACIP) nor the American Academy of Pediatrics recommends administering vaccines on separate days.

- **Hypotonic-hyporesponsive episode.** Hypotonic-hyporesponsive episodes (HHEs) (also termed “collapse” or “shock-like state”) occur significantly less often after immunization with DTaP than previously shown with DTwP and are not a contraindication to subsequent dose(s).
- **Other reactions.** Severe anaphylactic reactions are rare after pertussis immunization. Transient urticarial rashes that occur occasionally after pertussis immunization, unless appearing immediately (ie, within minutes), are unlikely to be anaphylactic (IgE-mediated) in origin.

Contraindications and Precautions to DTaP Immunization.

Contraindications to DTaP and Tdap occur only very rarely, and in questioning about them, providers should probe whether a true contraindication actually exists. DTaP and Tdap contraindications are limited to **only** the following:

- **Severe allergic reaction (eg, anaphylaxis)** to a dose of DTaP or Tdap or to a vaccine component (Td) is a contraindication to DTaP, Tdap, or Td. Because of the importance of tetanus vaccination, people who experience anaphylactic reactions should be referred to an allergist to determine whether they have a specific allergy to tetanus toxoid and can be desensitized to tetanus toxoid.
- **Encephalopathy (eg, coma, decreased level of consciousness, or prolonged seizures) not attributable to another identifiable cause** within 7 days after administration of a previous dose of diphtheria and tetanus toxoids and pertussis vaccine (DTwP, DTaP, or Tdap) is a contraindication to the pertussis component.

Precautions to DTaP and Tdap:

- **Guillain-Barré syndrome** within 6 weeks after a previous dose of tetanus toxoid-containing vaccine is a **precaution** to further doses of DTaP, Tdap, or Td.
- Moderate or severe acute illness with or without a fever is a reason to defer administration of any vaccine until the person has recovered.
- **Evolving neurologic disorder** generally is a reason to defer DTaP or Tdap immunization temporarily to reduce confusion about reason(s) for a change in the clinical course. Note that as of 2023 DT is no longer available in the United States (www.cdc.gov/vaccines/vpd/dtap-tdap-td/hcp/recommendations.html and www.cdc.gov/vaccines/vpd/dtap-tdap-td/hcp/td-offlabel.html) (see Diphtheria, p 357, and Tetanus, p 848). For young children with a contraindication to pertussis-containing vaccines, vaccine providers may administer Td for all recommended remaining doses in place of DTaP. Td contains a lower dose (approximately 1/12th the amount) of diphtheria toxoid compared with DT. The impact of this lower dose on the protection provided against diphtheria in young children is uncertain. Available evidence suggests young children who receive Td in place of DTaP may have suboptimal protection against diphtheria.

Recommendations for Routine Adolescent Immunization With Tdap.^{1,2} Adolescents 11 years and older should receive a single dose of Tdap instead of Td for booster immunization

¹ Centers for Disease Control and Prevention. Prevention of pertussis, tetanus, and diphtheria with vaccines in the United States: recommendations of the Advisory Committee on Immunization Practices, 2018. *MMWR Morb Mortal Wkly Rep.* 2018;67(2):1-44

² Havers FP, Moro PL, Hunter P, Hariri S, Bernstein H. Use of tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccines: updated recommendations of the Advisory Committee on Immunization Practices—United States, 2019. *MMWR Morb Mortal Wkly Rep.* 2020;69(3):77-83

against tetanus, diphtheria, and pertussis. The preferred age for Tdap immunizations is 11 through 12 years of age.

- Adolescents who received Td but not Tdap should receive a single dose of Tdap to provide protection against pertussis regardless of time since receipt of Td.
- Simultaneous administration of Tdap and all other recommended vaccines is recommended when feasible.
- Inadvertent administration of DTaP instead of Tdap in people 7 years and older is counted as a valid dose of Tdap.

Recommendations for Scheduling Tdap in Children 7 Years and Older Who Did Not Complete Recommended DTaP Doses Before 7 Years of Age.¹

- Children 7 through 10 years of age who have not completed their immunization schedule with DTaP before 7 years of age or who have an unknown vaccine history should receive at least 1 dose of Tdap. If further dose(s) of tetanus and diphtheria toxoids are needed in a catch-up schedule, either Td or Tdap can be used. The preferred schedule is Tdap followed by Td or Tdap at 2 months and 6 to 12 months (if needed).
- Children 7 through 9 years of age who receive Tdap or DTaP for any reason should receive the adolescent Tdap booster at 11 through 12 years of age.
- A Tdap or DTaP dose received by a 10 year-old for any reason can count as the adolescent Tdap booster dose.

Recommendations for Adolescent and Adult Immunization With Tdap in Special Situations.¹

Despite the burden of pertussis in the community, a decision analysis conducted by the CDC concluded that a routine second dose would have a limited effect on overall disease rates. However, repeat doses of Tdap are generally well tolerated, and either Td or a Tdap can be used regardless of prior receipt of Tdap for catchup immunization of individuals 7 years and older, for the routine decennial tetanus-diphtheria booster, and for wound prophylaxis when indicated. Special situations for use of Tdap, or repeated use of Tdap off label, are provided in the following sections.

Use of Tdap in Pregnancy.² Tdap is approved for use by the US Food and Drug Administration (FDA) for use in the third trimester of pregnancy to prevent pertussis in infants younger than 2 months of age. In order to protect infants, who have a high risk for severe or fatal pertussis, the ACIP recommends that a dose of Tdap be administered during **each** pregnancy, irrespective of the pregnant individual's prior history of receiving Tdap or having had pertussis. Immunization during pregnancy leads to transplacental transfer of antibody that has been shown to provide protection to the infant. Tdap may be administered at any time during pregnancy, but current evidence suggests that immunization early in the interval between 27 and 36 weeks of gestation will maximize passive antibody transfer to the infant. For people not previously vaccinated with Tdap and in whom Tdap was not administered during pregnancy for some reason, Tdap should be administered immediately postpartum. Postpartum Tdap is

¹ Havers FP, Moro PL, Hunter P, Hariri S, Bernstein H. Use of tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccines: updated recommendations of the Advisory Committee on Immunization Practices—United States, 2019. *MMWR Morb Mortal Wkly Rep.* 2020;69(3):77–83

² Centers for Disease Control and Prevention. Prevention of pertussis, tetanus, and diphtheria with vaccines in the United States: recommendations of the Advisory Committee on Immunization Practices, 2018. *MMWR Morb Mortal Wkly Rep.* 2018;67(2):1–44

not recommended for people who have received a previous Tdap dose unless they are due for their decennial tetanus booster.

Protection of Young Infants: The Cocoon Strategy. Tdap vaccination during each pregnancy is the preferred strategy for protecting young infants from pertussis in the early months of life. In addition, the American Academy of Pediatrics, CDC, American College of Obstetricians and Gynecologists, American Academy of Family Physicians, American College of Nurse-Midwives, American Academy of Physician Associates, and National Association of Pediatric Nurse Practitioners recommend the “cocoon” strategy to help protect infants from pertussis by immunizing those around them. This strategy may offer indirect protection by decreasing their likelihood of acquisition and subsequent development of clinical pertussis. Immunizing parents or other adult family contacts in the pediatric office setting could increase immunization coverage for this population.¹

- Underimmunized children younger than 7 years should receive DTaP, and underimmunized children 7 years and older should receive Tdap (see previous discussion).
- All adolescents and adults should have received a single dose of Tdap, ideally at least 2 weeks before beginning close contact with the infant. There is no minimum interval required between Tdap and prior Td.
- Cough illness in contacts of neonates should be investigated and managed promptly, with consideration given for azithromycin prophylaxis for the neonate if pertussis contact is likely (see Control Measures).

Special Situations.

- **Wound management.**² A tetanus toxoid-containing vaccine is indicated for wound management when >5 years have passed since the last tetanus toxoid-containing vaccine dose. If a tetanus toxoid-containing vaccine is indicated for persons aged ≥11 years, Tdap is preferred for persons who have not previously received Tdap or whose Tdap history is unknown. If a tetanus toxoid-containing vaccine is indicated for a pregnant person, Tdap should be used. For nonpregnant persons with documentation of previous Tdap vaccination, either Td or Tdap may be used if a tetanus toxoid-containing vaccine is indicated.
- **Pregnant people for whom tetanus booster is due.** If Td booster immunization is indicated during pregnancy (ie, 10 years or more since previous Td), Tdap should be administered, preferably early in the interval between weeks 27 and 36 of gestation.
- **Pregnant people with unknown or incomplete tetanus vaccination.** To ensure protection against maternal and neonatal tetanus, pregnant people who never have been immunized against tetanus should receive 3 doses of Td-containing vaccines during pregnancy. The recommended schedule is 0, 4 weeks, and 6 to 12 months, and at least 1 Tdap dose should be used in this series, preferably early in the interval between 27 and 36 weeks of gestation; either Td or Tdap can be used to complete the series.

¹ Lessin HR; Edwards KM; American Academy of Pediatrics, Committee on Practice and Ambulatory Medicine, Committee on Infectious Diseases. Immunizing parents and other close family contacts in the pediatric office setting. *Pediatrics*. 2012;129(2):e247-e253

² Havers FP, Moro PL, Hunter P, Hariri S, Bernstein H. Use of tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccines: updated recommendations of the Advisory Committee on Immunization Practices—United States, 2019. *MMWR Morb Mortal Wkly Rep*. 2020;69(3):77–83

Health Care Professionals. The CDC recommends a single dose of Tdap as soon as is feasible for HCP of any age who previously have not received Tdap. There is no minimum interval suggested or required between Tdap and prior Td.

In certain cases (eg, documented transmission in the health care setting), revaccination of HCP with Tdap may be considered (www.cdc.gov/vaccines/vpd/pertussis/tdap-revac-hcp.html). In such a case, Tdap is not a substitute for infection prevention and control measures, including PEP for exposed HCP. If implemented, HCP who work with infants or pregnant people should be prioritized for revaccination.

Hospitals and ambulatory care facilities should provide Tdap for HCP and maximize immunization rates (eg, education about the benefits of immunization or mandatory requirement, convenient access, and provision of Tdap at no charge).

Recommendations for Adult Immunization With Tdap. The CDC recommends administration of a single dose of Tdap universally for adults of any age who previously have not received Tdap, with no minimum interval required between Tdap and prior dose of Td.

Adverse Events After Administration of Tdap. Local adverse events after administration of Tdap in adolescents and adults are common but usually are mild. Systemic adverse events also are common but usually are mild (eg, any fever, 3%–14%; any headache, 40%–44%; tiredness, 27%–37%). Postmarketing data suggest that these events occur at approximately the same rate and severity as following receipt of Td.

Contraindications, Precautions, and Deferral of Use of Tdap in Adolescents and Adults.

Anaphylaxis that occurred after any component of the vaccine is a **contraindication** to Tdap (see Tetanus, p 848, for additional recommendations regarding tetanus immunization). In individuals with **latex allergy**, package inserts should be consulted regarding latex content.

History of **Guillain-Barré syndrome** within 6 weeks of a dose of a tetanus toxoid vaccine is a **precaution** to Tdap immunization. If the decision is made to continue tetanus toxoid immunization, Tdap is preferred if indicated. A history of severe **Arthus hypersensitivity reaction** after a previous dose of a tetanus or diphtheria toxoid-containing vaccine administered less than 10 years previously should lead to **deferral** of Tdap or Td immunization for 10 years after administration of the tetanus or diphtheria toxoid-containing vaccine.

Public Health Reporting. Pertussis is a nationally notifiable disease in the United States.

Pinworm Infection

(Enterobius vermicularis)

CLINICAL MANIFESTATIONS: Pinworm infection (enterobiasis) commonly is asymptomatic but may cause pruritus ani and, rarely, pruritus vulvae. Pruritus ani can be severe enough to cause sleep disturbance. Bacterial superinfections can result from scratching and excoriation of the irritated area. Pinworms have been found in the lumen of the appendix, and in some cases, these intraluminal parasites have been associated with signs of acute appendicitis, but they have also been observed in histologically normal appendices removed for incidental reasons. Urethritis, vaginitis, salpingitis, or pelvic peritonitis uncommonly may occur from aberrant migration of an

adult worm from the perineum. Eosinophilic enterocolitis has been reported, although peripheral eosinophilia generally is not seen in any form of enterobiasis. No proof of a causal relationship has been established for pinworms causing nonspecific clinical findings such as grinding of teeth at night, weight loss, or enuresis.

ETIOLOGY: *Enterobius vermicularis* is a nematode helminth (roundworm).

EPIDEMIOLOGY: Enterobiasis occurs worldwide and commonly clusters within families. Prevalence rates are higher in preschool- and school-aged children, in primary caregivers of infected children, and in institutionalized people. An estimated 40 million people in the United States have been infected with pinworms, with a prevalence as high as 20% to 30% in some age groups and communities.

Initial infection occurs by ingestion of contaminated food, or contact with hands, clothing, bedding, or other items contaminated with eggs. Infection may also occur by person-to-person transmission, including during sexual activity or via fecal-oral or oral-genital contact. Eggs hatch and release larvae in the small intestine, and adult worms then locate themselves usually in the cecum, appendix, and ascending colon. Adult male worms die soon after copulating. Gravid female worms migrate, usually at night while the host is resting, to the perianal area to deposit eggs containing larvae, which mature in 6 to 8 hours. Female worms begin to oviposit after 30 days and have an overall lifespan of up to 100 days. Adult female worms and eggs may induce intense perianal pruritus, leading to an autoinfection cycle during which the area is scratched and then eggs are lodged on the hands and under the fingernails and ingested when hands are put in the mouth. Retroinfection, in which newly hatched larvae migrate back into the rectum, has been hypothesized, but its role in transmission of infection is uncertain. A person remains infectious as long as female pinworms are discharging eggs on perianal skin. Eggs may remain infective in an indoor environment for up to 2 weeks. Humans are the only known natural hosts. Pets are not reservoirs of infection.

The **incubation period** from ingestion of an egg until an adult gravid female worm migrates to the perianal region is 2 to 6 weeks or longer.

DIAGNOSTIC TESTS: Diagnosis is established via the classic cellulose tape test ("Scotch tape test") or with a commercially available pinworm paddle test, which is a clear plastic paddle coated with an adhesive surface on one side that is pressed on both sides of the perianal region during the night or at the time of waking and before bathing. The tape or paddle is then pressed on a slide and eggs can be visualized by microscopy. Eggs are 50 to 60 microns by 20 to 30 microns and flattened on one side, giving them a "bean-shaped" appearance. Testing on 3 different days will increase the sensitivity from around 65% for a single test to approximately 90%. Adult female worms, which are white and measure 8 to 13 mm, also can be seen in the perineal region. Stool examination is not helpful, because worms or eggs are found infrequently (only in about 10% or less) in the stool. Neither peripheral eosinophilia nor elevated immunoglobulin E concentrations are typical because of low pinworm invasiveness and, if present, should not be attributed to pinworm infection.

TREATMENT: Several drugs will treat pinworms (see Drugs for Parasitic Infections, p 1068), including pyrantel pamoate, mebendazole, and albendazole. Pyrantel pamoate, available as an over-the-counter drug in the United States, is significantly less expensive than the prescription benzimidazole medications mebendazole and

albendazole. Albendazole currently is not approved by the US Food and Drug Administration for treatment of pinworms. Each medication has high potency against adult pinworms, but overall effectiveness of therapy depends on existing larval and egg burden in the child and reinfection from close contacts. Each medication (pyrantel pamoate or a benzimidazole) is recommended to be given in a single dose and repeated in 2 weeks, in order to treat nematodes developed from eggs or larvae during that period. For children younger than 2 years, in whom experience with these 3 drugs is limited and use is off-label, risks and benefits should be considered before drug administration. Ivermectin has been evaluated and is partially effective, but should not be used in children weighing less than 15 kg, because it blocks essential neural transmission if it crosses the blood-brain barrier and young children may be at higher risk of this adverse drug reaction. Because reinfection is common even when effective therapy is given, treatment of the entire household as a group should be considered. Repeated infections should be treated by the same method as the first infection. Vaginitis is self-limited and does not require separate treatment. “Pulse” treatment with a single dose of mebendazole every 14 days for a period of 16 weeks has been used in refractory cases with multiple recurrences. Alternative diagnoses in cases being attributed to recurrent pinworm infections can include *Dipylidium caninum*, which is characterized by proglottid segments being visible in the stool, and is definitively diagnosed by stool ova and parasite analysis and treated with praziquantel (see Other Tapeworm Infections [Including Hydatid Disease], p 845, and Table 4.11, p 1068), as well as, uncommonly, delusional parasitosis.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are indicated.

CONTROL MEASURES: Control is difficult in child care centers and schools, because the rate of reinfection is high. In institutions, mass and simultaneous treatment, repeated in 2 weeks, can be successful. Hygienic measures, such as bathing in the morning to remove eggs, frequent hand hygiene, and clipping of fingernails, all are helpful for decreasing the risk of autoinfection and continued transmission. Bed linens and underclothing of infected children should be handled carefully, should not be shaken (to avoid scattering eggs), and should be laundered promptly.

Pityriasis Versicolor (Formerly Tinea Versicolor)

CLINICAL MANIFESTATIONS: Pityriasis versicolor (formerly tinea versicolor) is a common and benign superficial infection of the skin, classically manifesting on the seborrheic (sebum-rich) areas of the upper trunk (chest, shoulders, upper arms) and neck. Most patients are asymptomatic, although some may complain of pruritus. In infants and children, the infection is likely to involve the face, particularly the temples. Infection can include other areas, including the scalp, genital area, and thighs. Symmetrical involvement with ovoid discrete or coalescent lesions of varying size is typical; these macules or patches vary in color, even in the same person. White, pink, tan, or brown coloration is often surmounted by faint dusty scales. Lesions fail to tan during the summer and are relatively darker than the surrounding skin during the winter, hence the term versicolor. The differential diagnosis includes pityriasis alba, vitiligo, seborrheic dermatitis, pityriasis rosea, pityriasis lichenoides, progressive

macular hypopigmentation, and dyschromatosis universalis hereditaria. Coexisting pityrosporum folliculitis also can occur, particularly in immunocompromised patients. More exuberant cases of pityriasis versicolor have been documented in the context of therapy with immunosuppressive systemic agents, including ixekizumab and immune checkpoint inhibitors for melanoma. Invasive infections can occur in neonates, particularly those receiving total parenteral nutrition with lipids.

ETIOLOGY: Pityriasis versicolor is caused by several species of the *Malassezia furfur* complex, a group of lipid-dependent yeasts that exist on healthy skin in yeast phase and causes clinical lesions only when substantial growth of hyphae occurs. Moisture, heat, and the presence of lipid-containing sebaceous secretions encourage rapid overgrowth of hyphae.

EPIDEMIOLOGY: Pityriasis versicolor can occur in any climate or age group but tends to favor adolescents and young adults. Living in hot and humid climates, sweating excessively, or a weakened immune system allows the fungus to flourish. Pityriasis versicolor is not contagious.

The **incubation period** is unknown.

DIAGNOSTIC TESTS: The presence of symmetrically distributed faintly scaling macules and patches of varying color concentrated on the upper back and chest is close to diagnostic. The “evoked scale” sign is when the clinician uses thumb and forefinger to stretch the skin, eliciting a visible white patch of scale overlying the affected area, which is still visible when the affected area is released. Another technique to evoke scales is scraping the involved skin with a scalpel blade or glass microscope slide, again yielding a pale and fuzzy scale that is confined to the lesion. Involved areas fluoresce yellow-green under Wood lamp evaluation. Potassium hydroxide wet mount prep of scraped scales reveals the classic “spaghetti and meatballs” short hyphae and clusters of yeast forms. Because this yeast is a common inhabitant of the skin, fungal culture from the skin surface is nondiagnostic. To grow the fungus in the laboratory, samples from pustules (if folliculitis is present) or sterile sites should be placed in media enriched with olive oil or another long-chain fatty acid.

TREATMENT: Multiple topical and systemic agents are efficacious, and recommendations vary substantially depending on expert opinion. For uncomplicated cases, most experts recommend initiating therapy with topical agents. The most cost-effective treatments are selenium sulfide shampoo/lotion and clotrimazole cream. Selenium sulfide shampoo is used for 3 to 7 days; application is once daily for 5 to 10 minutes, followed by rinsing. Topical azole therapy (eg, clotrimazole cream) is applied twice daily for 2 to 3 weeks. Adherence with these agents may be low because of unpleasant adverse effects (the shampoo has a sulfur-like odor) or duration and anatomic extent of required therapy. Other effective topical agents include ketoconazole and off-label bifonazole, miconazole, econazole, oxiconazole, terbinafine, and ciclopirox, as well as zinc pyrithione shampoo. Shampoos are easier to disperse, particularly on wet skin, than topical creams, and may increase compliance. One randomized controlled trial demonstrated that topical retinoids such as adapalene gel can produce clinical benefit either as monotherapy or in conjunction with topical ketoconazole cream when used twice daily for 4 weeks.

Treatment response is measured by resolution of scale and/or disappearance of “spaghetti and meatball” microscopic findings. Restoration of normal pigmentation may take months after successful treatment.

Recurrence following discontinuation of therapy may approach 60% to 80%, and preventive treatments sometimes are used to decrease recurrences. Off-label regimens to decrease recurrence include use of the aforementioned shampoos/lotions on a weekly or monthly basis.

Systemic therapy is reserved for resistant infection or extensive involvement. Medications, including fluconazole, itraconazole, and pramiconazole, are not approved by the US Food and Drug Administration (FDA) for pityriasis versicolor. Fluconazole (preferred) can be administered at 300 mg weekly for 2 to 4 weeks or itraconazole 200 mg daily for 1 week. Although oral agents may be easier to use than topical agents, they are not necessarily more effective and have possible serious adverse effects. Drug interactions can occur when using oral drugs, and monitoring for liver toxicity must be considered in patients receiving systemic therapy, particularly if they receive multiple courses. Although ketoconazole can treat pityriasis versicolor effectively, the FDA reaffirmed in 2016 that it strongly discourages use of systemic ketoconazole for uncomplicated skin and nail infections because of significant risks of liver toxicity, adrenal insufficiency, and interactions with multiple medications, which have resulted in at least 1 fatality. In several studies, topical therapy has appeared to be equivalent or superior to systemic therapy.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: The organism that causes pityriasis versicolor is commensal and resides on normal skin.

Plague

CLINICAL MANIFESTATIONS: Naturally acquired plague most commonly presents in the primary **bubonic form**, with fever and a painful swollen regional lymph node (bubo). Buboes develop most commonly in the inguinal region but also occur in axillary or cervical areas. Less commonly, plague manifests in the primary **septicemic form** without localizing signs (fever, hypotension, purpuric skin lesions, intravascular coagulopathy, organ failure) or as primary **pneumonic plague** (cough, fever, dyspnea, and hemoptysis) and rarely as **meningitic, pharyngeal, cutaneous, ocular, or gastrointestinal plague**. Occasionally, patients present with mild lymphadenitis or prominent gastrointestinal tract symptoms, which may obscure the correct diagnosis. Secondary pneumonic or other forms of plague can occur via hematogenous dissemination of bacteria. Untreated, plague often progresses to overwhelming sepsis and death. Plague was known as the Black Death in 14th century Europe because of the tissue necrosis that it induces.

ETIOLOGY: Plague is caused by *Yersinia pestis*, a pleomorphic, bipolar-staining (with Giemsa, Wright, and Wayson stains), facultative intracellular gram-negative coccobacillus. *Y. pestis* is a member of the *Enterobacterales* order, along with more common *Yersinia* species and other enteric bacteria.

EPIDEMIOLOGY: Plague is a zoonotic infection primarily maintained in rodents and their fleas. Humans are incidental hosts who develop bubonic or primary septicemic manifestations, typically through the bite of infected rodent fleas or through direct contact with tissues of infected animals. Primary pneumonic plague is acquired by inhalation of respiratory tract droplets from a human or animal with pneumonic

plague. Only the pneumonic form has been shown to be transmitted from person to person. Plague enzootic foci are found in parts of Asia, Africa, and the Americas. Most human plague cases are reported from rural, underdeveloped areas and mainly occur as isolated cases or in small, focal clusters. In the United States, plague is endemic in western states, with most cases reported from New Mexico, Colorado, Arizona, and California.¹ Cases of plague in states without endemic plague have been identified in travelers returning from these states.

Y. pestis has also been identified as a potential bioterrorism agent, particularly through widespread dispersal of an aerosolized form. Such an event would have potential for a large number of pneumonic plague cases. Contamination of food and water with *Y. pestis* would be expected to result in cases of pharyngeal or gastrointestinal plague, and release of infected fleas would be expected to produce a range of illness similar to naturally occurring plague, but with a higher number of cases.

The **incubation period** is 2 to 8 days for bubonic plague and 1 to 6 days for primary pneumonic plague.

DIAGNOSTIC TESTS: Diagnosis of plague usually is confirmed by culture of *Y. pestis* from blood, bubo aspirate, sputum, or another clinical specimen. The organism is slow growing but not fastidious and can be isolated on sheep blood agar with typical “fried-egg” colonies appearing after 48 to 72 hours of incubation. *Y. pestis* has a bipolar (safety-pin) appearance when stained with Wright-Giemsa or Wayson stains. Neither automated, commercially available biochemical identification systems nor matrix-assisted laser desorption/ionization–time-of-flight (MALDI-TOF) mass spectrometry are reliable for identification of *Y. pestis*, as they may misidentify the organism. Identification of suspected isolates of *Y. pestis* should be based on guidelines recommended for “sentinel level” clinical microbiology laboratories using preliminary characterization tests, followed by definitive identification performed at the state or federal public health laboratory. Nucleic acid amplification tests (NAATs) and immunohistochemical (IHC) staining for rapid diagnosis of *Y. pestis* are available in some reference and public health laboratories.

Presumptive laboratory evidence of plague includes detection of *Y. pestis* by NAAT or IHC from a clinical specimen or a positive serum antibody titer from a single specimen. Confirmatory laboratory evidence of plague includes isolation of the organism in culture with positive identification by *Y. pestis* bacteriophage lysis or seroconversion, defined as a fourfold or greater increase in serum antibody to the F1 antigen between paired specimens obtained 4 to 6 weeks apart.

Laboratory-acquired cases, including fatal cases, have been reported. Biosafety level 3 practices, containment equipment, and facilities are recommended for all manipulation of suspect cultures. Isolates suspected as *Y. pestis* should be reported immediately to the state health department.

TREATMENT: After obtaining diagnostic specimens, appropriate antibiotic therapy should be started immediately for any patient suspected of having plague. Pediatric treatment recommendations² are as follows (see also Table 3.48):

¹ Kwit N, Nelson C, Kugeler K, et al. Human plague—United States, 2015. *MMWR Morb Mortal Wkly Rep.* 2015;64(33):918-919

² Nelson CA, Meaney-Delman D, Fleck-Derderian S, Cooley KM, Yu PA, Mead PS. Antimicrobial treatment and prophylaxis of plague: recommendations for naturally acquired infections and bioterrorism response. *MMWR Morb Mortal Wkly Rep.* 2021;70(3):1-27

Table 3.48. Antimicrobial Dosing for Treatment of Plague in Children and Neonates^a

Drug	Dosage per kg per Day
Ciprofloxacin ^b	20–30 mg/kg, divided in 2 or 3 doses IV (maximum 400 mg/dose IV) 30–45 mg/kg, divided in 2 or 3 doses PO (maximum 500 mg/dose TID or 750 mg/dose BID) Neonates 20–30 mg/kg, divided in 2 or 3 doses IV
Levofloxacin ^b	<50 kg: 16 mg/kg, divided in 2 doses IV/PO (maximum 250 mg/dose) ≥50 kg: 500–750 mg once daily IV/PO Neonates 20 mg/kg, divided in 2 doses IV
Gentamicin ^c	4.5–7.5 mg/kg once daily IV/IM Neonates ≤7 days: 4 mg/kg once daily IV/IM 8–28 days: 5 mg/kg once daily IV/IM
Streptomycin ^d	30 mg/kg, divided in 2 doses IV/IM (maximum dose 1 g/dose) Neonates 30 mg/kg, divided in 2 doses IV/IM
Doxycycline ^b	<45 kg: 4.4 mg/kg load, then 4.4 mg/kg, divided in 2 doses IV/PO ≥45 kg: 200 mg load, then 200 mg divided in 2 doses IV/PO Neonates 4.4 mg/kg load, then 4.4 mg/kg, divided in 2 doses IV
Chloramphenicol ^{c,e}	50–100 mg/kg, divided in 4 doses IV (maximum 1 g/dose) Meningitis ≥29 days to ≥17 years: 100 mg/kg, divided in 4 doses IV (maximum 1 g/dose) Neonates: Meningitis 8–28 days: 50 mg/kg, divided in 2 doses IV ≤7 days: 25 mg/kg once daily IV All other forms ≤14 days: 25 mg/kg, divided in 4 doses IV/IM 15–28 days: 50 mg/kg, divided into 4 doses IV/IM
Moxifloxacin ^b	≥3 months to ≤23 months: 12 mg/kg, divided in 2 doses IV/PO 2 to 5 years: 10 mg/kg, divided in 2 doses IV/PO 6 to 11 years: 8 mg/kg, divided in 2 doses IV/PO 12 to ≤17 years, <45 kg: 8 mg/kg, divided in 2 doses IV/PO (maximum 200 mg/dose) 12 to ≤17 years, ≥45 kg: 400 mg once daily IV/PO

BID indicates twice per day; IM, intramuscular; IV, intravenous; PO, oral; TID, three times per day.

All dosages are applicable for all forms of disease, except for chloramphenicol, which is dosed as above.

^aAdapted from Nelson CA, Meaney-Delman D, Fleck-Dearden S, Cooley KM, Yu PA, Mead PS. Antimicrobial treatment and prophylaxis of plague: recommendations for naturally acquired infections and bioterrorism response. *MMWR Morb Mortal Wkly Rep.* 2021;70(3):1–27.

^bData on use in neonates are extremely limited.

^cNot currently approved by the Food and Drug Administration (FDA) for the treatment of plague.

^dThe intramuscular formulation of streptomycin has been given intravenously in an off label use (the intravenous formulation is not approved by FDA).

^eChloramphenicol is generally contraindicated for infants aged <6 months because of the risk for serious blood dyscrasias or circulatory collapse (gray baby syndrome), because of the severity of meningitis, it is still a treatment option. Levofloxacin can be used for treatment of plague meningitis in neonates and older children and moxifloxacin for plague meningitis for infants ≥3 months of age. After clinical improvement, chloramphenicol can be reduced to a lower dose of 12.5 mg/kg every 6 hours in adults and administered orally. Serum concentration monitoring should be performed when available, especially in children. Chloramphenicol is not considered a first-line drug for nonmeningitis forms of plague; rather, it is considered an alternative drug.

- Monotherapy with gentamicin, streptomycin, ciprofloxacin, or levofloxacin is recommended for naturally acquired primary bubonic or pharyngeal plague without signs of sepsis or secondary pneumonic plague and for early/mild primary pneumonic or septicemic plague.
- Doxycycline is a first-line option for treatment of naturally acquired bubonic or pharyngeal plague but is an alternative antibiotic for naturally acquired pneumonic plague.
- Dual therapy with 2 distinct antibiotic classes is recommended for initial treatment of patients with naturally acquired severe septicemic or pneumonic plague, or for infection following intentional release of *Y. pestis* (eg, acts of bioterrorism). Dual therapy can be considered for patients with naturally acquired primary bubonic disease with large buboes. The recommended drugs are those listed in the first bullet.
- Alternative antibiotics for pneumonic, septicemic, bubonic, or pharyngeal plague are listed in the Centers for Disease Control and Prevention (CDC) plague guidance.
- Dual therapy with 2 distinct antibiotic classes is recommended for initial treatment of patients who present with signs of meningitis or who are later found to have meningitis. The recommended antibiotics are chloramphenicol in combination with moxifloxacin or levofloxacin. If chloramphenicol is unavailable, a first-line or alternative nonfluoroquinolone antibiotic for the treatment of primary pneumonic or septicemic plague should be substituted as part of a dual class regimen that includes moxifloxacin or levofloxacin.
- Because of the potential for engineered antimicrobial resistance, if bioterrorism is suspected, dual therapy with 2 distinct classes of antibiotics should be used for all patients until susceptibility patterns are known.

A neonate born to a person infected with plague at or around the time of delivery should be treated if the infant is symptomatic, using the antibiotic regimens described (levofloxacin may be considered rather than chloramphenicol in the case of meningitis because of the toxicity of chloramphenicol in neonates; consultation with an expert in pediatric infectious diseases is recommended). An asymptomatic neonate born to a person infected with *Y. pestis* within 7 days of delivery should receive antimicrobial prophylaxis (see Care of Exposed People) if the birthing person is untreated or has only recently begun treatment (<48 hours before delivery). If the neonate is asymptomatic and the birthing person has been sufficiently treated and is improving, observation of the infant is acceptable.

The duration of antibiotic treatment for all forms of plague, including meningitis, is 10 to 14 days; treatment duration can be extended for patients with ongoing fever or other concerning signs or symptoms. Drainage of abscessed buboes may be necessary; drainage material is considered infectious.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

For patients with bubonic or septicemic plague, standard precautions are recommended. If aspiration of a bubo or another procedure that may generate sprays or splashes is performed, contact and droplet precautions should be used; health care personnel should wear appropriate personal protective equipment including a mask, eye protection (such as goggles or face shield), gown, and gloves. For patients with suspected pneumonic plague, respiratory droplet precautions in addition to standard precautions should be initiated immediately and continued for 48 hours after initiation of effective antibiotic treatment and until clinical improvement with decreased sputum production is documented.

CONTROL MEASURES:

Care of Exposed People. All people with exposure to a known or suspected source of plague, such as *Y. pestis*-infected fleas or infectious tissues, in the previous 6 days, should be offered antibiotic prophylaxis or be cautioned to report fever greater than 38.3°C (101.0°F) or other illness to their physician. Postexposure prophylaxis is recommended for people with close and sustained exposure (less than 2 meters) to a patient with pneumonic plague, who were not wearing adequate personal protective equipment (per standard and droplet precautions). Pneumonic transmission typically occurs in the later stages of disease in patients with hemoptysis, thereby placing caregivers and health care professionals at higher risk. Isolation of exposed, asymptomatic people is not recommended. For children, including those younger than 8 years, doxycycline, levofloxacin, or ciprofloxacin is recommended. The benefits of prophylactic therapy should be weighed against the risks. Prophylaxis is administered for 7 days (see Table 3.49). In the case of an intentional release of *Y. pestis*, postexposure prophylaxis should be started rapidly for exposed persons; specific recommendations regarding appropriate antibiotics will be issued by the public health authority. Recommendations will be guided by what is known about the strain. For further discussion, including alternative agents, see www.cdc.gov/mmwr/volumes/70/rr/rr7003a1.htm.

Breastfeeding. There are no reports of suspected *Y. pestis* transmission from human milk, and the risk is believed to be low. Breastfeeding parents with bubonic or septicemic plague and those taking antibiotic prophylaxis after exposure to *Y. pestis* can continue to breastfeed their infants. A breastfeeding parent with pneumonic plague may continue to breastfeed if receiving antibiotic treatment and the infant is receiving antibiotic treatment or postexposure prophylaxis for *Y. pestis*. Because of the risk of person-to-person transmission of pneumonic plague, a parent with primary or secondary pneumonic plague whose infant is not receiving antibiotic treatment or prophylaxis should avoid direct breastfeeding until the parent has received antibiotic treatment for ≥48 hours and demonstrated clinical improvement. The parent's expressed milk may be fed to the infant. The CDC has guidance about breastfeeding and drugs or metabolites

Table 3.49. Antimicrobial Dosing for Postexposure Prophylaxis for Plague in Neonates and Children^a

Drug	Dosage per kg per Day
Ciprofloxacin ^b	30 mg/kg, divided in 2 doses PO (maximum 750 mg/dose) Neonates 30 mg/kg, divided in 2 doses PO
Levofloxacin ^b	<50 kg: 16 mg/kg, divided in 2 doses PO (maximum 250 mg/dose) ≥50 kg: 500–750 mg once daily PO Neonates 20 mg/kg, divided in 2 doses PO
Doxycycline ^b	<45 kg: 4.4 mg/kg, divided in 2 doses PO ≥45 kg: 200 mg divided in 2 doses PO Neonates 4.4 mg/kg, divided in 2 doses PO

PO indicates oral.

^aAdapted from Nelson CA, Meaney-Delman D, Fleck-Derderian S, Cooley KM, Yu PA, Mead PS. Antimicrobial treatment and prophylaxis of plague: recommendations for naturally acquired infections and bioterrorism response. *MMWR Morb Mortal Wkly Rep.* 2021;70(3):1-27.

^bData on use in neonates are extremely limited.

present in human milk, potential consequences to infants, and specific recommendations regarding antibiotics.¹

Other Measures. People living in areas with endemic plague should be informed about the importance of eliminating sources of rodent food and harborage near residences, the role of dogs and cats in bringing plague-infected rodent fleas into peridomestic environments, the need for flea control and confinement of pets, and the importance of avoiding contact with sick and dead animals. Other preventive measures include surveillance of rodent populations and use of rodent control measures and insecticides by health authorities when surveillance indicates the occurrence of plague epizootics. For additional information on laboratory safety, see the CDC *Biosafety in Microbiological and Biomedical Laboratories* manual (www.cdc.gov/labs/pdf/SF_19_308133-A_BMBL6_00-BOOK-WEB-final-3.pdf).

Vaccine. There is no vaccine currently licensed for use in the United States. New vaccines based on recombinant capsular subunit protein F1 and the low-calcium response V antigen (LcrV) are under evaluation.

Public Health Reporting. Infection with *Y pestis* is nationally reportable. In the United States, *Y pestis* is classified as a select agent, and the possession and transport of the organism requires adherence to strict federal guidelines. State public health authorities should be notified immediately of any suspected cases of human plague.

***Pneumocystis jirovecii* Infections**

CLINICAL MANIFESTATIONS: Symptomatic infection with *Pneumocystis jirovecii* is extremely rare in healthy people. However, in immunocompromised infants and children, *P jirovecii* can cause a respiratory illness characterized by dyspnea, tachypnea, significant hypoxemia, nonproductive cough, chills, fatigue, and fever. The intensity of these signs and symptoms may vary, and in some immunocompromised children and adults, the onset may be acute and fulminant. Most children with *Pneumocystis* pneumonia are significantly hypoxic. Chest radiographs often show bilateral diffuse interstitial or alveolar disease but may appear normal in early disease. Atypical radiographic findings may include lobar, miliary, cavitary, and nodular lesions. The mortality rate in immunocompromised patients ranges from 5% to 40% in treated patients and approaches 100% without therapy.

Extrapulmonary *Pneumocystis* organisms, often associated with a localized inflammatory reaction, are found in <2.5% of adults and children living with human immunodeficiency virus (HIV). This can occur without concurrent *Pneumocystis* pneumonia and can be located at multiple noncontiguous sites. Involved sites have included the ear, eye, thyroid, spleen, gastrointestinal tract, peritoneum, stomach, duodenum, small intestine, transverse colon, liver, and pancreas. Less frequently involved sites include the adrenal glands, muscle, bone marrow, heart, kidney, ureter, lymph nodes, meninges, and cerebral cortex.

ETIOLOGY: Nomenclature for *Pneumocystis* species has evolved. Human *Pneumocystis* is called *Pneumocystis jirovecii*, although the familiar acronym PCP (originally *Pneumocystis*

¹ Nelson CA, Meaney-Delman D, Fleck-Derderian S, Cooley KM, Yu PA, Mead PS. Antimicrobial treatment and prophylaxis of plague: recommendations for naturally acquired infections and bioterrorism response. *MMWR Morb Mortal Wkly Rep*. 2021;70(3):1-27

carinii pneumonia) still is used commonly among clinicians. *P. jirovecii* is an atypical fungus (based on DNA sequence analysis) with several morphologic and biologic similarities to protozoa, including susceptibility to a number of antiprotozoal agents but resistance to most antifungal agents. In addition, the organism exists as 2 distinct morphologic forms: the 5- to 7- μ m-diameter cysts, which contain up to 8 intracystic bodies or sporozoites, and the smaller, 1- to 5- μ m-diameter trophozoite or trophic form.

EPIDEMIOLOGY: *Pneumocystis* species are ubiquitous in mammals worldwide and have a tropism for respiratory tract epithelium. Asymptomatic or mild human infection occurs early in life, with more than 85% of healthy children showing seropositivity by 20 months of age. Animal models and studies of patients with acquired immunodeficiency syndrome (AIDS) do not support the existence of latency and suggest that disease after the second year of life is likely reinfection.

The single most important factor in susceptibility to PCP is the status of cell-mediated immunity of the host, reflected by a marked decrease in percentage and numbers of CD4+ T-lymphocytes or a decrease in CD4+ T-lymphocyte function. In resource-limited countries and in times of famine, *Pneumocystis* pneumonia can occur in epidemics, primarily affecting malnourished infants and children. In industrialized countries, PCP occurs almost entirely in immunocompromised people with deficient cell-mediated immunity, particularly people with HIV infection, recipients of immunosuppressive therapy after solid organ and hematopoietic cell transplantation, people undergoing treatment for hematologic malignancy, and children with primary immunodeficiency syndromes. Although onset of disease can occur at any age, PCP most commonly occurs in children living with HIV in the first year of life, with peak incidence at 3 through 6 months of age. In patients with cancer, the disease can occur during remission or relapse of the malignancy.

The incidence of PCP has dramatically decreased in the United States as a result of antiretroviral therapy for people living with HIV and the general adoption of recommendations for prophylaxis. Despite this decrease, it is still one of the leading opportunistic infections among people living with HIV, particularly those not aware of their infection or not receiving antiretroviral therapy or who are not adherent with their indicated PCP prophylaxis.

Animal studies have demonstrated animal-to-animal transmission by the airborne route; human-to-human transmission has been suggested by molecular epidemiology and global clustering of PCP cases in several studies. Outbreaks in hospitals have been reported. Vertical transmission has been postulated but never proven. The period of communicability is unknown.

The **incubation period** is unknown, but outbreaks of PCP in transplant recipients have demonstrated a median of 53 days from exposure to clinically apparent infection.

DIAGNOSTIC TESTS: A definitive diagnosis of PCP is made by microscopic visualization of organisms (*Pneumocystis* cysts) in lung tissue or respiratory tract secretion specimens. Bronchoscopy with bronchoalveolar lavage (BAL) is the diagnostic procedure of choice for most infants and children. Methenamine silver stain, toluidine blue stain, and fluorescently conjugated monoclonal antibody are useful tools for identifying the thick-walled cysts of *P. jirovecii*. Sporozoites (within cysts) and trophozoites are identified with Giemsa or modified Wright-Giemsa stain. A cyst wall, trophozoite, and

immunofluorescent antibody stain is recommended for each specimen studied. The sensitivity of all microscopy-based methods depends on the skill of the laboratory technician and the quality of the specimen.

Nucleic acid amplification tests (NAATs) to diagnose PCP are becoming more widely available. They are highly sensitive with a variety of specimen types from the respiratory tract, including nasopharyngeal aspirates. However, there are currently no US Food and Drug Administration (FDA)-cleared NAATs for *P. jirovecii*. Because highly sensitive NAATs may detect colonization with these organisms, results from such assays must be interpreted in the context of clinical presentation.

Limited data suggest that serum 1,3- β -D-glucan (BG) assay, which is available as an FDA-cleared test in the United States for invasive fungal infections, may be a potential marker for *Pneumocystis* infection. This compound is a component of the cell wall of the cyst stage of the organism and may be found in high concentrations in serum of patients infected with *P. jirovecii*; however, most other fungi also secrete the compound during infection, so correlation with clinical presentation is imperative.

TREATMENT¹: The drug of choice is trimethoprim-sulfamethoxazole (TMP-SMX), usually administered intravenously. Oral therapy should be reserved for patients with mild disease who do not have malabsorption or diarrhea and for patients with a favorable clinical response to initial intravenous therapy. See Table 4.3 (p 993) for dosages. Duration of therapy is 21 days. The rate of adverse reactions to TMP-SMX (eg, rash, neutropenia, anemia, thrombocytopenia, renal toxicity, hepatitis, nausea, vomiting, and diarrhea) is higher in children living with HIV than in patients without HIV. It is not necessary to discontinue therapy for mild adverse reactions (eg, vomiting). At least half of patients with more severe reactions that include rash require interruption of therapy. Desensitization to TMP-SMX may be considered after the acute reaction has abated.

Pentamidine, administered intravenously, is an alternative drug for treatment of *Pneumocystis* infection in children and adults who cannot tolerate TMP-SMX or who have severe disease and have not responded to TMP-SMX after 5 to 7 days of therapy. The therapeutic efficacy of intravenous pentamidine in adults with PCP is similar to that of TMP-SMX. Pentamidine is associated with a high incidence of adverse reactions, including renal toxicity, pancreatitis, diabetes mellitus, electrolyte abnormalities, hypoglycemia, hyperglycemia, hypotension, cardiac arrhythmias, fever, and neutropenia. Aerosolized pentamidine should not be used for treatment, because its efficacy is limited.

Atovaquone is approved for oral treatment of mild to moderate PCP in adults who are intolerant of TMP-SMX. Experience with use of atovaquone in children is limited, although a study comparing the efficacy of bacterial prophylaxis of atovaquone-azithromycin versus TMP-SMX noted that prevention of PCP was equivalent between the 2 drug regimens. Adverse reactions to atovaquone are limited to rash, nausea, and diarrhea.

Other potentially useful drugs for mild to moderate PCP in adults include clindamycin with primaquine (adverse reactions are rash, nausea, and diarrhea), dapsone with trimethoprim (associated with neutropenia, anemia, thrombocytopenia,

¹ Panel on Opportunistic Infections in Children with and Exposed to HIV. Guidelines for the Prevention and Treatment of Opportunistic Infections in Children with and Exposed to HIV. Department of Health and Human Services. Available at: <https://clinicalinfo.hiv.gov/en/guidelines/pediatric-opportunistic-infection>

Table 3.50. Dosing of Oral Prednisone in the Treatment of *Pneumocystis pneumonia*^{a,b}

Age	Days 1–5	Days 6–10	Days 11–21
<13 y	1 mg/kg/dose, twice daily	0.5 mg/kg/dose, twice daily	0.5 mg/kg/dose daily
≥13 y	40 mg, twice daily	40 mg daily	20 mg daily

^aThe maximum doses should not exceed the dose for children older than 13 years.

^bFor those unable to take oral therapy, intravenous methylprednisolone can be administered as follows: 1 mg/kg/dose every 6 hours on days 1 through 7; 1 mg/kg/dose twice daily on days 8 through 9; 0.5 mg/kg/dose twice daily on days 10 and 11; and 1 mg/kg/dose once daily on days 12–16.

methemoglobinemia, rash, and aminotransferase elevation), and trimetrexate with leucovorin. Experience with the use of these combinations in children is limited.

On the basis of studies in both adults and children, a course of corticosteroids is recommended in patients with moderate to severe PCP (as defined by an arterial oxygen pressure [PaO₂] of less than 70 mm Hg in room air or an arterial-alveolar gradient ≥35 mm Hg), starting within 72 hours of diagnosis. The recommended scheduled dosing of oral prednisone during treatment is presented in Table 3.50.

Coinfection with other organisms, such as cytomegalovirus, histoplasmosis, or *Streptococcus pneumoniae*, has been reported in children living with HIV. Children with dual infections may have more severe disease.

Chemoprophylaxis. Chemoprophylaxis is highly effective in preventing PCP among high-risk groups. Prophylaxis against a first episode of PCP is indicated for many patients with significant immunosuppression, including people living with HIV (see Table 3.51 and Human Immunodeficiency Virus Infection, p 489) and people with primary or acquired cell-mediated immunodeficiency.

The recommended drug regimen for PCP prophylaxis for all immunocompromised patients is TMP-SMX. Acceptable dosing intervals and schedules are presented in Table 3.52. For patients who cannot tolerate TMP-SMX, alternative oral choices include atovaquone or dapsone. Atovaquone is effective and safe but expensive. Dapsone is effective and inexpensive but associated with more serious adverse effects than atovaquone. Aerosolized pentamidine is recommended for children who cannot tolerate TMP-SMX, atovaquone, or dapsone and are old enough to use a Respigard II nebulizer. Intravenous pentamidine has been used but is not recommended for prophylaxis unless no other options are available. Another drug combinations with potential for prophylaxis is pyrimethamine-sulfadoxine, although experience in children for this indication is limited.

In children living with HIV, risk of PCP is associated with age-specific CD4+ T-lymphocyte cell counts and percentages that define severe immunosuppression (Immune Category 3). Because CD4+ T-lymphocyte counts and percentages can decline rapidly in infants with HIV, prophylaxis for PCP is recommended for all infants born to a person living with HIV in resource-limited settings beginning at 4 to 6 weeks of age and continuing until 12 months of age unless a diagnosis of HIV has been excluded presumptively or definitively, in which case prophylaxis should be discontinued (see Table 3.52). Children who are HIV infected or whose HIV status is indeterminate should continue prophylaxis throughout the first year of life. In the United

Table 3.51. Recommendations for *Pneumocystis jirovecii* Pneumonia (PCP) Prophylaxis for Human Immunodeficiency Virus (HIV)-Exposed Infants and Children, by Age and HIV Infection Status^a

Age and HIV Infection Status	Initiation of PCP prophylaxis ^b	Discontinuation of PCP prophylaxis ^b
Birth through 4 to 6 wk of age, HIV exposed or HIV infected	No prophylaxis	Not applicable
4 to 6 wk through 12 mo of age		
HIV infected or indeterminate	Prophylaxis	Administer throughout first year of life
HIV infection presumptively or definitively excluded ^c	No prophylaxis	Not applicable
1 through 5 y of age, HIV infected	Prophylaxis if: CD4+ T-lymphocyte count is less than 500 cells/ μ L or percentage is less than 15% ^d	Discontinue if antiretroviral therapy (ART) administered for >6 months, and the following have been sustained for >3 consecutive months: CD4+ T-lymphocyte count 500 cells/ μ L or greater or percentage is 15% or greater
6 y of age or older, HIV infected	Prophylaxis if: CD4+ T-lymphocyte count is less than 200 cells/ μ L or percentage is less than 15% ^d	Discontinue if ART administered for >6 months, and the following have been sustained for >3 consecutive months: CD4+ T-lymphocyte count 200 cells/ μ L or greater or percentage is 15% or greater

^aPanel on Opportunistic Infections in Children with and Exposed to HIV. Guidelines for the Prevention and Treatment of Opportunistic Infections in Children with and Exposed to HIV. Department of Health and Human Services. Available at: <https://clinicalinfo.hiv.gov/en/guidelines/pediatric-opportunistic-infection>

^bChildren who have had PCP should receive lifelong (“secondary”) PCP prophylaxis unless/until they have been on ART for at least 6 months and their CD4+ T-lymphocyte cell counts and percentages achieve and maintain designated age-specific values greater than those indicative of severe immunosuppression (Immune Category 3) for at least 3 months (see Human Immunodeficiency Virus Infection, p 489).

^cSee Human Immunodeficiency Virus Infection, p 489.

^dProphylaxis should be considered on a case-by-case basis for children who might otherwise be at risk of PCP, such as children with rapidly declining CD4+ T-lymphocyte counts or percentages.

Table 3.52. Drug Regimens for *Pneumocystis jirovecii* Pneumonia Prophylaxis for Children 4 Weeks and Older^a

Recommended daily dose:

Trimethoprim-sulfamethoxazole (trimethoprim, 5–10 mg/kg per day; and sulfamethoxazole, 25–50 mg/kg per day, orally). The total daily dose should not exceed 320 mg TMP and 1600 mg SMX.

Acceptable dosing intervals and schedules:

- In divided doses twice daily, given 3 days per week on consecutive days or on alternate days
- In divided doses twice daily, given 2 days per week on consecutive days or on alternate days
- Total dose once daily, given 7 days per week

Alternative regimens if trimethoprim-sulfamethoxazole is not tolerated:

• **Atovaquone**

- **children 1 through 3 mo of age and older than 24 mo through 12 y of age:**

30 mg/kg (maximum 1500 mg), orally, once a day

- **children 4 through 24 mo of age:** 45 mg/kg (maximum 1500 mg), orally, once a day

- **children older than 12 y:** 1500 mg, orally, once a day

• **Dapsone (children 1 mo or older)**

2 mg/kg (maximum 100 mg), orally, once a day or 4 mg/kg (maximum 200 mg), orally, every week

• **Aerosolized pentamidine (children 5 y or older)**

300 mg, inhaled monthly via Respigard II nebulizer

^aPanel on Opportunistic Infections in Children with and Exposed to HIV. Guidelines for the Prevention and Treatment of Opportunistic Infections in Children with and Exposed to HIV. Department of Health and Human Services. Available at: <https://clinicalinfo.hiv.gov/en/guidelines/pediatric-opportunistic-infection>

States, in HIV-exposed infants who are deemed low risk for HIV seroconversion, PCP prophylaxis is not indicated unless there is evidence of HIV transmission in the infant.

For children with HIV ages 12 months or older, initiation and discontinuation of PCP prophylaxis is detailed in Table 3.51. In patients with AIDS who had PCP, prophylaxis should be initiated at the end of therapy for acute infection. In most cases, secondary prophylaxis can be discontinued using the same criteria as for primary prophylaxis (see Table 3.51). Prophylaxis should be continued at least through 12 months of life for infants with HIV, or lifelong if CD4+ T-lymphocyte counts or percentages do not exceed the thresholds shown in Table 3.51 in response to antiretroviral therapy.

Prophylaxis for PCP is recommended for children who have received hematopoietic cell transplants (HCTs)¹ or solid organ transplants; children with hematologic malignancies (eg, leukemia or lymphoma) and some nonhematologic malignancies; children with severe cell-mediated immunodeficiency, including children who received adrenocorticotrophic hormone for treatment of infantile spasms; and children who otherwise are immunocompromised and who have had a previous episode of PCP. For this diverse group of immunocompromised hosts, the risk of PCP varies with duration and

¹ Center for International Blood and Marrow Research; National Marrow Donor program; European Blood and Marrow Transplant Group; American Society of Blood and Marrow Transplantation; Canadian Blood and Marrow Transplant Group; Infectious Diseases Society of America; Society for Healthcare Epidemiology of America; Association of Medical Microbiology and Infectious Disease Canada; Centers for Disease Control and Prevention. Guidelines for preventing infectious complications among hematopoietic cell transplant recipients: a global perspective. *Biol Blood Marrow Transplant*. 2009;15(10):1143-1238

intensity of chemotherapy, with other immunosuppressive therapies, with coinfection with immunosuppressive viruses (eg, cytomegalovirus), and local epidemiologic rates of PCP. Guidelines for allogeneic HCT recipients recommend that PCP prophylaxis be initiated at engraftment (or before engraftment, if engraftment is delayed) and administered for at least 6 months in autologous HCT recipients and for at least 1 year in allogeneic transplant recipients, especially matched unrelated or haploidentical transplants who may receive in vivo T-lymphocyte depletion with antithymocyte globulin (ATG) or with Campath (alemtuzumab). Prophylaxis should be continued in all children receiving ongoing or intensified immunosuppressive therapy (eg, prednisone or cyclosporine) or in children with chronic graft-versus-host disease. Guidelines for PCP prophylaxis for solid organ transplant recipients are less definitive. In general, PCP prophylaxis is recommended for all solid organ transplant recipients for at least 6 to 12 months post-transplant, although longer durations should be considered. For lung and small bowel transplant recipients, as well as any transplant patient with a history of prior PCP infection or chronic cytomegalovirus disease, lifelong prophylaxis may be indicated.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended. Some experts recommend that because of the theoretical risk for airborne transmission, patients with PCP should not share a room with other immunocompromised patients, especially patients who are not receiving PCP prophylaxis. Data are insufficient to support this recommendation as standard practice.

CONTROL MEASURES: Appropriate therapy for infected patients and prophylaxis in immunocompromised patients are the only available means of control. Detailed guidelines for children, adolescents, and adults with HIV have been issued by the Department of Health and Human Services.^{1,2}

Poliovirus Infections

CLINICAL MANIFESTATIONS: Approximately 70% of poliovirus infections in susceptible children are asymptomatic. Nonspecific illness with low-grade fever and sore throat (minor illness) occurs in approximately 25% of infected people, and viral meningitis (nonparalytic polio), sometimes accompanied by paresthesias, occurs in 1% to 5% of patients a few days after the minor illness has resolved. Rapid onset of asymmetric acute flaccid paralysis with areflexia of the involved limb (paralytic poliomyelitis) occurs in fewer than 1% of infections, with residual paresis in approximately two thirds of patients. Classical paralytic polio begins with a minor illness characterized by fever, sore throat, headache, nausea, constipation, and/or malaise for several days, followed by a symptom-free period of 1 to 3 days. Rapid onset of paralysis then follows.

¹ Panel on Opportunistic Infections in Children with and Exposed to HIV. Guidelines for the Prevention and Treatment of Opportunistic Infections in Children with and Exposed to HIV. Department of Health and Human Services. Available at: <https://clinicalinfo.hiv.gov/en/guidelines/pediatric-opportunistic-infection>

² Panel on Guidelines for the Prevention and Treatment of Opportunistic Infections in Adults and Adolescents with HIV. Guidelines for the Prevention and Treatment of Opportunistic Infections in Adults and Adolescents with HIV. National Institutes of Health, Centers for Disease Control and Prevention, HIV Medicine Association, and Infectious Diseases Society of America. Available at: <https://clinicalinfo.hiv.gov/en/guidelines/adult-andadolescent-opportunistic-infection>

Typically, paralysis is asymmetric and affects the proximal muscles more than the distal muscles. Cranial nerve involvement (bulbar poliomyelitis) and paralysis of the diaphragm and intercostal muscles may lead to impaired respiration requiring assisted ventilation. Sensation usually is intact. The cerebrospinal fluid (CSF) profile is characteristic of viral meningitis, with mild pleocytosis and lymphocytic predominance.

Adults who contracted paralytic poliomyelitis during childhood may develop the noninfectious post-polio syndrome 15 to 40 years later, characterized by slow and irreversible exacerbation of weakness in the muscle groups affected during the original infection. Muscle and joint pain also are common manifestations. The estimated incidence of post-polio syndrome in poliomyelitis survivors is 25% to 40%.

ETIOLOGY: Polioviruses are classified as members of the family *Picornaviridae*, genus *Enterovirus*, in the species enterovirus C, and include 3 serotypes. They are nonenveloped, positive-sense, single-stranded RNA viruses that are stable in moderate environmental conditions. Acute paralytic disease may be caused by naturally occurring (wild) polioviruses (WPVs) or by circulating vaccine-derived polioviruses (cVDPVs) that have acquired virulence properties that are indistinguishable from WPVs as a result of sustained person-to-person transmission in the absence of adequate population immunity. Rarely, oral poliovirus vaccine (OPV) viruses may cause vaccine-associated paralytic poliomyelitis (VAPP) in vaccine recipients or their close contacts. People with primary (but not acquired) B-lymphocyte immunodeficiencies are at increased risk both of VAPP and of persistent infection (immunodeficiency-associated vaccine-derived polioviruses, or iVDPVs) from vaccine virus.

EPIDEMIOLOGY: Humans are the only natural reservoir for poliovirus. Spread is by contact with feces and/or respiratory secretions. Infection is more common in infants and young children and occurs at an earlier age among children living in poor hygienic conditions. In temperate climates, poliovirus infections are most common during summer and autumn; in the tropics, the seasonal pattern is less pronounced. With continuing progress toward global polio eradication, more cases of paralytic disease are now caused by cVDPVs than by wild polioviruses.

The last cases of poliomyelitis attributable to indigenously acquired WPVs in the United States were reported in 1979. Subsequently, there have been rare, imported cases and rare cases of VAPP (6–8 people annually) prior to the shift in US immunization policy in 1997 from use of OPV to a sequential inactivated (non-live) poliovirus (IPV) vaccine/OPV schedule. Implementation of an all-IPV vaccine schedule in 2000 halted the occurrence of VAPP cases in the United States. In 2011, a case of iVDPV serotype 2 (iVDPV2) was reported in a patient with common variable immunodeficiency who was chronically infected for about 12 years. In 2022, a case of poliomyelitis attributable to cVDPV serotype 2 (cVDPV2) occurred in an unvaccinated young adult who was part of an undervaccinated community.¹ Strong efforts to increase vaccination in undervaccinated communities are essential to prevent cases of poliomyelitis, even in the United States.

WPV serotype 2 (WPV2) and WPV serotype 3 (WPV3) were declared eradicated by the World Health Organization (WHO) in 2015 and 2019, respectively; the last

¹ Link-Gelles R, Lutterloh E, Schnabel Ruppert P, et al. Public health response to a case of paralytic poliomyelitis in an unvaccinated person and detection of poliovirus in wastewater—New York, June–August 2022. *MMWR Morb Mortal Wkly Rep.* 2022;71(33):1065–1068

WPV2 poliomyelitis case was detected in 1999 in India, and the last WPV3 poliomyelitis case occurred in Nigeria in 2012. WPV serotype 1 (WPV1) now accounts for all cases attributable to wild poliovirus. WPV1 remains endemic in Afghanistan and Pakistan, and in 2022, there was importation of WPV1 into Malawi and Mozambique.

Because the only source of disease from serotype 2 poliovirus was related to vaccine use, there was a global switch from trivalent OPV (tOPV) to bivalent OPV (bOPV) in April 2016, thus ending all routine immunization with live serotype 2 poliovirus-containing oral vaccines. Concurrent recommendations were made for all countries to provide at least 1 dose of IPV to all vaccinees. Following this vaccine change, the remaining risk of serotype 2 infection comes from continued transmission of serotype 2 OPV viruses administered before the switch, ongoing cVDPV outbreaks, long-term iVDPV2 excretors, and breach of containment at facilities maintaining serotype 2 polioviruses. Containment of infectious and potentially infectious materials containing polioviruses by destroying the materials or transferring material to accredited polio essential facilities is an important part of the strategy for global polio eradication. The National Authority for the Containment of Polio at the Centers for Disease Control and Prevention (CDC) is responsible for containment activities in the United States (www.cdc.gov/orr/polioviruscontainment/index.htm).

Communicability of poliovirus is greatest shortly before and after onset of clinical illness, when the virus is present in the throat and excreted in high concentrations in feces. Virus persists in the throat for approximately 1 to 2 weeks after onset of illness and is excreted in feces for an average of 3 to 6 weeks. In recipients of OPV, virus also persists in the throat for 1 to 2 weeks and is excreted in feces for several weeks, although in rare cases, excretion for more than 2 months can occur. Immunocompromised patients with significant primary B-lymphocyte immune deficiencies have excreted iVDPV for periods of more than 30 years.

The **incubation period of nonparalytic polio** is 3 to 6 days. For the onset of poliomyelitis, the **incubation period to paralysis** usually is 7 to 21 days (range, 3–35 days).

DIAGNOSTIC TESTS: Poliovirus can be detected in specimens from the pharynx and feces, less commonly from urine, and rarely from CSF by isolation in cell culture or a nucleic acid amplification test (NAAT). The relatively low sensitivity of isolation in cell culture from CSF is likely attributable to low viral load. Fecal material and pharyngeal swab specimens are most likely to yield virus in cell culture.

The diagnostic test of choice for confirming polio is viral culture of stool specimens and throat swab specimens obtained as early in the course of illness as possible. There currently are nucleic acid amplification tests for enteroviruses from CSF and at least several multiplexed assays that detect enteroviruses, in addition to other bacterial and viral agents. Such commonly used molecular tests for enteroviruses will detect poliovirus but will not differentiate poliovirus from other enteroviruses and, therefore, are insufficient to demonstrate that poliovirus is the etiology of disease. In these situations, additional testing of the virus will be necessary to confirm the diagnosis of poliovirus-related disease.

NAATs generally have sensitivity that is comparable to or better than cell culture and may be more likely to identify poliovirus in CSF. Two or more stool and throat swab specimens for enterovirus isolation or detection by NAAT should be obtained at least 24 hours apart from patients with suspected paralytic poliomyelitis as early in the

course of illness as possible, ideally within 14 days of onset of symptoms. Poliovirus may be excreted intermittently, and a single negative test result does not rule out infection.

Molecular methods have replaced neutralization for identification and typing to differentiate wild type from vaccine derived virus strains.

Because OPV no longer is available in the United States, the chance of exposure to OPV viruses has become remote. Therefore, if a poliovirus is isolated in the United States, the isolate should be reported immediately to the state health department and sent to the CDC through the state health department for further testing.

TREATMENT: Management is supportive. There are no antiviral agents approved by the US Food and Drug Administration for the treatment of poliovirus infections. Several poliovirus antivirals are in early stage development, however, including pocapavir (a capsid inhibitor), which is being evaluated in combination with V-7404 (a protease inhibitor). However, safety and dosing information for these products is limited, especially in children.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, contact precautions are indicated for infants and young children for the duration of hospitalization.

CONTROL MEASURES:

Immunization of Infants and Children.

Vaccines. Only IPV is available in the United States. IPV contains the 3 serotypes, which are grown in Vero cells or human diploid cells and inactivated with formaldehyde. IPV also is available in combination with other childhood vaccines (see Table 1.10, p 65). In 2016, bivalent live attenuated oral poliovirus vaccine (bOPV), which contains types 1 and 3 poliovirus serotypes, became the primary vaccine used in low- and middle-income countries that rely on OPV for routine infant immunization. bOPV is produced in monkey kidney cells or human diploid cells.

Immunogenicity and Efficacy. Both IPV and OPV, in their recommended schedules, are highly immunogenic and effective in preventing poliomyelitis. Administration of IPV results in seroconversion in 95% or more of vaccine recipients to each of the 3 serotypes after 2 doses and results in seroconversion in 99% to 100% of recipients after 3 doses. Immunity probably is lifelong. Following exposure to live poliovirus, most IPV-immunized children will excrete virus from stool but not from the oropharynx. Stool excretion quantities and duration are modestly reduced compared with shedding from unimmunized people. Immunization with 3 or more doses of OPV induces excellent serum antibody responses and substantial intestinal immunity against poliovirus reinfection. A 3-dose series of OPV, as formerly used in the United States, results in sustained, probably lifelong immunity. After 3 doses of OPV, seroconversion rates are lower in some low-income countries, likely because of chronic enteropathy and interference by other enteric pathogens with the replication of the OPV vaccine strains.

Administration With Other Vaccines. Either IPV or OPV may be administered concurrently with other routinely recommended childhood vaccines (see Simultaneous Administration of Multiple Vaccines, p 63). For administration of combination vaccines containing IPV (see Table 1.10, p 65) with other vaccines and interchangeability of the combined vaccine with other vaccine products, see Pertussis (p 656), Hepatitis B (p 437), *Haemophilus influenzae* Infections (p 400), and *Streptococcus pneumoniae* [Pneumococcal] Infections (p 810).

Adverse Reactions. Most adverse reactions to IPV are mild and self-limited (eg, injection site pain and fever). Serious reactions to IPV are rare. Because IPV may contain trace amounts of streptomycin, neomycin, and polymyxin B, allergic reactions are possible in recipients with hypersensitivity to one or more of these antimicrobial agents. Allergic reactions to other ingredients or components of IPV are also possible.

OPV can cause VAPP. Before exclusive use of IPV in the United States beginning in 2000, the overall risk of VAPP associated with OPV was approximately 1 case per 2.4 million doses of OPV distributed. The rate of VAPP following the first dose, including vaccine recipient and contact cases, was approximately 1 case per 750 000 doses.

Schedule.¹ Four doses of IPV are recommended for routine immunization of all infants and children in the United States.

Refugee and Immigrant Children. Refugee and immigrant children should meet recommendations of the Advisory Committee on Immunization Practices of the CDC for poliovirus vaccination, which include protection against all 3 poliovirus serotypes by age-appropriate vaccination with IPV or trivalent OPV (tOPV). Only written documentation or receipt of IPV or tOPV constitutes proof of vaccination according to US polio vaccination recommendations. If OPV was administered prior to April 1, 2016, OPV can be counted as tOPV. If OPV was administered after April 1, 2016, it may not be counted as tOPV unless the written documentation denotes that it is tOPV. For children incompletely immunized with tOPV, the series should be completed with IPV according to the catch-up schedule outlined below. In the absence of adequate written vaccination records, vaccination or revaccination in accordance with the age appropriate IPV schedule for the United States is recommended. Serologic testing to assess immunity no longer is available.²

- The first 2 doses of the 4-dose IPV series should be administered at 2-month intervals beginning at 2 months of age (minimum age, 6 weeks), and a third dose is recommended at 6 through 18 months of age. Doses may be administered at 4-week intervals when accelerated protection is indicated.
- Administration of the third dose at 6 months of age has the potential advantage of enhancing the likelihood of completion of the primary series and does not compromise seroconversion.
- A fourth and final dose in the series should be administered at 4 years or older and at a minimum interval of 6 months from the third dose.
- The final dose in the IPV series at 4 years or older should be administered regardless of the number of previous doses; a fourth dose is not necessary if the third dose was administered at 4 years or older and a minimum of 6 months after the second dose.
- When IPV is administered in combination with other vaccines at 2, 4, 6, and 12 through 15 months of age, it is necessary to administer a fifth and final dose of IPV at 4 years or older. The minimum interval from dose 4 to dose 5 should be at least 6 months.

¹ Centers for Disease Control and Prevention. Updated recommendations of the Advisory Committee on Immunization Practices (ACIP) regarding routine poliovirus vaccination. *MMWR Morb Mortal Wkly Rep.* 2009;58(30):829-830

² Marin M, Patel M, Oberste S, Pallansch MA. Guidance for assessment of poliovirus vaccination status and vaccination of children who have received poliovirus vaccine outside the United States. *MMWR Morb Mortal Wkly Rep.* 2017;66(1):23–25

- If a child misses an IPV dose at 4 through 6 years of age, the child should receive a booster dose as soon as feasible. More information on the polio vaccine schedule can be found at: www.cdc.gov/vaccines/schedules/hcp/imz/child-adolescent.html.

OPV remains the vaccine of choice for global eradication, although the Strategic Advisory Group of Experts on Immunization (SAGE) of the WHO has recommended that all countries currently using bOPV now include 2 doses of IPV into their routine immunization schedules to mitigate the risk of VDPV serotype 2 poliomyelitis.¹ A novel OPV serotype 2 vaccine (nOPV2), which provides comparable protection but is more genetically stable than serotype 2 monovalent OPV, is available to countries through the WHO Emergency Use Listing procedures for deployment in responding to cVDPV2 outbreaks (<https://polioeradication.org/nopv2/>).

Children Incompletely Immunized. Children who have not received the recommended doses of poliovirus vaccines on schedule should receive sufficient doses of IPV to complete the immunization series for their age (<http://aapredbook.aappublications.org/site/resources/izschedules.xhtml>).

Vaccine Recommendations for Adults. Most adults residing in the United States are presumed to be immune to poliovirus from previous immunization and have only a small risk of exposure to wild poliovirus in the United States. For those traveling to areas where poliovirus infection occurs, immunization or booster should be provided as per CDC guidance (wwwnc.cdc.gov/travel/yellowbook/2024/infections-diseases/poliomyelitis). Countries are considered to have active poliovirus circulation if they have ongoing endemic circulation, active outbreaks, or environmental evidence of active circulation with either WPV or VDPVs.

For unimmunized adults, primary immunization with IPV is recommended. Adults without documentation of vaccination history should be considered unimmunized. Two doses of IPV should be administered at intervals of 1 to 2 months (4–8 weeks); a third dose is administered 6 to 12 months after the second dose. If time does not allow 3 doses of IPV to be administered according to the recommended schedule before protection is required, the following alternatives are recommended:

- If protection is not needed until 8 weeks or more, 3 doses of IPV should be administered at least 4 weeks apart (eg, at weeks 0, 4, and 8).
- If protection is not needed for 4 to 8 weeks, 2 doses of IPV should be administered at least 4 weeks apart (eg, at weeks 0 and 4).
- If protection is needed in fewer than 4 weeks, a single dose of IPV should be administered.

The remaining doses of IPV to complete the primary immunization schedule should be administered subsequently at the recommended intervals if the person remains at an increased risk.

Recommendations in other circumstances are as follows:

- **Incompletely immunized adults.** Adults who previously received less than a full primary series of OPV or IPV should receive the remaining required doses of IPV, a minimum of 4 weeks since the last dose.

¹ World Health Organization. Weekly Epidemiological Record. 2020;95:596-598. Available at: <https://apps.who.int/iris/bitstream/handle/10665/337100/WER9548-eng-fre.pdf>

- **Adults who are at an increased risk of exposure to WPV or cVDPV and who previously completed primary immunization with OPV or IPV.**

These adults can receive a single dose of IPV. Available data do not indicate the need for more than a single lifetime booster dose with IPV.

Travelers also may be affected by WHO and CDC polio vaccination recommendations for people residing for 4 or more consecutive weeks in countries with ongoing poliovirus transmission and who are traveling to polio-free countries.¹

- All residents and long-term visitors (defined as a duration of more than 4 weeks) should receive an additional dose of IPV between 4 weeks and 12 months before international travel and have the dose documented.
- Residents and long-term visitors who currently are in those countries who must travel with fewer than 4 weeks' notice and have not been vaccinated with OPV or IPV within the previous 4 weeks to 12 months should receive a dose at least by the time of departure.

The list of countries affected by this recommendation can be found online (<http://polioeradication.org/polio-today/polio-now/public-health-emergency-status/>).

Precautions and Contraindications to Immunization.

Immunocompromised People. Immunocompromised patients, including people with human immunodeficiency virus (HIV) infection; combined immunodeficiency; abnormalities of immunoglobulin synthesis (ie, antibody deficiency syndromes); leukemia, lymphoma, or generalized malignant neoplasm; or people receiving immunosuppressive therapy with pharmacologic agents (see Immunization and Other Considerations in Immunocompromised Children, p 93) or radiation therapy should receive IPV. OPV should not be used. The immune response to IPV in immunocompromised patients may vary depending on their level of immunosuppression.

Household Contacts of Immunocompromised People or People With Altered Immune States or Immunosuppression Attributable to Therapy for Other Disease. IPV is recommended for these people, and OPV should not be used. If OPV inadvertently is introduced into a household of an immunocompromised person, close contact between the patient and the OPV recipient should be minimized for approximately 4 to 6 weeks after immunization. Household members should be counseled on practices that will minimize exposure of the immunocompromised to excreted poliovirus vaccine. These practices include exercising hand hygiene after contact with the child by all and avoiding diaper changing by the immunosuppressed person.

Pregnancy. If a pregnant person is at increased risk of exposure and protection against polioviruses is needed, IPV is recommended. There is no evidence that IPV is unsafe in pregnant people or their developing fetuses.

Hypersensitivity or Anaphylactic Reactions to IPV Vaccine or Antimicrobial Agents Contained in IPV. IPV is contraindicated for people who have experienced an anaphylactic reaction after a previous dose of IPV attributable to any component of the vaccine.

Breastfeeding. Breastfeeding is not a contraindication to IPV or OPV administration.

Reporting of Adverse Events After Immunization. Any case of VAPP should be reported to the Vaccine Adverse Event Reporting System (VAERS). This and other reporting

¹ Centers for Disease Control and Prevention. Interim CDC guidance for polio vaccination for travel to and from countries affected by wild poliovirus. *MMWR Morb Mortal Wkly Rep*. 2014;63(27):591-594

requirements for adverse events following IPV and OPV are listed in the VAERS Table of Reportable Events (https://vaers.hhs.gov/docs/VAERS_Table_of_Reportable_Events_Following_Vaccination.pdf). In addition, reporting is encouraged for any clinically significant adverse event following a vaccination, even if uncertainty exists as to whether a vaccine caused the event (see Understanding Vaccine Evaluation and Safety as an Approach to Addressing Parental Concerns, p 27).

Public Health Reporting. A suspected case of poliomyelitis or a nonparalytic poliovirus infection, regardless of whether the virus is suspected to be WPV or VDPV, should be considered a **public health emergency** and **reported immediately** to the state health department; this results in an immediate epidemiologic investigation. Poliomyelitis should be considered in the differential diagnosis of all cases of acute flaccid paralysis, including Guillain-Barré syndrome, transverse myelitis, and acute flaccid myelitis (acute neurologic illness associated with limb weakness in children, which is associated with enterovirus D68 and less commonly with enterovirus A71, or other nonpolio enteroviruses; see Enterovirus [Nonpoliovirus], p 369).¹ If the course is compatible clinically with poliomyelitis, specimens should be obtained for virologic studies (see Diagnostic Tests, p 684). If evidence implicates wild poliovirus or a VDPV infection, an intensive investigation will be conducted, and a public health decision will be made about the need for supplementary immunizations, choice of vaccine, and other actions. Because most people who transmit poliovirus either are clinically asymptomatic or have a minor illness, the source person who transmitted virus to the patient with paralytic polio may be difficult to identify (eg, there may be no known contact with someone who traveled to an area with endemic or epidemic polio). Therefore, pediatricians should be guided by the clinical presentation in deciding whether a child with acute paralysis might have polio and warrant reporting the suspected case to public health authorities.

Polyomaviruses (BK, JC, and Other Polyomaviruses)

CLINICAL MANIFESTATIONS: BK virus (BKV) infection and JC virus (JCV) infection in humans usually occur in childhood and seemingly result in lifelong persistence. More than 80% of adults are seropositive for BKV. Primary infection with BKV in immunocompetent children generally is asymptomatic, although it may result in mild upper respiratory tract symptoms. BKV is more likely to cause disease in immunocompromised people, including hemorrhagic cystitis in hematopoietic cell transplant recipients and interstitial nephritis and ureteral stenosis in renal transplant recipients. BKV-associated nephropathy occurs in 3% to 8% of renal transplant recipients and less frequently in other solid organ transplant recipients. The primary symptom of BKV-associated hemorrhagic cystitis among immunocompromised children is painful hematuria; blood clots in the urine and secondary obstructive nephropathy also can occur. Often, however, BKV nephropathy is asymptomatic, and therefore should be suspected in any renal transplant recipient with allograft dysfunction. More than half of renal allograft patients with BKV-associated nephropathy may experience allograft loss.

¹ Centers for Disease Control and Prevention. Acute neurologic illness of unknown etiology in children—Colorado, August–September 2014. *MMWR Morb Mortal Wkly*. 2014;63(40):901-902

JCV is the cause of progressive multifocal leukoencephalopathy (PML), a demyelinating disease of the central nervous system that occurs in severely immunocompromised patients, including patients with acquired immunodeficiency syndrome (AIDS), patients receiving intensive chemotherapy, hematopoietic cell or solid organ transplant recipients, and patients receiving various monoclonal antibody therapies for treatment of autoimmune, oncologic, and neurologic diseases. PML, the only known disease caused by JCV, occurs in approximately 3% to 5% of untreated adults with acquired immunodeficiency syndrome (AIDS) but is rare in children with AIDS. Symptoms include cognitive disturbance, hemiparesis, ataxia, cranial nerve dysfunction, and aphasia. Lytic infection of oligodendrocytes by JCV is the primary mechanism of pathogenesis for PML. In the absence of restored T-lymphocyte function, PML almost always is fatal. PML is an AIDS-defining illness in people with human immunodeficiency virus (HIV) infection.¹ Approximately 50% to 60% of adults are infected by JCV, with infections being acquired during adolescence and early adulthood.

Of the polyomaviruses catalogued to date, 14 have been detected in humans, but only a few have been associated with disease, including BK and JC viruses. The Merkel cell polyomavirus (MCPyV) has been detected in >80% of Merkel cell carcinomas, which are rare neuroendocrine tumors of the skin. The trichodysplasia spinulosa-associated polyomavirus (TSPyV) has been identified in tissue from patients with trichodysplasia spinulosa, a rare follicular disease of immunocompromised patients that primarily affects the face. The KI polyomavirus (KIPyV) and WU polyomavirus (WUPyV) have been identified in respiratory tract secretions, primarily in association with known pathogenic viruses of the respiratory tract. Human polyomaviruses 6 and 7 (HPyV6 and HPyV7) have been detected as asymptomatic inhabitants of human skin. Human polyomavirus 9 (HPyV9) has been detected in the serum of some renal transplant recipients. The natural history, prevalence, and pathogenic potential of these recently discovered human polyomaviruses have not been established.

ETIOLOGY: Polyomaviruses are members of the family *Polyomaviridae*. BKV, JCV, WUPyV, and KIPyV are members of the genus *Betapolyomavirus*; MCPyV, TSPyV, HPyV9, HPyV12, and New Jersey polyomavirus are members of the genus *Alphapolyomavirus*; HPyV6, HPyV7, Malawi polyomavirus, and St. Louis polyomavirus are members of the genus *Deltapolyomavirus*. They are nonenveloped viruses with a circular double-stranded DNA genome with icosahedral symmetry of the capsid ranging 40 to 50 nm in diameter. One of the biological characteristics of the polyomaviruses is the maintenance of a chronic viral infection in their host with few or no symptoms. Symptomatic disease caused by human polyomavirus infections occurs almost exclusively in immunosuppressed people. Four genotypes of BKV have been identified; genotype 1 BKV accounts for the majority of cases of BKV nephropathy.

EPIDEMIOLOGY: Humans are the only known natural hosts for BKV and JCV. The mode of transmission of BKV and JCV is uncertain, but the respiratory route and the oral route by water or food have been postulated. BKV and JCV are ubiquitous in the human population, with BKV infection occurring in early childhood and JCV

¹ Panel on Opportunistic Infections in Children with and Exposed to HIV. Guidelines for the Prevention and Treatment of Opportunistic Infections in Children with and Exposed to HIV. Department of Health and Human Services. Available at: <https://clinicalinfo.hiv.gov/en/guidelines/pediatric-opportunistic-infection>

infection occurring primarily in adolescence and adulthood. BKV persists in the renal epithelial and urothelial cells and gastrointestinal tract of healthy subjects, with urinary excretion occurring in 3% to 5% of healthy adults. JCV persists in the kidney, gastrointestinal tract, and brain of healthy people. The prevalence of urinary excretion of JCV increases with age.

DIAGNOSTIC TESTS: Detection of BKV T-antigen by immunohistochemical analysis of renal biopsy material with characteristic cytopathic changes is the gold standard for diagnosis of BKV-associated nephropathy, but nucleic acid amplification tests (NAATs) are the most sensitive tools for rapid viral screening for polyomaviruses and quantification of viral load. Prospective monitoring of BK viral DNA load in plasma using NAATs is common after renal transplantation to monitor for BKV-associated nephropathy. Detection of BKV nucleic acid in plasma by NAAT is associated with an increased risk of BKV-associated nephropathy, especially when BKV viral loads exceed 10 000 genomes/mL, but detection of BKV in urine of renal transplant recipients is common and does not predict BKV disease after renal transplantation. Both BKV and JCV can be propagated in cell culture, but culture plays no role in the laboratory diagnosis of infection attributable to these agents. Antibody assays are used commonly to detect presence of specific antibodies against individual viruses, but their use in clinical practice is limited.

Diagnosis of BKV-associated hemorrhagic cystitis is made clinically when other causes of urinary tract bleeding are excluded. Among hematopoietic cell transplant recipients, detection of BKV by NAAT in urine is common (more than 50%), but BKV-associated hemorrhagic cystitis is much less common (10%–15%). Prolonged urinary shedding of BKV and detection of BKV in plasma after hematopoietic cell transplantation has been associated with increased risk of developing BKV-associated hemorrhagic cystitis. Urine cytologic testing may suggest urinary shedding of BKV on the basis of presence of decoy cells, which resemble renal carcinoma cells, but decoy cells do not have high sensitivity or specificity for BKV disease.

A confirmed diagnosis of PML attributable to JCV requires a compatible clinical syndrome and magnetic resonance imaging or computed tomographic findings showing lesions in the brain white matter coupled with brain biopsy findings. JCV can be demonstrated by in situ hybridization, electron microscopy, or immunohistochemistry of brain biopsy or autopsy material. There are no FDA-cleared NAATs for detection of JCV. Diagnosis of PML can be facilitated when JCV DNA is detected in cerebrospinal fluid by a NAAT, which may obviate the need for a brain biopsy. Early in the course of PML, false-negative NAAT results have been reported, so repeat testing is warranted when clinical suspicion of PML is high. Measurement of JCV DNA concentrations in cerebrospinal fluid samples may be a useful marker for managing PML in patients with AIDS who are receiving antiretroviral therapy.

TREATMENT: Multiple studies evaluating treatment options for polyomavirus diseases are ongoing (www.clinicaltrials.gov). At this time there is no proven antiviral therapy for BKV nephropathy. Closely monitored reduction of immunosuppression remains the mainstay of treatment. Efficacy of other agents used as adjunctive therapy (immune globulin intravenous [IGIV], leflunomide, cidofovir) has not been established. Fluoroquinolones are not recommended for prophylaxis or treatment of BKV-associated nephropathy based on results of prospective, controlled studies.

Most patients with BKV-hemorrhagic cystitis after hematopoietic cell transplantation require only supportive care because restoration of immune function by cell engraftment ultimately will control BKV replication. In severe cases, surgical intervention may be required to stop bladder hemorrhage. Parenteral and/or intravesicular cidofovir have been used for treatment, but data from prospective, controlled studies on its efficacy and safety are lacking. Use of systemic cidofovir must be balanced against its high risk of nephrotoxicity. Adoptive transfer of BKV-specific T lymphocytes has been used with varying success at some transplant centers.

Restoration of immune function (eg, antiretroviral therapy for patients with AIDS) is necessary for survival of patients with PML. Cidofovir has not been shown to be effective for treatment of PML. For patients with monoclonal antibody-associated PML (eg, natalizumab), plasmapheresis and/or immune stimulatory agents (eg, granulocyte colony-stimulating factor) may be useful to improve outcomes. Infusion of allogeneic BKV-specific T-lymphocytes, IL-7 homologues, and the use of monoclonal antibodies to inhibit programmed cell death protein 1 (PD-1) have shown encouraging results for patients with PML but remain experimental at this time.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: None.

Prion Diseases: Transmissible Spongiform Encephalopathies

CLINICAL MANIFESTATIONS: Prion diseases, or transmissible spongiform encephalopathies (TSEs), constitute a group of rare, rapidly progressive, universally fatal, transmissible neurodegenerative diseases of humans and animals characterized by neuronal degeneration, reactive gliosis, and most often, spongiform degeneration in the cerebral cortical, subcortical, and cerebellar gray matter. These findings are accompanied by accumulation of an abnormal misfolded, partially protease-resistant “prion” (proteinaceous infectious) protein. The normal protease-sensitive isomer of the protein is called “cellular” prion protein or PrP^C. The protease-resistant pathogenic form of the prion protein is variably called PrP^{res}, scrapie prion protein (PrP^{sc}, named for the first known prion disease affecting sheep), or as suggested by the World Health Organization, TSE-associated PrP (PrP^{TSE}). PrP^{TSE} distributes widely, albeit unevenly, throughout the central nervous system, sometimes forming plaques of varying morphologies.

Human prion diseases include several sporadic, genetic, and acquired diseases: Creutzfeldt-Jakob disease (CJD), variably protease-sensitive prionopathy (VPSPr), Gerstmann-Sträussler-Scheinker disease, fatal familial insomnia and sporadic fatal insomnia, kuru, and variant CJD (vCJD, caused by the agent of bovine spongiform encephalopathy [BSE], commonly called “mad cow” disease). CJD can be sporadic (approximately 85% of cases), genetic (approximately 10%–15% of cases), or iatrogenic (fewer than 1% of cases). Sporadic CJD most commonly is a disease of older adults (median age of death in the United States, 68 years) but also has been described in adolescents and young adults. Iatrogenic CJD has been acquired through intramuscular injection of contaminated cadaveric pituitary hormones (growth hormone and human gonadotropin), dura mater allografts, corneal transplantation, use of contaminated instruments in neurosurgery, and electroencephalographic probe electrodes.

In 1996, an outbreak of a new variant of CJD (vCJD) was linked to consumption of beef from BSE-infected cattle in the United Kingdom and France, with index cases occurring in teenagers. Since the end of 2003, 4 presumptive cases of transfusion-transmitted vCJD have been reported: 3 clinical cases as well as 1 asymptomatic case in which PrP^{TSE} was detected in the spleen and lymph nodes but not brain tissues. A fifth possible iatrogenic vCJD infection was reported in the United Kingdom, affecting a patient with hemophilia, also asymptomatic, who had PrP^{TSE} in the spleen; preclinical vCJD was attributed to treatment with plasma-derived coagulation factor fractionated in the United Kingdom; the plasma product implicated in transmitting vCJD was never marketed in the United States.

The best-known prion diseases affecting animals include scrapie of sheep and goats, BSE of cattle, and a chronic wasting disease (CWD) of North American deer, elk, and moose (www.cdc.gov/prions/index.html). CWD recently was detected in reindeer and moose (European elk) in Norway, Sweden, and Finland. Except for vCJD, no human prion disease has been attributed convincingly to infection with an agent of animal origin.

CJD manifests most typically as a rapidly progressive neurologic disease with escalating defects in memory, personality, and other higher cortical functions. Approximately one third of patients have cerebellar dysfunction at presentation, including ataxia, incoordination, and dysarthria. Iatrogenic CJD also may manifest as dementia with cerebellar signs. Myoclonus develops in at least 80% of affected patients at some point in the course of disease. Death usually occurs in weeks to months (median, 4–5 months); only 10% to 20% of patients with sporadic CJD survive for more than 1 year.

vCJD is distinguished from classic CJD by younger age at onset (median age at death around 28 years), early “psychiatric” manifestations, and other features such as painful sensations in the limbs, delayed onset of overt neurologic signs, relative absence of diagnostic electroencephalographic changes, and a more prolonged duration of illness (median, 13–14 months). A high proportion of people with vCJD, but not classic CJD, exhibit high signal abnormalities on T2-weighted brain magnetic resonance imaging in the pulvinar region of the posterior thalamus (known as the “pulvinar sign”). Neuropathologic examination in vCJD reveals highly reproducible pathology with spongiform vacuolation and numerous “florid” plaques (compact flower-like amyloid plaques surrounded by vacuoles) and exceptionally striking punctate deposition of PrP^{TSE} in the basal ganglia. PrP^{TSE} is detectable by immunohistochemistry in the tonsils, appendix, spleen, and lymph nodes of patients with vCJD.

ETIOLOGY: The proteinaceous infectious particle (or prion) widely believed to cause human and animal prion diseases consists of PrP^{TSE}, the misfolded form of PrP^C, a ubiquitous normal sialoglycoprotein of unknown function found on the surfaces of neurons and many other cells of humans and animals. It has been postulated by some authorities that sporadic CJD and atypical forms of BSE may result from a spontaneous structural change of host-encoded PrP^C into the self-replicating pathogenic PrP^{TSE} form. Prion propagation is proposed to occur by a “recruitment” reaction in which abnormal PrP^{TSE} serves as a template to convert PrP^C molecules into misfolded PrP^{TSE} molecules that precipitate in saline-detergent solutions, resist digestion with some proteolytic enzymes, and have a high potential to aggregate. Experimental efforts to confirm this hypothesis have yielded inconsistent results.

EPIDEMIOLOGY: Sporadic CJD is rare, occurring in the United States at a rate of approximately 1 to 1.5 cases per million people annually. Lifetime risk of CJD in the United States is approximately 1 in 6 239 people. Onset of disease peaks in the 60-through 74-year age group. Case-control studies of sporadic CJD have identified no consistent environmental risk factor. No increase in cases of sporadic CJD has been observed in people previously transfused with blood or blood components or injected with human plasma derivatives. The rate of sporadic CJD is not increased in patients with several diseases treated by repeated blood transfusions (eg, thalassemia and sickle cell disease) or in patients with hemophilia treated with human plasma derivatives. The American Red Cross traced a number of recipients of blood transfusions from donors later diagnosed with sporadic CJD; no cases of CJD were identified in recipients, some of whom survived for many years. Taken together, this information suggests that any risk of transfusion-transmitted sporadic CJD must be very low and appropriately regarded as theoretical. Except in families with genetic forms of the disease, CJD has not been reported in progeny of mothers who died with CJD. Genetic forms of prion diseases are expressed as autosomal dominant disorders with variable penetrance associated with a variety of mutations of the PrP-encoding gene (*PRNP*) located on chromosome 20. On average, genetic CJD begins approximately 10 years earlier than does sporadic CJD, but age at onset varies widely, even for members of the same family harboring identical mutations.

As of April 2021 (www.eurocjd.ed.ac.uk/data_tables), the total number of vCJD cases reported was 178 patients in the United Kingdom, 28 in France, 5 in Spain, 4 in Ireland, 4 in the United States, 3 in the Netherlands, 3 in Italy, 2 in Portugal, 2 in Canada, and 1 each in Taiwan, Japan, and Saudi Arabia. Two of the 4 patients in the United States, 2 of the 4 in Ireland, and 1 each of the patients in France, Canada, and Taiwan are believed to have acquired vCJD during residence in the United Kingdom. A study using statistical analysis of probability density of exposure to BSE concluded that 2 vCJD patients in the United States and another in Canada probably were infected during childhood residence in the Kingdom of Saudi Arabia. On the basis of animal inoculation studies, comparative PrP immunoblotting, and epidemiologic investigations, almost all cases of vCJD are believed to have resulted from exposure to tissues from cattle infected with BSE. Authorities suspect that the Japanese patient was infected during a short visit of 24 days to the United Kingdom in 1990, 12 years before onset of vCJD. Most patients with vCJD were younger than 30 years at onset, and several were adolescents. Median age at death of the 175 primary UK vCJD cases was 27 years. The ages at death of the 3 iatrogenic vCJD transfusion-transmitted cases were 32, 69, and 75 years; they developed typical vCJD 6.3 to 8.5 years after transfusions with nonleukoreduced red blood cells from apparently healthy individuals who donated the blood 1.4 to 3.5 years before onset of vCJD, demonstrating that blood contained the infectious agent during a substantial part of the asymptomatic incubation period. One patient with hemophilia, also showing no clinical signs of prion disease, probably was infected through injections of human plasma-derived clotting factors.

The **incubation periods** for iatrogenic classic CJD vary by route of exposure and range from about 14 months to at least 42 years. No transfusion-transmitted cases of nonvariant forms of CJD have been recognized.

DIAGNOSTIC TESTS: The diagnosis of human prion diseases can be made with certainty only by neuropathologic examination of affected brain tissue, usually obtained at autopsy. Immunodetection methods for PrP such as immunohistochemistry with sections and Western blot with saline-detergent extracts can be used to test brain tissues. Electroencephalography (EEG), magnetic resonance imaging (MRI), and cerebrospinal fluid (CSF) testing can be used to diagnose prion disease in living patients. In most patients with classic CJD, characteristic 1-cycle to 2-cycles per second triphasic sharp-wave discharges on EEG tracing indicate CJD. The likelihood of finding this abnormality is enhanced by serial EEG recordings.

Validated assays that detect 2 protein markers, 14-3-3 and tau, in CSF showed 83% to 90% sensitivity and 78% specificity. These proteins, sometimes detected in other neurologic diseases, are surrogate nonspecific markers found in CSF, probably as a result of the death of neurons.

Brain MRI is a highly sensitive and specific diagnostic tool for CJD, demonstrating hyperintensity in the basal ganglia and/or at least 2 cortical areas (excluding the frontal lobe) on diffusion-weighted imaging (DWI) or fluid attenuated inversion recovery (FLAIR) sequences.

No validated blood test is available. Recent promising developments exploit the in vivo prion replication process to amplify and detect even minute amounts of prions in biological samples. One such technique, real-time quaking-induced conversion (RT-QuIC), has been applied successfully in the clinical diagnosis of CJD in CSF samples with high specificity and sensitivity.¹ RT-QuIC also has been applied to diagnose CJD in olfactory epithelium brushings and, with additional validation, may be used in clinical settings.² RT-QuIC has not been applied successfully to blood samples. Some success has been reported with blood samples tested using another PrP^{TSE} amplification technique called protein misfolding cyclic amplification (PMCA).³ These are currently “research-use-only” tests not marketed for human diagnosis.

Any person bearing a pathogenic mutation of the *PRNP* gene (not a normal polymorphism) with progressive neurologic signs suggestive of a TSE can be presumed to have a prion disease. Because no unique nucleic acid has been detected in prions causing TSEs, nucleic acid amplification tests (NAATs) are not possible. Brain biopsies for patients with possible CJD should be considered only when other potentially treatable diseases remain in the differential diagnosis. Complete postmortem examination of the brain is encouraged to confirm the clinical diagnosis of prion disease, to detect emerging forms of CJD, such as vCJD, and to survey for potential zoonotic transmission of CWD. State-of-the-art diagnostic testing, including assays of 14-3-3 and tau and RT-QuIC in CSF, *PRNP* gene sequencing, histopathology and Western blot analysis of brain to identify and characterize PrP^{TSE}, as well as expert neuropathologic consultation, are offered by the National Prion Disease Pathology Surveillance Center (telephone, 216-368-0587; www.cjdsurveillance.com). Clinical specimens that may

³ Kramm C, Pritzkow S, Lyon A, Nichols T, Morales R, Soto C. Detection of prions in blood of cervids at the asymptomatic stage of chronic wasting disease. *Sci Rep*. 2017;7(1):17241

contain prions, particularly specimens with substantial amounts of infectivity, including brain, spinal cord, and CSF, should be handled with extreme caution. Amounts of infectivity can be significantly but not completely inactivated by physical or chemical means commonly used in the laboratory. Potentially contaminated laboratory waste should be steam autoclaved, when possible, at 134°C, and then sent to incineration as medical-pathological waste.

TREATMENT: No treatment has stopped or slowed the progressive neurodegeneration in prion diseases. Experimental treatments are being studied. Supportive therapy aids in managing dementia, spasticity, rigidity, and seizures occurring during the course of illness. Compassionate counseling and emotional support should be offered to families of affected people. Skilled genetic counseling is indicated for genetic disease, taking into account that penetrance has been variable in some kindreds in which people with a *PRNP* mutation survived to an advanced age without developing neurodegenerative disease. A family support and patient advocacy group, the CJD Foundation (telephone 800-659-1991; www.cjdfoundation.org), offers helpful information and advice together with information for professionals.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended. Available evidence indicates that even prolonged intimate contact with CJD patients has not transmitted disease. Tissues with high levels of infectivity (eg, brain, eyes, spinal cord) and instruments in contact with those tissues are considered biohazards; incineration, prolonged autoclaving at high temperature and pressure after thorough cleaning, and, especially, exposure to a solution of 1 N or greater sodium hydroxide for 1 hour has been reported to decrease markedly or eliminate infectivity of contaminated surgical instruments. Work surfaces can be decontaminated effectively by exposure to 5.25% or stronger sodium hypochlorite (NaOCl, undiluted household chlorine bleach), but many surgical instruments corrode when exposed to NaOCl. The Centers for Disease Control and Prevention (CDC) offers advice for dealing with CJD patients (www.cdc.gov/prions/index.html) and recommendations for CJD infection control. Information on distribution of infectivity in various tissues and specific decontamination protocols are available online (www.cdc.gov/prions/cjd/infection-control.html and apps.who.int/iris/bitstream/handle/10665/66707/WHO_CDS_CSR_APH_2000.3.pdf). Person-to-person transmission of sporadic CJD by blood, milk, saliva, urine, or feces has not been reported. Body fluids should be handled using standard infection control procedures. Universal blood precautions, recommended for all patients, should be sufficient to prevent bloodborne transmission of TSEs.

CONTROL MEASURES: Immunization against prion diseases is not available, and no protective immune response to infection has been demonstrated. Iatrogenic transmission of CJD through cadaveric pituitary hormones has been obviated by use of recombinant products. Recognition that CJD had been spread by transplantation of infected dura mater allografts and corneal transplantation led to improved sourcing of those materials. After reports of transfusion-transmitted vCJD in the United Kingdom, blood establishments implemented more stringent blood and plasma donor selection criteria and improved collection protocols. Health care professionals should follow their state's prion disease reporting requirements and indicate CJD or other prion disease diagnoses appropriately on death certificates; the CDC uses mortality data from the United

States to help monitor prion diseases. In addition, any suspected or confirmed diagnosis of a prion disease of special public health concern (eg, any suspected iatrogenic TSE, vCJD, or human TSE with onset before age of 55 years) should be reported promptly to the appropriate state or local health departments and to the CDC (telephone, 404-639-3091 or 404-639-4435; www.cdc.gov/prions/cjd/index.html). Current precautionary policies of the US Food and Drug Administration to reduce the risk of transmitting CJD by human blood or blood products are available online (www.fda.gov/regulatory-information/search-fda-guidance-documents/recommendations-reduce-possible-risk-transmission-creutzfeldt-jakob-disease-and-variant-creutzfeldt). General information about BSE and CWD is available from the US Food and Drug Administration (www.fda.gov/AnimalVeterinary/ResourcesforYou/AnimalHealthLiteracy/ucm136222.htm), from the US Department of Agriculture (www.usda.gov/topics/animals/bse-surveillance-information-center), from the CDC (www.cdc.gov/prions/bse/index.html), and from the World Organization for Animal Health (www.oie.int/en/animal-health-in-the-world/bse-portal/).

***Pseudomonas aeruginosa* Infections**

CLINICAL MANIFESTATIONS: *Pseudomonas aeruginosa* causes a variety of localized and systemic infections including otitis externa, mastoiditis, folliculitis, cellulitis, ecthyma gangrenosum, wound infection, ocular infection, pneumonia, osteomyelitis, bacteremia, endocarditis, meningitis, peritonitis, and urinary tract infection. It is a common cause of health care-associated infections (particularly in the presence of invasive devices), infections in immunocompromised children, pulmonary infections in children with cystic fibrosis, and infections in children with burns. *Pseudomonas* ophthalmia occurs predominantly in preterm infants and presents with eyelid edema and erythema, purulent discharge, and pannus formation. It can progress to corneal perforation, endophthalmitis, sepsis, and meningitis.

ETIOLOGY: *P aeruginosa* is an aerobic, gram-negative, nonfermenting bacillus that is commonly found in the environment. It is a member of the *Pseudomonas* genus and the *Pseudomonadaceae* family. The organism has multiple virulence factors, including the ability to form biofilms. *P aeruginosa* can convert to a mucoid phenotype, particularly in the setting of prolonged colonization, such as in individuals with cystic fibrosis.

EPIDEMIOLOGY: *P aeruginosa* is an opportunistic pathogen, causing infections in immunocompromised hosts (particularly those with neutropenia or poor granulocyte function), those with indwelling devices, burns, or cystic fibrosis. Children with cystic fibrosis commonly develop chronic endobronchial colonization with *P aeruginosa*, which is often associated with a more rapid decline in pulmonary function. Children with cystic fibrosis can share epidemic strains of *P aeruginosa*. Hospital-acquired *P aeruginosa* infections include ventilator-associated pneumonia, catheter-associated urinary tract infections, surgical site infections, and peritonitis associated with peritoneal dialysis. Community-associated infections include “hot tub” folliculitis, otitis externa after swimming in fresh water, osteomyelitis after a puncture wound (particularly through a sneaker), and endocarditis in people who inject drugs. It is a common cause of “contact lens” keratitis. Auricular chondritis has occurred after upper ear piercing. Outbreaks of infection have occurred from contaminated bronchoscopes.

P aeruginosa has intrinsic resistance to a variety of antibiotics and circulating strains are often multidrug resistant. Resistance may emerge during therapy. Production of beta-lactamases, loss of outer membrane proteins, and multidrug efflux pumps are common. Carbapenemase-producing strains (most commonly IMP and VIM) also occur.

The **incubation period** is variable depending on the host and site of colonization/infection. Incubation period for folliculitis following immersion in a whirlpool is a few hours to several days after exposure.

DIAGNOSTIC TESTS: Diagnosis is established by growth of *P aeruginosa* from culture of clinical specimens. Isolates may be identified by traditional biochemical tests, by a variety of commercially available biochemical test systems, by matrix-assisted laser desorption/ionization–time-of-flight (MALDI-TOF) mass spectrometry of bacterial cell components, or by molecular methods.

TREATMENT:

- Empiric combination therapy from different antimicrobial classes (eg, adding a fluoroquinolone or an aminoglycoside to an antipseudomonal β -lactam) may be indicated in severe sepsis, in patients with neutropenia, in patients who recently received broad-spectrum β -lactams, or in settings where antibiotic resistance is high to increase the probability of covering the infecting organism prior to knowing its identification and susceptibility.
- Cultures and susceptibilities should be sent prior to initiation of empiric therapy and therapy adjusted as per susceptibility data. In most patients, therapy can be simplified to a single active agent; there are no data to support continuation of combination therapy for an isolate susceptible to an appropriate antipseudomonal drug (see below). When the clinical course is complicated or when there is multidrug resistance to commonly used anti-pseudomonal agents (eg, antipseudomonal beta-lactam agents), it is recommended that an expert in infectious diseases assist in the management, particularly in the setting of carbapenem resistance.
- An important component of treatment is timely source control (ie, removal of catheters and devices, drainage of abscesses).
- Antimicrobial agents that have activity against *P aeruginosa* include piperacillin-tazobactam, ceftazidime, cefepime, aztreonam, ciprofloxacin, levofloxacin, meropenem, and imipenem/cilastatin (see Tables of Antibacterial Drugs, p 987); however, susceptibility patterns vary regionally, and local epidemiology and individual patient antibiotic exposure history should inform empiric therapy. Aminoglycosides are often used as adjunctive therapy (but not as monotherapy beyond urinary tract infections). Polymyxins (ie, colistin and polymyxin B) can be considered in the setting of highly resistant organisms but should not be used as first-line treatments if newer agents (eg, imipenem/cilastatin-relebactam, ceftazidime-avibactam, ceftolozane-tazobactam, or cefiderocol [experience for this agent is limited in children]) are available because of the general lower efficacy and higher adverse event rates of polymyxins compared with these newer agents.
- Management of children with cystic fibrosis should occur in conjunction with an expert in cystic fibrosis. Treatment for pulmonary exacerbation often includes 2 antipseudomonal agents in patients known to be chronically colonized with *P aeruginosa*. The Cystic Fibrosis Foundation recommends early eradication of *P aeruginosa*.

with inhaled tobramycin (300 mg twice daily for 28 days). Once *P aeruginosa* becomes established, it can persist for years. Chronic suppressive treatment with inhaled antibiotics can decrease the bacterial burden. Inhaled antibiotics are generally not indicated for pulmonary exacerbations.

- Management of *Pseudomonas* neonatal ophthalmia urgently requires a combination of systemic and topical therapy, because systemic antibiotics alone have poor penetration in the anterior chamber of the eye. The diagnosis should be suspected when Gram-stained specimens of exudate contain gram-negative bacilli and should be confirmed by culture. Ophthalmology consultation is recommended.
- Duration of therapy is based on clinical and bacteriologic response of the patient and the site(s) of infection. Most bloodstream infections, ventilator-associated pneumonias, and urinary tract infections in immunocompetent people beyond the neonatal period can be treated with 7 days of antibiotic therapy if source control is achieved. In immunocompromised hosts (eg, those with neutropenia) and neonates, the duration of antibiotic therapy is usually 10 to 14 days.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions for routine patients are recommended. For carbapenemase-producing organisms, contact precautions are indicated.¹ The Cystic Fibrosis Foundation recommends implementation of contact precautions in addition to standard precautions for care of all patients with cystic fibrosis in inpatient or ambulatory care settings, regardless of respiratory tract cultures.

CONTROL MEASURES: The Cystic Fibrosis Foundation recommends that all cystic fibrosis care centers limit contact between patients. This includes inpatient, outpatient, and social settings. When in a health care setting, patients with cystic fibrosis should wear a mask while outside of a clinic examination room or a hospital room. Education of patients and families about hand hygiene and appropriate personal hygiene is recommended.

Q Fever (*Coxiella burnetii* Infection)

CLINICAL MANIFESTATIONS: Approximately half of acute Q fever infections result in symptoms. Acute and chronic forms of the disease exist, and both can present as fever of unknown origin. Q fever is rare in children. Acute Q fever is typically characterized by abrupt onset of fever and is often accompanied by chills, headache, weakness, cough, and other nonspecific systemic symptoms. Illness typically is self-limited, although a relapsing febrile illness lasting for several months has been documented in children. Gastrointestinal tract symptoms, such as diarrhea, vomiting, abdominal pain, and anorexia, are reported in 50% to 80% of children. Rash has been observed in some patients. Q fever pneumonia usually manifests with a mild cough and shortness of breath but can progress to respiratory distress. Chest radiographic patterns are variable. In immunocompromised patients, a nodular pattern accompanied by a halo of ground-glass opacification and vessel connection, or findings suggestive of a necrotizing process, may be seen. More severe manifestations of acute Q fever include

¹ Centers for Disease Control and Prevention. Facility Guidance for Control of Carbapenem Resistant Enterobacteriaceae (CRE) November 2015 Update. Available at: www.cdc.gov/hai/pdfs/cre/CRE-guidance-508.pdf

hepatitis, hemolytic-uremic syndrome, myocarditis, pericarditis, encephalitis, meningitis, hemophagocytosis, lymphadenitis, cholecystitis, and rhabdomyolysis. The presence of anticardiolipin antibodies during acute Q fever has been associated with severe complications in adults. People who are infected during pregnancy may be at risk for miscarriage or preterm delivery. Chronic (persistent, localized) Q fever can present as blood culture-negative endocarditis, vascular infection, chronic relapsing or multifocal osteomyelitis, chronic hepatitis, or infection of the reproductive organs. Osteomyelitis is a common presentation of chronic Q fever in children. Children who are immunocompromised or have underlying valvular heart disease may be at higher risk of chronic Q fever.

ETIOLOGY: *Coxiella burnetii*, the cause of Q fever, previously was considered to be a rickettsial organism but is a gram-negative intracellular bacterium that belongs to the order *Legionellales*, family *Coxiellaceae*. It shares many features, including relatedness of several virulence genes, with *Legionella pneumophila*. The infectious form of *C. burnetii* is highly resistant to heat, desiccation, and disinfectant chemicals and can persist for long periods of time in the environment. *C. burnetii* is classified as a category B bioterrorism agent by the Centers for Disease Control and Prevention (CDC).

EPIDEMIOLOGY: Q fever is a zoonotic infection that has been reported worldwide, including in every state in the United States. The “Q” comes from “query” fever, the name of the disease until its etiologic agent was identified in the 1930s. *C. burnetii* infection usually is asymptomatic in animals, but can cause abortions when introduced into naïve herds, particularly in goats. Many different species can be infected, although cattle, sheep, and goats are the primary reservoirs for human infection. Tick vectors may be important for maintaining animal and bird reservoirs but are not believed to be important in transmission to humans. Humans most often acquire infection by inhalation of fine-particle aerosols of *C. burnetii* generated from birthing fluids or other excreta of infected animals or through inhalation of dust contaminated by these materials. Infection can occur by exposure to contaminated materials, such as wool, straw, bedding, or laundry. Windborne particles containing infectious organisms can travel long distances, contributing to sporadic cases for which no apparent animal contact can be demonstrated. Unpasteurized dairy products also can contain the organism.¹ Seasonal trends occur in farming areas with predictable frequency, and the disease often coincides with the livestock birthing season in spring.

The **incubation period** is 14 to 22 days, with a range from 9 to 39 days, depending on the inoculum size. Chronic Q fever can develop months to years after initial infection.

DIAGNOSTIC TESTS: Serologic evidence of a fourfold increase in phase II immunoglobulin (Ig) G via immunofluorescent assays (IFAs) between paired sera obtained 3 to 6 weeks apart is the most commonly used method to diagnose acute Q fever. A single high serum phase II IgG titer ($\geq 1:128$) by IFA in the convalescent stage may be considered as evidence of probable infection. Confirmation of persistent (chronic) Q fever is based on an increasing phase I IgG titer (typically $\geq 1:1024$) **and** an identifiable nidus of infection (eg, endocarditis, vascular infection, osteomyelitis, chronic hepatitis). Use

¹ American Academy of Pediatrics, Committee on Infectious Diseases, Committee on Nutrition. Consumption of raw or unpasteurized milk and milk products by pregnant women and children. *Pediatrics*. 2014;133(1):175-179 (Reaffirmed November 2019)

of a nucleic acid amplification test (NAAT) on whole blood or serum may be useful in the first 2 weeks of symptom onset and before antimicrobial administration. Although a positive NAAT result can confirm the diagnosis, a negative NAAT result does not rule out Q fever. NAATs and serologic testing for *C burnetii* are available through state public health laboratories and from some commercial diagnostic laboratories. Detection of *C burnetii* in tissues (eg, heart valve) by immunohistochemistry or NAAT can also confirm a diagnosis of chronic Q fever. However, NAAT results may be negative in up to 66% of patients with endocarditis attributable to Q fever. Isolation of *C burnetii* from blood or tissue using tissue culture, embryonated eggs, or animal inoculation can be performed only in special laboratories with biosafety level 3 facilities because of the potential hazard to laboratory workers.

TREATMENT: Acute Q fever generally is a self-limited illness, and many patients recover without antimicrobial therapy. However, early treatment is effective in shortening illness duration and symptom severity and should be initiated in all symptomatic patients. For symptomatic patients with suspected Q fever, immediate empiric therapy should be given because laboratory results are often negative early in the illness onset before the production of quantifiable antibody. Doxycycline administered for 14 days is the drug of choice for patients with severe infections and can be used for acute Q fever regardless of patient age. Pregnant people and patients allergic to doxycycline can be treated with trimethoprim-sulfamethoxazole.

Chronic Q fever is much more difficult to treat, and relapses can occur despite appropriate therapy, necessitating repeated courses of therapy. For Q fever endocarditis in adults, the recommended therapy is a combination of doxycycline and hydroxychloroquine for a minimum of 18 months. There are limited data available on effective treatment of chronic Q fever in children, and in some cases, surgical replacement of infected tissue and/or surgical débridement may be required. In the few cases of pediatric chronic Q fever in the published literature, the combination of doxycycline plus hydroxychloroquine has been the most commonly used treatment.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended for routine care. Airborne precautions should be used for patients who are undergoing procedures that could cause aerosolization or for pregnant people with Q fever who are delivering.

CONTROL MEASURES: Strict adherence to proper hygiene when handling infected parturient animals or their excreta can help decrease the risk of infection in the farm setting, as can ensuring that people do not consume unpasteurized milk and milk products.¹ Improved prescreening of animal herds used by research facilities may decrease the risk of infection. Biosafety level 2 practices and facilities are recommended for nonpropagative laboratory procedures involving *C burnetii* and biosafety level 3 practices for all propagative procedures and necropsy of infected animals. Special safety practices are recommended during high-risk worker exposures in biomedical facilities that house sheep and goats. Vaccines for domestic animals and people working in high-risk occupations have been developed but are not licensed in the United States. A small number of high-risk children in Australia have safely received the vaccine.

¹ American Academy of Pediatrics, Committee on Infectious Diseases, Committee on Nutrition. Consumption of raw or unpasteurized milk and milk products by pregnant women and children. *Pediatrics*. 2014;133(1):175-179 (Reaffirmed November 2019)

Additional information about Q fever, is available on the CDC website (www.cdc.gov/qfever/index.html).

Public Health Reporting. Q fever is a nationally notifiable disease, and all human cases should be reported to the state or local health department.

Rabies

CLINICAL MANIFESTATIONS: Infection with rabies virus and other lyssaviruses characteristically produces nonspecific prodromal symptoms (eg, low grade fever, myalgias) followed by an acute illness with rapidly progressive central nervous system manifestations that may include anxiety, radicular pain, dysesthesia or pruritus, hydrophobia, unconsciousness, and dysautonomia. Some patients may have paralysis. Illness almost invariably progresses to death. The differential diagnosis of acute encephalitic illnesses of unknown cause or with features of Guillain-Barré syndrome should include rabies.

ETIOLOGY: Rabies virus is a single-stranded RNA virus classified in the *Rhabdoviridae* family, *Lyssavirus* genus. The genus *Lyssavirus* currently contains 17 species and 1 related unclassified virus species divided into 3 phylogroups.

EPIDEMIOLOGY: Understanding the epidemiology of rabies has been aided by viral variant identification using monoclonal antibodies and nucleotide sequencing. In the United States, human cases have decreased steadily since the 1950s, reflecting widespread immunization of dogs and the availability of effective human prophylaxis after exposure to a rabid animal. From 2009 through 2021, 21 of 30 cases of human rabies reported in the United States were acquired indigenously. Among the indigenously acquired cases, all but 5 were associated with bats. Despite the large focus of rabies in raccoons in the eastern United States, only 3 cases during this time period were found to have the raccoon rabies virus variant. Historically, 2 cases of human rabies were attributable to probable aerosol exposure in laboratories, and 2 unusual cases have been attributed to possible airborne exposures in caves inhabited by millions of bats, although alternative infection routes cannot be discounted. Transmission also has occurred by transplantation of organs, corneas, and other tissues from patients dying of undiagnosed rabies.

Rabies virus variants from bats perpetuate throughout the United States except Hawaii, which remains “rabies free.” Wildlife, including bats, raccoons, skunks, foxes, and mongoose, are the most important potential sources of infection for humans and domestic animals in the United States and its territories, but the prevalence of each of these differs geographically (see www.cdc.gov/rabies/location/usa/surveillance/wild_animals.html for a map of rabies variants by reservoir hosts). The virus is present in saliva and is transmitted by bites or, rarely, by contamination of mucosa or skin lesions by saliva or other potentially infectious material (eg, neural tissue). Worldwide, most rabies cases in humans result from dog bites in areas where canine rabies is enzootic. The largest burden of disease is in rural, low-income populations because of inadequate implementation of control measures and lack of access to postexposure prophylaxis. Half of the 59 000 estimated yearly global deaths occur in children. The World Health Organization (WHO) has developed a plan in collaboration with partner organizations to eliminate canine rabies by 2030 (www.who.int/publications/i/item/WHO-UCN-NTD-VVE-2021.1). Most rabid dogs, cats, and ferrets shed virus for a few days before there are obvious signs of illness. No case

of human rabies in the United States has been attributed to a dog, cat, or ferret that has remained healthy throughout the standard 10-day period of confinement after an exposure.

The **incubation period** in humans averages 1 to 3 months but ranges from days to years.

DIAGNOSTIC TESTS: Infection in animals can be diagnosed by demonstration of the presence of rabies virus antigen in brain tissue using a direct fluorescent antibody (DFA) test, direct rapid immunohistochemical test (dRIT), or a pan-lyssavirus real-time polymerase chain reaction (PCR) assay. Suspected rabid animals should be euthanized in a manner that preserves brain tissue for appropriate laboratory diagnosis. Diagnosis in suspected human cases can be made postmortem by either immunofluorescent or immunohistochemical examination of brain tissue or by detection of viral nucleotide sequences. Antemortem diagnosis can be made by DFA testing on skin biopsy specimens from the nape of the neck, by isolation of the virus from saliva or other clinical specimens, by detection of antibody in serum (neutralization or indirect fluorescent antibody methods generally are used) in people without a history of immunization and in cerebrospinal fluid (CSF) regardless of immunization history, or by detection of viral nucleotide sequences in saliva, skin, or other tissues. In order for rabies to be ruled out in a patient, specimens from saliva, serum, CSF and skin biopsy must all be tested. No single test is sufficiently sensitive because of the unique nature of rabies pathobiology. State or local health departments should be consulted before submission of specimens to the Centers for Disease Control and Prevention (CDC). Consultation with public health authorities facilitates cases inconsistent with rabies to be identified before specimens are collected and enables appropriate collection and transport of materials to be arranged when rabies testing is indicated. Step-by-step instructions can be found at **www.cdc.gov/rabies/resources/specimen-submission-guidelines.html**.

TREATMENT: There is no specific treatment. Once symptoms have developed, neither rabies vaccine nor rabies immune globulin (RIG) improves the prognosis. Experimental therapies have been tried but are often not successful (for additional information, see **www.cdc.gov/rabies/specific_groups/hcp/human_rabies.html** and **www.mcw.edu/rabies**). Reasons for the rare instances of patient survival after clinical presentation of rabies are poorly understood.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended, including face mask, eye protection, gown, and gloves for procedures and patient care activities that could generate splashes or sprays or when contact with potentially infectious fluids is anticipated. If the patient has bitten another person or potentially infectious material from the patient has contaminated an open wound or mucous membrane, the involved area should be washed thoroughly with soap and water, and risk assessment should be completed to determine whether postexposure prophylaxis should be administered (see Care of Exposed People, p 706).

CONTROL MEASURES: In the United States, animal rabies is common. Education of children to avoid contact with bats and stray or wild animals is of primary importance. Inadvertent contact of family members and pets with potentially rabid animals, such as raccoons, foxes, and skunks, may be decreased by securing garbage and pet food outdoors to decrease attraction of domestic and wild animals. Chimneys and other

potential entrances for wildlife, including bats, should be identified and covered. Bats should be excluded from human living quarters (although some restrictions on exclusion may apply based on the conservation status of the bat species and local regulations). International travelers to areas with enzootic canine rabies should be warned to avoid exposure to stray dogs, and if traveling to an area with enzootic infection where immediate access to medical care or availability of biologic agents is limited, preexposure prophylaxis is indicated in addition to postexposure prophylaxis if an exposure occurs.

Exposure Risk and Decisions to Administer Prophylaxis. Exposure to rabies results from a break in the skin caused by the teeth of a rabid animal or by contamination of scratches, abrasions, or mucous membranes with saliva or other potentially infectious material, such as neural tissue, from a rabid animal. The decision to immunize a potentially exposed person should be made in consultation with the state or local health department, which can provide information on risk of rabies in a particular area for each species of animal and in accordance with the guidance in Table 3.53. Consultation with experts at the CDC may be helpful to guide decisions on prophylaxis (www.cdc.gov/rabies/resources/contacts.html).

In the United States and Puerto Rico, all mammals are believed to be susceptible, but bats, raccoons, skunks, foxes, and mongooses are reservoir species more likely to

Table 3.53. Rabies Postexposure Prophylaxis Guide

Animal Type	Evaluation and Disposition of Animal	Postexposure Prophylaxis Recommendations
Dogs, cats, and ferrets	Healthy and available for 10 days of observation	Prophylaxis only if animal develops signs of rabies ^b
	Rabid or suspected of being rabid ^a	Immediate immunization and RIG ^c
	Unknown (escaped)	Consult public health officials for advice
Bats, skunks, raccoons, foxes, mongooses, ^c and most other carnivores; groundhogs	Regarded as rabid unless geographic area is known to be free of rabies or until animal proven negative by laboratory tests ^a	Immediate immunization and RIG ^c
Livestock, rodents, and lagomorphs (rabbits, hares, and pikas)	Consider individually	Consult public health officials; bites of squirrels, hamsters, guinea pigs, gerbils, chipmunks, rats, mice and other rodents, rabbits, hares, and pikas almost never require rabies postexposure prophylaxis

RIG indicates rabies immune globulin.

^aThe animal should be euthanized and tested as soon as possible. Holding for observation is not recommended. Immunization is discontinued if immunofluorescent test result for the animal is negative.

^bDuring the 10-day observation period, at the first sign of rabies in the biting dog, cat, or ferret, prophylaxis of the exposed person with RIG (human) and vaccine should be initiated. The animal should be euthanized immediately and tested.

^cSee text.

be infected than are other animals.¹ Postexposure prophylaxis typically should be initiated as soon as possible following a high-risk exposure; however, if the animal is available for observation (ie, dogs, cats, ferrets) or can be euthanized and tested (eg, bats and other wildlife), public health authorities may recommend delaying postexposure prophylaxis pending these results. Alternatively, if postexposure prophylaxis has been initiated and subsequent testing shows that the exposing animal was not rabid, postexposure prophylaxis can be discontinued. In many cases, persons who discontinue postexposure prophylaxis after 3 doses can be considered previously immunized. Cattle, horses, and other large mammals occasionally are infected. Bites of small rodents (such as squirrels, hamsters, guinea pigs, gerbils, chipmunks, mice, and rats) and lagomorphs (rabbits, hares, and pikas) rarely require prophylaxis, because these animals almost never are found to be infected with rabies and have not been known to transmit rabies to humans. Rabies in larger rodents, such as groundhogs, is more prevalent and presents a higher risk compared to small rodents. Additional factors must be considered when deciding whether postexposure prophylaxis is indicated. An unprovoked attack may be more suggestive of a rabid animal than a bite that occurs during attempts to feed or handle an animal. Properly immunized dogs, cats, and ferrets have only a minimal chance of developing rabies. However, in rare instances, rabies has developed in properly immunized animals.

Postexposure prophylaxis for rabies is recommended for all people bitten by animals that are suspected to be rabid unless laboratory tests prove that the animal does not have rabies. The CDC Advisory Committee on Immunization Practices (ACIP) recommends dogs, cats, and ferrets be observed for 10 days after exposure, if healthy and available to observe.² If the animal shows clinical signs of rabies, the exposed person should begin prophylaxis. Postexposure prophylaxis also is recommended for people who report an open wound, scratch, or mucous membrane that has been contaminated with saliva or other potentially infectious material (eg, brain tissue) from an animal suspected to be rabid. The injury inflicted by a bat bite or scratch may be small and not readily evident, so any direct contact with a bat should prompt consideration of postexposure prophylaxis regardless of the visible presence of a bite or scratch. The circumstances of contact with a bat may preclude accurate recall (eg, a bat in the room of a deeply sleeping or medicated person or a previously unattended child, especially an infant or toddler who cannot reliably communicate about a potential bite). Hence, postexposure prophylaxis may be indicated, following proper risk assessment, for situations in which a bat physically is present in the same room if a bite or mucous membrane exposure cannot reliably be excluded, unless prompt testing of the bat has excluded rabies virus infection. In the wild, approximately 1% of bats are infected with rabies. Among bats that have contact with humans (and therefore are being tested for rabies), approximately 6% to 12% are infected with rabies. Prophylaxis should be initiated as soon as possible after bites by known or suspected rabid animals.

² Centers for Disease Control and Prevention. Human rabies prevention: United States, 2008. Recommendations of the Advisory Committee on Immunization Practices. *MMWR Recomm Rep.* 2008;57(RR-3):1-28

Risk Assessments for Contacts of Humans With Rabies. Risk assessment for the administration of postexposure prophylaxis is recommended for people who report a possibly infectious exposure (eg, bite, scratch, or open wound or mucous membrane contaminated with saliva or other infectious material, such as tears, CSF, or brain tissue) to a human with rabies. Rabies virus transmission after exposure to a human with rabies has not been documented convincingly in the United States, except after tissue or organ transplantation from donors who died of unsuspected rabies encephalitis. Casual contact with an infected person (eg, by touching a patient) or contact with noninfectious fluids or tissues (eg, blood or feces) alone does not constitute an exposure and is not an indication for prophylaxis. Administration of postexposure prophylaxis to hospital contacts of patients with rabies is required only in situations in which potentially infectious material (such as saliva, CSF, or brain tissue) comes into direct contact with broken skin or mucous membranes. In cases in which people are using the protective equipment appropriate for the given interaction with the patient, there likely will be no risk of exposure.

Handling of Animals Suspected of Having Rabies. An animal that is suspected of having rabies and has bitten a human should be humanely captured, confined, euthanized, and tested. Alternatively, as noted earlier, if the dog, cat, or ferret appears healthy, it can be observed by a veterinarian for 10 days by order of public health authorities. If signs of rabies develop, the animal should be humanely euthanized in a manner to allow its head to be removed and shipped to a qualified laboratory for examination. Instructions for packing can be found at www.cdc.gov/rabies/resources/specimen-submission-guidelines.html; freshly frozen and shipped with dry ice is preferred to refrigerated specimens.

Other biting animals that may have exposed a person to rabies virus should be reported immediately to the state, local health department, animal control or police. Management of animals depends on the species, the circumstances of the bite, and the epidemiology of rabies in the area. Previous immunization of an animal may not preclude the necessity for euthanasia and testing. Because clinical manifestations of rabies in a wild animal cannot be interpreted reliably, a wild mammal suspected of having rabies should be euthanized at once, and its brain should be examined for evidence of rabies virus infection. The exposed person need not receive prophylaxis if the result of rapid examination of the brain by a qualified test is negative for rabies virus infection.

Care of Exposed People.

Local Wound Care. The immediate objective of postexposure prophylaxis is to prevent virus from entering neural tissue. Prompt and thorough local treatment of all lesions is essential, because virus may remain localized to the area of the bite for a variable time. All wounds should be flushed thoroughly and cleaned with soap and water. Quaternary ammonium compounds (such as benzalkonium chloride) no longer are considered superior to soap. The need for tetanus prophylaxis and measures to control bacterial infection should be considered. The wound can be loosely sutured but only after RIG is infiltrated around the wound. For severe facial wounds, which often also are infected with bacteria, better cosmesis results from single sutures, widely placed, several hours after local instillation of RIG, followed by plastic surgery days later.

Prophylaxis (see Table 3.53, p 704). After wound care is completed, concurrent use of passive (RIG) and active (rabies vaccine) immunization is optimal, with the exceptions of people who previously have received complete vaccination regimens (preexposure [see www.cdc.gov/mmwr/volumes/71/wr/mm7118a2.htm] or postexposure) with a cell culture vaccine or people who have been vaccinated with other types of rabies vaccines and have previously had a documented rabies virus-neutralizing antibody titer; these people should receive only vaccine. Prophylaxis should begin as soon as possible after exposure is confirmed, ideally within 24 hours. Although not ideal, a delay of several days or more may not compromise effectiveness, and prophylaxis should be initiated if reasonably indicated, regardless of the interval between exposure and initiation of therapy. Physicians can obtain expert counsel from their state or local health departments when uncertain about administering these products.

Active Immunization (Postexposure). Human diploid cell vaccine (HDCV) and purified chicken embryo cell vaccine (PCECV) are licensed in the United States (see Table 3.54). A 1.0-mL dose of vaccine is injected intramuscularly in the deltoid area or other nongluteal muscle mass (virus-neutralizing antibody responses in adults who received vaccine in the gluteal area sometimes have been inferior to those who received vaccine in the deltoid muscle). In infants and young children, the anterolateral aspect of the thigh is used for intramuscular injection of vaccine. For a previously unvaccinated immunocompetent person, vaccine is administered on the first day of postexposure prophylaxis (day 0), and repeated doses are administered on days 3, 7, and 14

Table 3.54. US Food and Drug Administration-Licensed Rabies Vaccines^a and Rabies Immune Globulin Products

Category	Product	Manufacturer	Dose and Route of Administration
Human rabies vaccine	Human diploid cell vaccine (HDCV) (Imovax Rabies)	Sanofi Pasteur	1 mL, IM
	Purified chicken embryo cell vaccine (PCECV) (RabAvert)	Novartis Vaccines and Diagnostics	1 mL, IM
Rabies immune globulin	Imogam Rabies-HT	Sanofi Pasteur	20 IU/kg, infiltrate around wound ^b
	HyperRab	Grifols USA	20 IU/kg, infiltrate around wound ^b
	Kedrab	Kedrion Biopharma	20 IU/kg, infiltrate around wound ^b

IM indicates intramuscular.

^aRabies vaccine adsorbed (RVA) is licensed in the United States but no longer is distributed in the United States.

^bAny remaining volume should be administered intramuscularly.

after the first dose, for a total of 4 doses,¹ with 1 dose of RIG (based on body weight) administered on day 0. Rabies vaccine and RIG should never be administered in the same muscle.

For a person with altered immunocompetence, postexposure prophylaxis is the same vaccination regimen, however, an antibody titer of the recipient's serum should be evaluated to ensure the minimum antibody titer cut-off (0.5 IU/mL) has been reached or exceeded. The serum specimen can ideally be obtained with the fourth dose of rabies vaccine (ie, day 14) or up to 2 weeks after completion of the series. Serologic testing to document seroconversion after administration of a rabies vaccine series given for postexposure prophylaxis is only advised for recipients who may be immunocompromised, for people with deviations from the recommended vaccination schedule, or for those who initiated vaccination outside of the United States with a product of questionable quality. Ideally, a vaccination series should be initiated and completed with 1 vaccine product unless serious adverse reactions occur. Clinical studies evaluating efficacy or frequency of adverse reactions when the series is completed with a second product have not been conducted.

Care should be taken to ensure that the vaccine is administered intramuscularly. Vaccines licensed in the United States are not approved or packaged for intradermal administration in the postexposure setting, although the World Health Organization (WHO) has recommended postexposure intradermal regimens as an alternative to intramuscular administration for reasons of cost and availability, and these are used in some countries (apps.who.int/iris/handle/10665/272364).

ADVERSE REACTIONS AND PRECAUTIONS WITH HDCV AND PCECV. Reactions are uncommon in children. In adults, mild local reactions, such as pain, erythema, and swelling or itching at the injection site, are reported in 15% to 25%, and mild systemic reactions, such as headache, nausea, abdominal pain, muscle aches, and dizziness, are reported in 10% to 20% of recipients. Immune complex-like reactions in people receiving booster doses of HDCV have been observed, possibly because of interaction between propiolactone contained in the vaccine and human albumin. The reaction, characterized by onset 2 to 21 days after inoculation, begins with generalized urticaria and can include arthralgia, arthritis, angioedema, nausea, vomiting, fever, and malaise. The reaction is not life threatening, occurs in as many as 6% of adults receiving booster doses as part of a preexposure immunization regimen, and is rare in people receiving primary immunization with HDCV. Similar reactions with primary or booster doses have been reported with PCECV. If the patient has a serious allergic reaction to HDCV, PCECV may be administered according to the same schedule as HDCV, and vice-versa. If reactions following vaccine are mild, pretreatment with antihistamines just before the next vaccination can be considered. All suspected serious, systemic, paralytic, or anaphylactic reactions to rabies vaccine should be reported immediately to the Vaccine Adverse Event Reporting System (VAERS).

Rabies vaccines have been safely administered to pregnant people. Pregnancy is not a contraindication to use of vaccine or RIG after exposure.

Passive Immunization (Postexposure). RIG should be used concomitantly with the first dose of vaccine for postexposure prophylaxis to bridge the time between possible

¹ Centers for Disease Control and Prevention. Use of a reduced (4-dose) vaccine schedule for postexposure prophylaxis to prevent human rabies: recommendations of the Advisory Committee on Immunization Practices. *MMWR Recomm Rep*. 2010;59(RR-02):1–9

infection and antibody production induced by the vaccine (see Table 3.54). If vaccine is not available immediately, RIG should be administered alone, and vaccination should be started as soon as possible. If RIG is not available immediately, vaccine should be administered, and RIG should be administered subsequently if obtained within 7 days after initiating vaccination. If administration of both vaccine and RIG is delayed, both should be used regardless of the interval between exposure and treatment.

Only human RIG is available in the United States; the recommended dose is 20 IU/kg. RIG should never be administered in the same syringe as vaccine. As much of the RIG dose as is safely possible should be used to infiltrate the wound(s) if present. The remainder is administered intramuscularly into muscle that is not the same one where rabies vaccine was administered. In cases of multiple severe wounds in which RIG is insufficient for infiltration, dilution in saline solution to an adequate volume (twofold or threefold) has been recommended to ensure that all wound areas receive infiltrate. For children with small muscle mass, it may be necessary to administer RIG at multiple sites. Since 2018, a concentrated RIG product, HyperRab, has been licensed for use in the United States; this product requires 5% dextrose in water to be used as the diluent (rather than normal saline) and may be preferable for infiltrating small wounds (eg, those from a bat). Passive antibody can, in some cases, slightly reduce the level of neutralizing antibodies in the response to rabies vaccines. Therefore, the recommended dose should ideally not be exceeded; however, up to 2 times the recommended RIG dose is typically not clinically significant. Hypersensitivity reactions to human RIG are rare.

Purified equine RIG containing rabies antibodies may be available outside the United States and generally is accompanied by a low rate of serum sickness (less than 1%). Equine RIG is administered at a dose of 40 IU/kg.

Management of Postexposure Prophylaxis In Previously Immunized People. Administration of RIG is not recommended for people who are considered “previously vaccinated.” A previously vaccinated person is defined as someone who has received one of the recommended pre- or postexposure regimens of HDCV, PCECV, or rabies vaccine adsorbed (the latter is a vaccine no longer available in the United States). Also acceptable is receipt of another vaccine along with a documented rabies virus neutralizing titer. Such individuals should receive two 1.0-mL booster doses of HDCV or PCECV; the first dose ideally is administered as soon as possible after exposure, and the second dose is administered 3 days later.

Preexposure Control Measures, Including Vaccination. The relatively low frequency of reactions to HDCV and PCECV has made provision of preexposure vaccination practical for people in high-risk groups, including veterinarians, animal handlers, certain laboratory workers, and people moving or traveling to areas where canine rabies is common. Others, such as spelunkers (cavers) or animal rehabilitators, who may have frequent exposures to bats and other wildlife, also should be considered for preexposure prophylaxis. Please refer to Table 3.55 and the 2022 ACIP guidance for detailed recommendations (www.cdc.gov/mmwr/volumes/71/wr/mm7118a2.htm)¹; note the

Table 3.55. Rabies Preexposure Prophylaxis (PrEP) Recommendations in Immunocompetent and Immunocompromised Individuals^a

Risk Category	Examples of Typical Population	PrEP Rabies Vaccine Recommendation	Assessment of Long-Term Immunogenicity ^b
Elevated risk for unrecognized and recognized exposures, including unusual or high-risk exposures	Individuals working with live rabies virus (research or vaccine production facilities or performing rabies testing)	IM rabies vaccine on days 0 and 7	Check rabies titers every 6 months ; booster if titer <0.5 IU/mL
Elevated risk for unrecognized and recognized exposures	Individuals who frequently handle bats, have contact with bats, enter high-density bat environments, perform animal necropsies	IM rabies vaccine on days 0 and 7	Check rabies titers every 2 years ; booster if titer <0.5 IU/mL
Elevated risk for recognized exposures, sustained risk	Individuals who interact with animals that could be rabid; occupational or recreational activities that involve contact with animals (veterinarians, technicians, animal control officers, persons who handle wildlife reservoir species, spelunkers)	IM rabies vaccine on days 0 and 7	• Check one-time titer during years 1–3 after 2-dose primary series; booster if titer <0.5 IU/mL OR • Provide IM rabies vaccine booster no sooner than day 21 to no later than year 3 after completing the 2-dose primary series
Elevated risk for recognized exposures, risk not sustained	Similar population for risk category 3, but risk duration is ≤3 y	IM rabies vaccine on days 0 and 7	None
Low risk for exposure	Typical person living in the United States	None	None

Adapted from Rao AK, Briggs D, Moore SM, et al. Use of a modified preexposure prophylaxis vaccination schedule to prevent human rabies: recommendations of the Advisory Committee on Immunization Practices—United States, 2022. *MMWR Morb Mortal Wkly Rep.* 2022;71(18):619-627.

^aIf PrEP is provided to an immunocompromised individual, an antibody titer should be checked 2 to 4 weeks after completion of the 2-dose PrEP primary series and all booster doses; administer booster dose if titer <0.5 IU/mL. If 2 booster doses fail to elicit a titer ≥0.5 IU/mL, contact local or state public health authorities to provide case-specific guidance.

^bImmunogenicity defined as rabies titer ≥0.5 IU/mL, obtained 2 to 4 weeks after completing the recommended primary vaccination schedule.

risk categories and recommendations, including those regarding serologic testing. In children, the most common reason for preexposure prophylaxis is travel.

HDCV and PCECV are licensed in the United States for intramuscular administration. The preexposure prophylaxis schedule is two 1-mL intramuscular injections each, administered on days 0 and 7. This series of immunizations has resulted in development of rabies virus-neutralizing antibodies in immunocompetent people properly immunized.

For immunocompromised persons, serum should be collected no sooner than 1 week after the second PrEP dose, but ideally 2 to 4 weeks after. Up to 2 additional doses should be administered before public health authorities are consulted for guidance for persons who have not reached or exceeded the minimum acceptable antibody titer cut-off of 0.5 IU/mL.

Persons who have received preexposure immunization and are exposed to rabies should receive booster doses of vaccine at days 0 and 3 as postexposure prophylaxis (see “Management of Postexposure Prophylaxis in Previously Immunized People,” above).

Public Health. A variety of approved public health measures, including vaccination of dogs, cats, and ferrets and management of the stray dog population and selected wildlife, are used to control rabies in animals.¹ In regions where oral vaccination of wildlife with recombinant rabies vaccine is undertaken, the prevalence of rabies among foxes, coyotes, and raccoons may be decreased. Unvaccinated dogs, cats, ferrets, or other pets bitten by a known rabid animal should be euthanized immediately. If the owner is unwilling to allow the animal to be euthanized, the animal should be placed in strict isolation for 6 months and immunized, at the latest, 1 month before release. The isolation should be instituted under the supervision of the appropriate public health authority. If the exposed animal has been immunized within 1 to 3 years, depending on the vaccine administered and local regulations, the animal should be revaccinated and observed for 45 days.

Public Health Reporting. A confirmatory diagnosis of rabies in humans or animals is reportable to the state health department and notifiable to the CDC. All suspected human cases of rabies should be reported promptly to state or local health departments.

Rat-Bite Fever

CLINICAL MANIFESTATIONS: Rat-bite fever is typically caused by infection with either *Streptobacillus moniliformis* or *Spirillum minus*. *S. moniliformis* infection (streptobacillary fever or Haverhill fever) is characterized by relapsing fever, rash, and migratory polyarthritides, although variable presentations outside this classic triad increasingly are reported. There is an abrupt onset of fever, chills, muscle pain, vomiting, headache, and rarely (unlike *S. minus*) lymphadenopathy. A maculopapular, purpuric, or petechial rash develops, predominantly on the peripheral extremities including the palms and soles, typically within a few days of fever onset. The skin lesions may become purpuric or confluent and may desquamate. The bite site usually heals promptly and exhibits no or minimal inflammation. Nonsuppurative migratory polyarthritides or arthralgia follows

¹ National Association of State Public Health Veterinarians Inc. Compendium of animal rabies prevention and control, 2011. *MMWR Recomm Rep*. 2011;60(RR-6):1-15

in approximately 50% of patients and especially affects the knees, followed by wrists, ankles, and occasionally hips. Symptoms of untreated infection may resolve within 2 weeks, but fever occasionally can relapse for weeks or months, and infection can lead to serious complications including soft tissue and solid-organ abscesses (brain, myocardium), septic arthritis, pneumonia, endocarditis, myocarditis, pericarditis, sepsis, and meningitis. The case fatality rate is 7% to 13% in untreated patients, and fatal cases have been reported in children.

With *S minus* infection (“sodoku”), a period of initial apparent healing at the site of the bite usually is followed by fever and ulceration, discoloration, swelling, and pain at the site (about 1 to 4 weeks later), regional lymphangitis and lymphadenopathy, and a distinctive rash of red or purple plaques. Arthritis is rare.

ETIOLOGY: The major causes of rat-bite fever are *S moniliformis*, a microaerophilic, facultatively anaerobic, gram-negative, pleomorphic bacillus, and *S minus*, a small, gram-negative, spiral-shaped bacterium with bipolar flagellar tufts. Other members of the *Streptobacillus* genus, including *Streptobacillus notomys*, are rare causes of disease.

EPIDEMIOLOGY: Rat-bite fever is a zoonotic illness. The natural habitat of *S moniliformis* and *S minus* is the oropharynx and nasopharynx of rodents. *S moniliformis* is transmitted by bites, scratches, or exposure to oral secretions (eg, via kissing pet rodents) of infected rats, other rodents (eg, mice, gerbils, squirrels, weasels), or rodent-eating animals, including cats and dogs. Infection via contact with contaminated fomites (eg, rat cages or bedding) has been reported rarely. Haverhill fever refers to infection after ingestion of unpasteurized milk, water, or food contaminated with urine containing *S moniliformis* and may be associated with an outbreak of disease. *S minus* is transmitted by bites of rats and mice. *S moniliformis* infection accounts for almost all cases of rat-bite fever in the United States; *S minus* infections occur primarily in Asia.

The **incubation period** for *S moniliformis* usually is less than 7 days but can range from 3 days to 3 weeks; for *S minus*, the **incubation period** is 7 to 21 days.

DIAGNOSTIC TESTS: *S moniliformis* is a fastidious, slow-growing organism isolated from blood, synovial fluid, abscesses, or aspirates from the bite lesion. Growth is best in bacteriologic media enriched with blood (15% rabbit blood seems optimal), serum, and ascitic fluid; cultures should be kept in 5% to 10% carbon dioxide atmosphere at 37°C. Sodium polyanethol sulfonate (SPS), a common anticoagulant in blood culture media, inhibits growth. The laboratory should be alerted that *S moniliformis* is suspected and asked to hold the culture for at least 1 week. Nucleic acid amplification tests (NAATs) are increasingly available in hospital and commercial laboratories. The use of 16S ribosomal RNA gene sequencing and matrix-assisted laser desorption/ionization-time of flight (MALDI-TOF) mass spectrometry improve the diagnostic sensitivity and specificity of culture-based practices.

S minus has not been recovered on artificial media but can be visualized by dark-field microscopy in wet mounts of blood, exudate of a lesion, and lymph nodes or by Giemsa or Wright stain of blood specimens.

TREATMENT: Penicillin G procaine administered intramuscularly or penicillin G administered intravenously for 7 to 10 days is the treatment for rat-bite fever caused by either agent; currently in the United States and other countries, intravenous administration is the more acceptable route. Conversion to oral penicillin after a minimum of 5 days of intravenous therapy can be considered in uncomplicated cases, to complete

a full 10-day course. There is limited experience using ampicillin, cefuroxime, ceftriaxone, and cefotaxime for treatment. Doxycycline or streptomycin can be substituted when a patient has a serious allergy to penicillin or while awaiting laboratory results when rickettsial infections (eg, Rocky Mountain spotted fever) are also among the differential diagnoses. Patients with endocarditis should receive intravenous high-dose penicillin G for at least 4 weeks. The addition of streptomycin or gentamicin for initial therapy may be useful in severe infections including endocarditis.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: Exposed people should be observed for symptoms. Rat control is important in the control of disease. Rodents and other small pets are not recommended for children younger than 5 years or people with weakened immune systems, because they are at a greater risk for serious illness from pathogens that pets can carry. Adults should supervise the touching, feeding, or caring for pets by young children and hand washing for young children. People with frequent rodent exposure should wear gloves and avoid hand-to-mouth contact during animal handling. Regular hand hygiene should be practiced, and surfaces that the rodent contacted should be disinfected.

Respiratory Syncytial Virus

CLINICAL MANIFESTATIONS: Respiratory syncytial virus (RSV) causes acute respiratory tract infections in people of all ages and is one of the most common diseases of early childhood. Most infants infected with RSV experience upper respiratory tract symptoms, and 20% to 30% develop lower respiratory tract disease (eg, bronchiolitis and/or pneumonia) with the first infection. Signs and symptoms of bronchiolitis typically begin with rhinitis and cough, which may progress to increased respiratory effort with tachypnea, wheezing, rales, intercostal and/or subcostal retractions, grunting, and nasal flaring. Fever may, but does not always, occur. Infection with RSV during the first few weeks of life, particularly among preterm infants, may present with more general symptoms such as lethargy, irritability, and poor feeding, accompanied by minimal respiratory tract symptoms; these infants are at risk of developing apnea, even in the absence of other respiratory symptoms.

Most previously healthy infants who develop RSV bronchiolitis do not require hospitalization, and most who are hospitalized improve with supportive care and are discharged after 2 or 3 days. However, approximately 1% to 3% of all children in the first 12 months of life will be hospitalized because of severe RSV lower respiratory tract disease, with the highest rate of RSV hospitalizations occurring in the first 6 months of life. Factors that increase the risk of severe RSV lower respiratory tract illness include preterm birth, especially birth before 29 weeks of gestation; chronic lung disease of prematurity (CLD [formerly called bronchopulmonary dysplasia]); certain types of hemodynamically significant congenital heart disease (CHD), especially conditions associated with pulmonary hypertension; certain immunodeficiency states; and neurologic and neuromuscular conditions. Other risk factors with a more limited correlation with disease severity include low birth weight, maternal smoking during pregnancy, exposure to secondhand smoke in the household, family history of atopy, lack of breastfeeding, and household crowding. Mortality is rare when supportive care is available.

Children hospitalized for RSV bronchiolitis in infancy are at increased risk of recurrent wheezing in early childhood. The association between RSV infection early in life and subsequent asthma, however, remains incompletely understood. Infants who experience severe lower respiratory tract disease (eg, bronchiolitis or pneumonia) from RSV have an increased risk of developing asthma later in life. This association is also seen with other respiratory viral infections, particularly those caused by rhinoviruses. The unresolved question is whether the association between severe infection and reactive airway disease is causal and attributable to direct damage caused by viral replication and the host's response. Alternatively, the association may reflect a common genotype, indicating the same anatomic or immunologic abnormalities that predispose to asthma also predispose to severe viral lower respiratory tract disease. Results from 2 randomized, placebo-controlled trials demonstrated that providing RSV immunoprophylaxis with palivizumab to term and preterm infants had no measurable effect on medically attended wheezing, physician-diagnosed asthma, or lung function at 3 to 6 years of age.

Almost all children are infected by RSV at least once by 24 months of age, and reinfection throughout life is common. Particularly among otherwise healthy older children and adults, recurrent RSV infection manifests as mild upper respiratory tract illness and seldom involves the lower respiratory tract. However, serious disease involving the lower respiratory tract may develop in older children and adults, especially in immunocompromised people and elderly people, particularly those with cardiopulmonary comorbidities. Each year in the United States, the burden of RSV disease in adults ≥ 65 years of age includes approximately 2 200 000 symptomatic illnesses, approximately 177 000 hospitalizations, and approximately 14 000 deaths. This is comparable to influenza disease burden in this older age group.

ETIOLOGY: RSV is an enveloped, nonsegmented, negative-strand RNA virus of the genus *Orthopneumovirus* of the family *Pneumoviridae*. Human RSV exists as 2 antigenic subgroups, A and B, and often these cocirculate during the same RSV season. A consistent correlation between RSV subgroup and disease severity is unclear. The RSV envelope contains 3 surface glycoproteins: glycoprotein G, fusion protein F, and a small hydrophobic protein (SH). Antibodies directed against F and G are neutralizing and protective. G protein is involved in viral attachment to the cell and assists in the ability of the virus to evade host immunity. F protein enables viral penetration of the epithelial cell once viral attachment occurs. In contrast to G protein, F protein is relatively conserved, making it an attractive target for vaccine and monoclonal antibody development.

EPIDEMIOLOGY: Humans are the only source of infection. RSV usually is transmitted by direct or close contact with contaminated secretions, which may occur from exposure to large-particle droplets at short distances (typically <6 feet) or by self-inoculation after touching contaminated surfaces or fomites. Viable RSV can persist on environmental surfaces for several hours and for 30 minutes or more on hands.

RSV typically occurs in annual epidemics beginning in fall and continuing through early spring in temperate climates, although RSV seasonality was unusual

during the COVID-19 pandemic and included significant circulation during the summer.¹ Spread among households and people in child care facilities, including adults, is common. Spread also can occur in the health care setting. The relationship between the presence of infectious virus and the duration of positive molecular testing is unclear. Most infections occur within 7 days of household exposure. The usual period of viral detection by molecular testing is 11 to 14 days, but it may be longer, especially in young infants, who may have positive test results for 3 to 4 weeks, and in immunosuppressed children, who may have positive test results for several months or longer.

The **incubation period** ranges from 2 to 8 days; 4 to 6 days is most common.

DIAGNOSTIC TESTS: Molecular diagnostic tests using reverse transcriptase-polymerase chain reaction (RT-PCR) assays have largely replaced viral isolation and antigen detection assays. Some commercially available assays are designed as multiplex assays to facilitate testing for multiple respiratory viruses from a single nasopharyngeal specimen. Some complex multiplex tests can distinguish between RSV A and B subgroups. Using RT-PCR assays, as many as 30% of symptomatic children will demonstrate the presence of a viral coinfection with 2 or more respiratory viruses. Whether symptomatic children who are coinfecting with more than one virus experience more severe or even less severe disease is not clear.

Testing for seroconversion with acute and convalescent serum specimens is rarely performed for the purposes of diagnosing RSV infection and may not be reliable in infants because the immune response to RSV infection may be limited.

Rapid diagnostic assays, including direct fluorescent antibody (DFA) assays and enzyme or chromatographic immunoassays, are available for detection of viral antigen in nasopharyngeal specimens and are reliable in infants and young children. The sensitivity of these tests is lower than for the molecular diagnostics. As with all antigen detection assays, the predictive value is high during the peak season, but false-positive test results are more likely to occur when the incidence of disease is low, such as in the summer in temperate areas.

In most outpatient settings for children with bronchiolitis, routine specific respiratory viral testing has little effect on management and is not recommended.² Among hospitalized children with bronchiolitis, testing for viral etiology is not routinely recommended, although it can aid in limiting unnecessary antibiotics. Additionally, if patient cohorting is necessary, identification of the specific viral etiology of a respiratory infection will aid hospital infection prevention efforts.

TREATMENT²: No available treatment shortens the course of bronchiolitis or hastens the resolution of symptoms. Management of young children hospitalized with bronchiolitis is supportive and should include hydration, and careful assessment of respiratory status. Supplemental oxygen is recommended only when oxyhemoglobin saturation persistently decreases below 90% in a previously healthy infant. Data

¹ Hamid S, Winn A, Parikh R, et al. Seasonality of respiratory syncytial virus—United States, 2017–2023. *MMWR Morb Mortal Wkly Rep*. 2023;72(14):355–361

² Ralston SL, Lieberthal AS, Meissner HC, et al. Clinical practice guideline: the diagnosis, management, and prevention of bronchiolitis. *Pediatrics*. 2014;134(5):e1474–e1502

support the use of heated humidified high-flow nasal cannula treatment as rescue therapy in infants who have continued hypoxemia despite standard oxygen therapy. Nasal continuous positive airway pressure and heliox have been used for respiratory support in hospitalized infants with bronchiolitis who are at risk for progression to respiratory failure. Only limited data are available on the effectiveness of these therapies in bronchiolitis specifically caused by RSV. Because these therapies, as well as intubation and ventilation, typically are used in severely or critically ill infants with bronchiolitis, they should be used only in consultation with a critical care or pulmonary specialist.

Early studies with aerosolized ribavirin therapy demonstrated a small increase in oxygen saturation in small clinical trials; however, a decrease in the need for mechanical ventilation or a decrease in the length of stay was not shown. Because of limited evidence for a clinically relevant benefit, potential toxic effects, and high cost, routine use of aerosolized ribavirin is not recommended.

Alpha- and Beta-Adrenergic Agents. Beta-adrenergic agents are not recommended for care of wheezing associated with RSV bronchiolitis, and a trial of albuterol no longer is included as a recommended option in the management of RSV bronchiolitis.¹ Evidence does not support the use of nebulized epinephrine in children hospitalized with bronchiolitis.

Glucocorticoid Therapy. Controlled clinical trials among children with bronchiolitis have demonstrated that corticosteroids do not reduce hospital admissions and do not reduce length of stay for inpatients. Corticosteroid treatment should not be used for infants and children with RSV bronchiolitis.

Antimicrobial Therapy. Antimicrobial therapy is not indicated for infants with RSV bronchiolitis or pneumonia unless there is evidence of concurrent bacterial infection. A young child with a distinct viral lower respiratory tract infection (bronchiolitis) has a low risk (<1%) of bacterial meningitis. Bacterial lung infections and bacteremia are uncommon in this setting. Acute otitis media (AOM) caused by RSV or bacterial superinfection may occur in infants with RSV bronchiolitis. Oral antimicrobial therapy for treatment of otitis media may be considered if bulging of the tympanic membrane is present.²

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, contact and droplet precautions are recommended for the duration of RSV-associated illness. In immunocompromised patients, the duration of precautions should be extended because of possible prolonged shedding. In addition, a variety of measures have been demonstrated to reduce the risk of health care-associated transmission, including: (1) placing in single rooms or cohorting of symptomatic patients with dedicated staff; (2) emphasizing hand hygiene before and after direct contact with patients, after contact with inanimate objects in the direct vicinity of patients because of the likelihood of skin contamination from contact with respiratory secretions (alcohol-based gels and antibacterial hand soaps rapidly

¹ Ralston SL, Lieberthal AL, Meissner HC, et al. Clinical practice guideline: the diagnosis, management, and prevention of bronchiolitis. *Pediatrics*. 2014;134(5):e1474-e1502

inactivate RSV), and after glove removal; (3) excluding visitors with current or recent respiratory tract infections from health care settings; and (4) limiting young children visiting during the RSV season.

PREVENTION OF RSV INFECTIONS:

Active Immunization. Two RSV vaccines have been approved by the US Food and Drug Administration (FDA) for use in adults ≥ 60 years of age.¹ Both are recombinant stabilized prefusion F protein (preF) vaccines. One of these products is also approved for use during pregnancy to prevent lower respiratory tract disease (LRTD) and severe LRTD caused by RSV in infants from birth through 6 months of age. The vaccine is administered to the pregnant person as a single intramuscular injection at 32 through 36 weeks' gestation. In clinical trials, vaccine efficacy (VE) for prevention of severe RSV-associated LRTD within 90 days after birth was 81.8% (99.5% confidence interval [CI]: 40.6, 96.3), and within 180 days after birth was 69.4% (97.6% CI: 44.3%, 84.1%). Safety assessments for both the pregnant and infant populations were similar for vaccine and placebo recipients. A slightly higher percentage of premature births occurred in the vaccine recipients compared with placebo recipients (5.6% [95% CI: 4.9%, 6.4%] versus 4.7% [95% CI: 4.1%, 5.5%]), but this did not reach statistical significance and was seen 30 days or more following vaccine administration. The vaccine is recommended for use in all pregnant people at 32 through 36 weeks' gestation, using seasonal administration, to prevent RSV lower respiratory tract infection in infants.

Passive Immunization. Two monoclonal antibodies against RSV have been licensed by the FDA, palivizumab and nirsevimab. Nirsevimab's long half-life allows for administration of a single dose that provides protection across the entire RSV season, while palivizumab requires monthly administration. Nirsevimab is recommended for universal use in all infants under 8 months of age to prevent RSV-associated LRTD (see Nirsevimab Recommendations for First RSV Season, below). It also is recommended for high-risk infants 8 through 19 months of age to prevent RSV LRTD during their second RSV season. Infants in certain risk categories are recommended to receive palivizumab if nirsevimab is not available (see Nirsevimab Recommendations for Second RSV Season, below).

In clinical trials, nirsevimab's pooled efficacy in preventing medically attended RSV-associated LRTD was 79.0% (95% CI: 68.5%, 86.1%), efficacy in preventing RSV-associated LRTD with hospitalization was 80.6% (95% CI: 62.3%, 90.1%), and efficacy in preventing RSV-associated LRTD with ICU admission was 90.0% (95% CI: 16.4%, 98.8%).

Nirsevimab Recommendations for First RSV Season. Recommendations for use of nirsevimab for the infant's first RSV season are dependent on whether the infant's birthing parent received the RSV vaccine during pregnancy and the timing of administration of that vaccine (if given) relative to birth. If the birthing parent: (1) either did not receive RSV vaccine during pregnancy ≥ 14 days prior to birth or maternal RSV vaccine status is unknown; AND (2) the time of year is during

¹ Melgar M, Britton A, Roper LE, et al. Use of respiratory syncytial virus vaccines in older adults: recommendations of the Advisory Committee on Immunization Practices—United States, 2023. *MMWR Morb Mortal Wkly Rep.* 2023;72(34):793–801

October through March (see Timing of Nirsevimab Administration, below); AND (3) the infant is <8 months of age, then the infant is recommended to receive 1 dose of nirsevimab for protection during the first RSV season. The nirsevimab dose is 50 mg for infants weighing <5 kg and 100 mg for infants weighing ≥5 kg. If nirsevimab is administered, palivizumab should not be administered later that season. An algorithm that details which infants under 8 months of age should receive nirsevimab is provided in Fig 3.15.

Nirsevimab Recommendations for Second RSV Season. In addition, 1 dose of nirsevimab is recommended for infants and children 8 months through 19 months of age who are at increased risk for severe RSV disease and are entering their second RSV season (see Timing of Nirsevimab Administration, below). The dose for these older infants is 200 mg, administered as two 100-mg injections given at the same time at different injection sites. Nirsevimab is recommended for use during the second RSV season for patients in the following risk categories:

- Children with chronic lung disease of prematurity who required medical support (chronic corticosteroid therapy, diuretic therapy, or supplemental oxygen) anytime during the 6-month period before the start of the second RSV season
- Children with severe immunocompromise
- Children with cystic fibrosis who have either:
 - ♦ Manifestations of severe lung disease (previous hospitalization for pulmonary exacerbation in the first year of life or abnormalities on chest imaging that persist when stable), or
 - ♦ Weight-for-length <10th percentile
- American Indian or Alaska Native children

An algorithm that details which infants 8 months through 19 months of age should receive nirsevimab is provided in Fig 3.15.

Timing of Nirsevimab Administration.¹ Nirsevimab should be administered to eligible infants and children beginning shortly before the start of the RSV season, which in most of the continental United States is from October through the end of March. Infants born shortly before or during the RSV season should receive nirsevimab within 1 week of birth. Nirsevimab administration can occur during the birth hospitalization or in the outpatient setting. Optimal timing for nirsevimab administration is shortly before the RSV season begins; however, nirsevimab may be administered to age-eligible infants and children who have not yet received a dose at any time during the season. Only a single dose of nirsevimab is recommended for an RSV season.

Infants with prolonged birth hospitalizations related to prematurity or other causes should receive nirsevimab shortly before or promptly after hospital discharge. No evidence is available to support use of nirsevimab for prevention of hospital-acquired RSV infection, and nirsevimab is not recommended for this indication.

Because the timing of the onset, peak, and decline of RSV activity may vary geographically, administration schedules can be adjusted based on local epidemiology. RSV seasonality in tropical climates (including southern Florida, Guam, Hawaii,

¹ Jones JM, Fleming-Dutra KE, Prill MM, et al. Use of nirsevimab for the prevention of respiratory syncytial virus disease among infants and young children: recommendations of the Advisory Committee on Immunization Practices—United States, 2023. *MMWR Morb Mortal Wkly Rep.* 2023;72(34):920–925

FIG 3.15. RESPIRATORY SYNCYTIAL VIRUS (RSV) MONOCLONAL ANTIBODY PROPHYLAXIS DECISION ALGORITHM FOR INFANTS <8 MONTHS AND 8 THROUGH 19 MONTHS OF AGE

^aPreterm infants with chronic lung disease of prematurity (CLD); infants with hemodynamically significant congenital heart disease (CHD); preterm infants without CLD or CHD but born before 29 weeks, 0 days gestation who are younger than 12 months at the start of the RSV season; children with anatomic pulmonary abnormalities or neuromuscular disorder; immunocompromised children; children with cystic fibrosis.

^bChildren with CLD who required medical support (chronic corticosteroid therapy, diuretic therapy, or supplemental oxygen) any time during the 6-month period before the start of the second RSV season; severe immunocompromise; cystic fibrosis who have either (1) manifestations of severe lung disease (previous hospitalization for pulmonary exacerbation in the first year of life or abnormalities on chest imaging that persist when stable), or (2) weight-for-length <10th percentile; American Indian or Alaska Native children.

**FIG 3.15. RESPIRATORY SYNCYTIAL VIRUS (RSV)
MONOCLONAL ANTIBODY PROPHYLAXIS DECISION
ALGORITHM FOR INFANTS <8 MONTHS AND 8 THROUGH
19 MONTHS OF AGE, CONTINUED**

^cPreterm infants with CLD requiring require medical support (chronic corticosteroid therapy, diuretic therapy, or supplemental oxygen) during the 6-month period before the start of the second RSV season; immunocompromised children; children with cystic fibrosis with manifestations of severe lung disease (previous hospitalization for pulmonary exacerbation in the first year or abnormalities on chest radiography or chest computed tomography that persist when stable) or weight-for-length less than the 10th percentile.

^dFor recommendations on use of palivizumab, see Ralston SL, Lieberthal AL, Meissner HC, et al. Clinical practice guideline: the diagnosis, management, and prevention of bronchiolitis. *Pediatrics*. 2014;134(5):e1474-e1502; and Caserta MT, O'Leary ST, Munoz FM, Ralston SL; American Academy of Pediatrics, Committee on Infectious Diseases. Technical report. Palivizumab prophylaxis in infants and young children at increased risk of hospitalization for respiratory syncytial virus infection. *Pediatrics*. 2023;152(1):e20230618.

^eIn jurisdictions with seasonality that differs from most of the continental United States (eg, Alaska, jurisdictions with tropical climates), providers should follow state, local, or territorial guidance on timing of administration.

Puerto Rico, US-affiliated Pacific Islands, and US Virgin Islands) might differ from that of most of the continental United States or be unpredictable. In Alaska, RSV seasonality is less predictable, and the duration of RSV activity is often longer than the national average duration. Providers in these jurisdictions should consult state, local, or territorial guidance on timing of nirsevimab administration.

Coadministration With Other Vaccines. Nirsevimab is not expected to interfere with the immune response to other routine childhood immunizations, and simultaneous administration of nirsevimab with age-appropriate vaccines is recommended.

Palivizumab. If nirsevimab is not available, palivizumab may be used in high risk patients in their first or second RSV seasons (see Fig 3.15 for definitions of who qualifies). If nirsevimab becomes available during the course of the season and before the fifth dose of palivizumab, a single dose should be administered and no additional palivizumab doses should be given.

Use of Nirsevimab in Children Who Already Have Had RSV in That Season. Nirsevimab should be administered for the first (or if high risk patients, the second) RSV season regardless of whether the infant has already had an RSV infection at any time previously, including during the current season. Reinfection with RSV, even during the same season, can occur. If there is a shortage of nirsevimab, this recommendation for its use regardless of prior RSV infection may need to be modified until the shortage is resolved. Children who are moderately or severely ill with or without fever including those who have known current RSV infection should defer nirsevimab until recovery from the acute illness.

Cardiopulmonary Bypass. Children undergoing cardiac surgery with cardiopulmonary bypass should receive an additional dose of nirsevimab after surgery during RSV season if age-eligible.

For the first RSV season, if cardiac surgery with cardiopulmonary bypass is performed within 90 days after receiving nirsevimab, an additional dose should be administered based on body weight at the time of the additional dose (50 mg if less than 5 kg and 100 mg if ≥ 5 kg). If cardiac surgery with cardiopulmonary bypass is performed

more than 90 days after receiving nirsevimab, an additional dose of 50 mg, regardless of body weight, should be administered.

For the second RSV season, if cardiac surgery with cardiopulmonary bypass is performed within 90 days after receiving nirsevimab, an additional dose of 200 mg, regardless of body weight, should be administered. If cardiac surgery with cardiopulmonary bypass is performed more than 90 days after receiving nirsevimab, an additional dose of 100 mg, regardless of body weight, should be administered.

Contraindications and Adverse Event Reporting.¹ Nirsevimab is contraindicated in persons with a history of severe allergic reaction (eg, anaphylaxis) after a previous dose or to a product component. Adverse reactions might occur after administration of nirsevimab alone, and should be reported to MedWatch online (www.fda.gov/medwatch), by fax, by mail, or by contacting FDA at 1-800-FDA-1088. Adverse reactions also might occur after the coadministration of nirsevimab with a vaccine, and these reactions should be reported to the Vaccine Adverse Event Reporting System (VAERS), with reports specifying that the patient received nirsevimab on the VAERS form (<https://vaers.hhs.gov>; 1-800-822-7967). When adverse reactions that occur after the coadministration of nirsevimab with a vaccine are reported to VAERS, additional reporting of the same adverse reactions to MedWatch is not necessary.

CONTROL MEASURES: A critical aspect of RSV prevention among high-risk infants is education of parents and other caregivers about the importance of decreasing exposure to and transmission of RSV. Preventive measures include limiting, where feasible, exposure to contagious settings (eg, child care centers); emphasis on hand hygiene in all settings, including the home, especially during periods when contacts of high-risk children have respiratory tract infections; and limiting exposure to secondhand smoke.

Rhinovirus Infections

CLINICAL MANIFESTATIONS: Rhinoviruses are the most frequent cause of the common cold, or rhinosinusitis. Typical clinical manifestations include sore throat, nasal congestion, and nasal discharge that initially is watery and clear but often becomes mucopurulent and viscous after a few days. Malaise, headache, myalgia, low-grade fever, cough, and sneezing may occur. Symptoms typically peak in severity after 2 to 3 days and have a median duration of 7 days but may persist for more than 10 days in approximately 25% of illnesses. Rhinoviruses also cause otitis media and lower respiratory tract infections (eg, bronchiolitis, pneumonia), particularly in infants, and are associated with approximately 60% to 70% of acute exacerbations of asthma in school-aged children.

ETIOLOGY: Rhinoviruses (RVs) are small, nonenveloped, single, positive-stranded RNA viruses classified into 3 species (RV-A, RV-B, and RV-C) in the family *Picornaviridae*, genus *Enterovirus*. Nearly 170 rhinovirus types have been identified by immunologic and molecular methods. Infection confers type-specific immunity, but protection is temporary.

¹Jones JM, Fleming-Dutra KE, Prill MM, et al. Use of nirsevimab for the prevention of respiratory syncytial virus disease among infants and young children: recommendations of the Advisory Committee on Immunization Practices—United States, 2023. *MMWR Morb Mortal Wkly Rep.* 2023;72(34):920–925

EPIDEMIOLOGY: Rhinovirus infection is ubiquitous in human populations. It is most frequent in infancy and early childhood; more than 20% of infants experience their first rhinovirus infection before 6 months of age. Children typically experience 2 to 4 rhinovirus infections each year, and 93% of adults experience at least 1 rhinovirus infection annually. Rhinoviruses may cause up to two thirds of cases of the common cold. They can cause sinusitis and otitis media, either as the sole pathogen or with secondary bacterial infections. Rhinovirus infections are a major viral cause of exacerbations of asthma, cystic fibrosis, and chronic obstructive pulmonary disease and have been detected in the lower respiratory tract in patients of all ages hospitalized with wheezing or pneumonia. Rhinovirus infection is associated with increased mortality in hematopoietic cell transplant recipients.

Person-to-person transmission occurs by self-inoculation of contaminated secretions on hands or by large-particle aerosol spread. Infections occur throughout the year, but peak activity occurs during fall and spring. Multiple types circulate simultaneously, and the prevalent types circulating in a given population change from season to season. Viral shedding in nasopharyngeal secretions is most abundant during the first 2 to 3 days of infection and usually ceases by 7 to 10 days. Viral RNA may be detectable in nasal secretions by molecular testing for as long as 30 days, although low amounts of virus detected by nucleic acid amplification tests (NAATs) in an asymptomatic person are unlikely to result in transmission. Young age and child care attendance are associated with more frequent rhinovirus infections. Those at increased risk for severe illness include those born preterm with or without chronic lung disease, respiratory syncytial virus coinfection, congenital heart disease, underlying pulmonary disease, immunocompromise, and history of atopy in the birthing parent.

The **incubation period** usually is 2 to 3 days.

DIAGNOSTIC TESTS: Rhinovirus infection is diagnosed by detection of virus in respiratory secretions, although a specific viral diagnosis may not be useful clinically in terms of patient management. Because of the lack of common group antigens among the various types, antigen detection is not practical for clinical diagnosis. If a viral diagnosis is necessary, NAATs are the preferred method to identify rhinovirus infections, with several commercial assays cleared by the US Food and Drug Administration. Most of these assays are designed as multiplexed tests that detect a wide variety of viral and, in some cases, bacterial respiratory pathogens. In general, these assays cannot clearly distinguish rhinoviruses from enteroviruses because of the genetic similarity of the 2 groups. Given the prevalence of rhinovirus infection and the occurrence of shedding following infection, rhinovirus detection, even in symptomatic patients, may not be causal. Serologic diagnosis of rhinovirus infection is impractical because of the large number of antigenic types and the absence of a common antigen.

TREATMENT: Treatment is supportive. Over-the-counter cough and cold medications are not recommended for use in children younger than 2 years. No specific antiviral therapy is currently available for treatment of rhinovirus infections. Antimicrobial agents should not be used for prevention of secondary bacterial infection, because their use may promote the emergence of resistant bacteria and subsequently

complicate treatment for a bacterial infection, and because of the risk of antibiotic-associated adverse effects (eg, *Clostridioides difficile* disease; see Antimicrobial Resistance and Antimicrobial Stewardship: Appropriate and Judicious Use of Antimicrobial Agents, p 978).

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, droplet precautions are recommended for symptomatic hospitalized infants and children for the duration of illness. Contact precautions should be added if copious moist secretions and close contact are likely to occur (eg, young infants). In symptomatic immunocompromised patients, the duration of contact precautions should be extended because of possible prolonged shedding.

CONTROL MEASURES: Appropriate respiratory hygiene and cough etiquette should be followed. Routine hand washing and alcohol-based hand sanitizers are effective for removal of rhinovirus from the hands.

Rickettsial Diseases

Rickettsial diseases comprise infections caused by bacterial species within the genera *Rickettsia* (endemic and epidemic typhus and spotted fever group rickettsioses), *Orientia* (scrub typhus), *Ehrlichia* (ehrlichiosis), *Anaplasma* (anaplasmosis), *Neoehrlichia*, and *Neorickettsia*. The genus *Rickettsia* is further divided into 4 groups based on serologic and genomic analyses, comprising the typhus group, spotted fever group, ancestral group, and transitional group.

CLINICAL MANIFESTATIONS: Early signs and symptoms can be nonspecific and often mimic viral illness. Rickettsial infections have many features in common. Fever, rash (especially in spotted fever and typhus group rickettsiae), headache, and myalgia are prominent features. The classic rash of Rocky Mountain spotted fever (RMSF) may not appear until 3 to 5 days after onset of symptoms, and approximately 10% of patients do not develop an identifiable rash. One or more inoculation eschars occur with many rickettsial diseases, especially most spotted fever group rickettsioses (but not RMSF), rickettsialpox, and scrub typhus. Systemic endothelial damage of small blood vessels resulting in increased vascular permeability is the hallmark pathologic feature of most severe spotted fever and typhus group rickettsial infections. Some rickettsial diseases, particularly RMSF, Mediterranean spotted fever, epidemic typhus, and scrub typhus, can rapidly become life threatening. Risk factors for severe disease include glucose-6-phosphate dehydrogenase deficiency, being male, and antecedent exposure to sulfonamides.¹

Anecdotal information suggests that prior infection confers some short-term immunity. Documented reinfections with *Rickettsia* and *Ehrlichia* species have been described only rarely.

ETIOLOGY: Rickettsiae are small, coccobacillary gram-negative bacteria that are obligate intracellular pathogens and cannot be grown in cell-free media such as routine blood agar. *Orientia* and *Rickettsia* organisms reside free within the cytosol whereas

¹ The term male refers to sex assigned at birth.

Anaplasmataceae organisms reside in phagosomes. Currently recognized rickettsial pathogens of humans include more than 20 species of *Rickettsia*, 5 species of *Ehrlichia*, at least 2 species each of *Orientia* and *Anaplasma*, and *Neorickettsia sennetsu*. Tick-borne neoehrlichiosis caused by *Candidatus Neoehrlichia mikurensis* is an emerging, increasingly recognized disease in Asia and Europe.

EPIDEMIOLOGY: Rickettsial diseases have various hematophagous (blood-feeding) arthropod vectors that include ticks, fleas, mites, and lice. Except for *Rickettsia prowazekii*, the cause of epidemic typhus, humans are incidental hosts for rickettsial pathogens. Rickettsial life cycles typically involve one or more arthropod species as well as various mammalian reservoirs or amplifying hosts, and transmission to humans occurs during environmental or occupational exposures to infected arthropods. Geographic and seasonal occurrences of each rickettsial disease are related directly to distributions and life cycles of the specific vector.

Incubation periods vary according to organism (see disease-specific chapters in Section 3).

Other Global Rickettsial Spotted Fever Infections. Other, epidemiologically distinct, flea-borne and tick-borne spotted fever rickettsioses have been recognized (also see www.cdc.gov/otherspottedfever/). These diseases can affect people living in, traveling to, or returning from areas where these pathogens are endemic. These infections have clinical and pathologic features that vary widely in severity. Most tick-borne rickettsioses present with an eschar at the site of the tick bite, and some present without rash or a sparse rash. Information about spotted fevers occurring outside the United States can be found at www.cdc.gov/otherspottedfever/imported/index.html. Causative agents of spotted fevers in the United States other than *R. rickettsii* and of other rickettsial diseases most important for travelers include the following:

- *Rickettsia africae*, the causative agent of African tick bite fever that is endemic in sub-Saharan Africa, Oceania, and some Caribbean islands.
- *Rickettsia akari*, the causative agent of rickettsialpox, which occurs sporadically throughout the United States but is often reported from metropolitan centers in the eastern United States, particularly New York City (see Rickettsialpox, p 726).
- *Rickettsia conorii* and subspecies, the causative agents of Mediterranean spotted fever, Indian tick typhus, Israeli tick typhus, and Astrakhan spotted fever, that are endemic in southern Europe, Africa, the Middle East, and the Indian subcontinent.
- *Rickettsia parkeri*, a causative agent of eschar-associated infections in the Americas.
- *Rickettsia* 364D, the causative agent of Pacific Coast tick fever, an eschar-associated rickettsiosis in California.

DIAGNOSTIC TESTS: Group-specific antibodies are detectable in the serum of most patients by 7 to 10 days after onset of illness, but slower antibody responses can occur, particularly in some diseases of lesser severity, such as African tick bite fever. The utility of serologic testing during the acute illness generally is of limited value, and a negative serologic test result during the initial stage of the illness should never be used to exclude a diagnosis of rickettsial disease. Serologic assays provide an excellent

method of retrospective confirmation when paired serum samples collected during the illness and 2 to 4 weeks later are tested in tandem and demonstrate a fourfold or greater increase in antibody titer. The indirect immunofluorescence antibody assay is recommended in most circumstances but cannot determine the causative agent to the species level. Treatment early in the course of illness can blunt or delay serologic responses. Once present, antibodies can persist for months or longer, and in some areas of the United States, 10% of people may have antibodies against *Rickettsia* or related organisms. Nucleic acid amplification tests (NAATs) can detect rickettsiae in whole blood or tissues collected during the acute stage of illness and before administration of antimicrobial agents; availability of these tests often is limited to reference and research laboratories. Immunohistochemical staining and NAATs of skin biopsy specimens from patients with rash or eschar lesions can help to diagnose rickettsial infections early in the course of disease. NAATs and sequencing of DNA collected during acute infection provide more accurate identification of the etiologic agent than serologic testing.

TREATMENT: Prompt initiation of treatment is indicated for all patients in all age groups with presumptive evidence of any rickettsial disease and is of paramount importance when there is clinical suspicion of a potentially life-threatening infection such as RMSF, ehrlichiosis, epidemic typhus, murine typhus, or scrub typhus. Treatment decisions should be made on the basis of clinical findings and epidemiologic data and never should be delayed until test results are known, because confirmatory laboratory tests are rarely available early in the course of illness. Therapy is less effective in preventing complications when disease remains untreated into the second week of illness. For all ages, the drug of choice for all rickettsioses, including RMSF and ehrlichiosis, is doxycycline. Treatment should be continued for at least 3 days after fever subsides and there is evidence of clinical improvement, with a typical minimum duration of therapy of 5 to 7 days. For patients with anaplasmosis, therapy should be extended for 10 days to provide appropriate length of therapy for possible coinfection with *Borrelia burgdorferi*. Antibiotic prophylaxis after a tick bite is not recommended to prevent any rickettsial infection.

CONTROL MEASURES: Limiting exposures to ticks, mites, chiggers, and their associated bites is the primary means of prevention (see Prevention of Mosquito-borne and Tick-borne Infections, p 207).

For more details, the following chapters in Section 3 on rickettsial diseases should be consulted:

- *Ehrlichia*, *Anaplasma*, and Related Infections, p 361 (or www.cdc.gov/ehrlichiosis/).
- Rickettsialpox, p 726.
- Rocky Mountain Spotted Fever, p 727 (or www.cdc.gov/rmsf/).
- Louse-borne Typhus (Epidemic or Sylvatic Typhus), p 932.
- Murine Typhus (Endemic or Flea-borne Typhus), p 934.

Public Health Reporting. Several rickettsial diseases, including spotted fevers, ehrlichiosis, and anaplasmosis, are nationally notifiable diseases and should be reported to state and local health departments.

Rickettsialpox

CLINICAL MANIFESTATIONS: Rickettsialpox is a febrile, eschar-associated illness characterized by generalized, relatively sparse, erythematous, papulovesicular eruptions on the trunk, face, extremities (less often on palms and soles), and occasionally involving the oral mucous membranes. The rash may resemble chickenpox and develops 1 to 4 days after onset of fever and 3 to 10 days after appearance of an eschar at the site of the bite of an infected house mouse mite. Eschars are generally 0.5 to 2.5 cm, are most frequently found on the extremities and torso, and may be nontender or mildly tender. Regional lymph nodes proximal to the inoculation eschar often become enlarged and tender. Without specific antimicrobial therapy, systemic disease lasts approximately 7 to 14 days; manifestations include fever, headache, malaise, and myalgia. Less frequent manifestations include anorexia, vomiting, conjunctivitis, hepatitis, nuchal rigidity, and photophobia. The disease is mild compared with Rocky Mountain spotted fever, and although no rickettsialpox-associated deaths have been described, disease occasionally is severe enough to warrant hospitalization.

ETIOLOGY: Rickettsialpox is caused by *Rickettsia akari*, a gram-negative intracellular bacillus now classified with *Rickettsia felis* and *Rickettsia australis* within the transitional group of the genus *Rickettsia*, so named because they have features of both the spotted fever and typhus groups.

EPIDEMIOLOGY: The natural host for *R akari* in the United States is *Mus musculus*, the common house mouse. The organism is transmitted by the bite of the house mouse mite, *Liponyssoides sanguineus*. Disease risk is heightened in areas infested with house mice. The disease can occur wherever the hosts, pathogens, and humans coexist but most frequently is reported in large urban settings. In the United States, rickettsialpox has been described predominantly in metropolitan centers, especially in New York City, as well as Boston, Baltimore, and other large cities along the Atlantic coast. It has been confirmed in many other countries, including the Netherlands, Croatia, Ukraine, Turkey, Russia, South Korea, South Africa, and Mexico. All age groups can be affected. No seasonal pattern of disease occurs. The disease is not communicable but occurs occasionally among families or people cohabiting a house mouse mite-infested dwelling.

The **incubation period** is 6 to 15 days.

DIAGNOSTIC TESTS: Serologic tests for antibodies reactive with spotted fever group rickettsial antigens are the most frequently used diagnostic assays. Immunoglobulin (Ig) M and IgG are generally detected 7 to 15 days after illness onset. *R akari* can be isolated in cell culture from blood and eschar biopsy specimens during the acute stage of disease, but culture is not attempted routinely. Because antigens of *R akari* have extensive cross-reactivity with antigens of *Rickettsia rickettsii* (the cause of Rocky Mountain spotted fever) and other spotted fever-group rickettsiae, an indirect immunofluorescence antibody assay for *R rickettsii* can be used to demonstrate a fourfold or greater change in antibody titers between acute and convalescent serum specimens obtained 2 to 6 weeks apart. Use of *R akari* antigen is recommended for a more accurate diagnosis but may be available only in specialized research laboratories. Immunohistochemical testing of formalin-fixed, paraffin-embedded eschars or papulovesicle biopsy specimens at specialized reference laboratories can also detect rickettsiae in the samples

and are useful diagnostic techniques, but because of antigenic cross-reactivity these assays are not able to confirm the etiologic agent. A polymerase chain reaction assay for detection of rickettsial DNA with subsequent sequence identification can confirm *R. akari* infection but currently is not cleared by the US Food and Drug Administration for use in the United States.

TREATMENT: Doxycycline is the drug of choice in all age groups. The minimum course of therapy is 5 days. Treatment is continued for at least 3 days after resolution of fever and until there is clinical improvement. Doxycycline shortens the course of disease, and symptoms typically resolve within 12 to 48 hours after initiation of therapy. Chloramphenicol is an alternative drug but carries a risk of serious adverse events and is not available as an oral formulation in the United States. Use of chloramphenicol should be considered only in rare cases, such as for patients with an absolute contraindication to receiving doxycycline, because rickettsialpox usually is mild and self-limited. Untreated rickettsialpox usually resolves within 2 weeks.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Person-to-person spread of rickettsialpox has not been reported. Standard precautions are recommended.

CONTROL MEASURES: Application of residual acaricides can be used in heavily mite-infested environments to eliminate the vector. Rodent-control measures are important in limiting or eliminating spread of rickettsialpox but they should be conducted only in conjunction with acaricide application to ensure vector control. No specific management of exposed people is necessary.

Rocky Mountain Spotted Fever

CLINICAL MANIFESTATIONS: Rocky Mountain spotted fever (RMSF) is a systemic, predominantly small-vessel vasculitis that often involves a characteristic rash. Unlike many other spotted fever rickettsioses, eschars at sites of tick bites do not develop with RMSF. High fever, myalgia, headache (less commonly reported in young children), nausea, vomiting, and malaise are typical presenting symptoms. Abdominal pain and diarrhea can be present and may obscure the diagnosis. Children may also experience peripheral and/or periorbital edema. The rash usually appears 2 to 4 days following the onset of fever; a faint maculopapular rash first appears on the wrists, forearms, or ankles and spreads centripetally to involve the limbs and trunk. The rash associated with RMSF can also involve the palms and soles. Although development of a rash is a useful diagnostic sign, fewer than 50% of patients have a rash during the first 3 days of illness, the early rash may be faint, and rash can be absent altogether in up to 10% of patients. As the disease progresses, the rash can become petechial, which is indicative of worsening small-vessel vasculitis and regional extravasation of red cells. A petechial rash is also indicative of progressive injury to small blood vessels of other organs and tissues. Delayed onset or atypical appearance of the rash is a risk factor for misdiagnosis and poor outcome. Meningismus, altered mental status, cerebral edema leading to life-threatening increases in intracranial pressure, and/or coma can occur with the progression of disease. Thrombocytopenia, elevated liver aminotransferases, and hyponatremia are the laboratory abnormalities seen most frequently and worsen as disease progresses. White blood cell count is often normal until later stages of disease,

but leukopenia and anemia can occur. When appropriate antibiotic therapy is initiated during the first few days of infection, patients typically recover completely, and fever resolves in the first 48 hours of treatment. If appropriate antimicrobial treatment is not initiated or is delayed past the fifth day of symptoms, the illness can be severe or life-threatening and can include prominent central nervous system, cardiac, pulmonary, gastrointestinal tract, and renal involvement; disseminated intravascular coagulation; necrosis of digits and gangrene; and shock leading to death. RMSF can progress rapidly, even in previously healthy people. Case fatality rates of untreated RMSF range from 20% to 80%, with a median time to death of 8 days. Significant long-term sequelae can occur in patients with severe RMSF, even if treated with appropriate antibiotics; these include neurologic (paraparesis; hearing loss; peripheral neuropathy; bladder and bowel incontinence; developmental and language delays; and cerebellar, vestibular, and motor dysfunction) and nonneurologic (disability from limb or digit amputation) sequelae.

ETIOLOGY: *Rickettsia rickettsii*, an obligate, intracellular, gram-negative bacillus and a member of the spotted fever group of rickettsiae, is the causative agent of RMSF. The primary targets of infection in mammalian hosts are endothelial cells lining the small blood vessels of all major tissues and organs. Diffuse small vessel vasculitis and vascular injury leads to increased permeability and tissue edema.

EPIDEMIOLOGY: The pathogen is transmitted to humans by the bites of several genera of hard ticks of the family *Ixodidae*. The principal recognized vectors of *R. rickettsii* are *Dermacentor variabilis* (the American dog tick) in the eastern and central United States and *Dermacentor andersoni* (the Rocky Mountain wood tick) in the northern and western United States. *Rhipicephalus sanguineus* (the brown dog tick) has been confirmed as a vector of *R. rickettsii* in Arizona and Mexico and may play a role in other regions. Ticks and their small mammal hosts serve as reservoirs of the pathogen in nature. Other wild animals and dogs have been found with antibodies to *R. rickettsii*, but their role as natural reservoirs is not clear. Dogs can experience clinical symptoms similar to those described in humans. People with occupational or recreational exposure to the tick vector (eg, pet owners, animal handlers, and people who spend more time outdoors) are at increased risk of exposure to the organism. People of all ages can be infected. The period of highest incidence in the United States is from April to September, although RMSF can occur year-round in certain areas with endemic disease. The geographic ranges of many ticks, including those that transmit *R. rickettsii* are expanding because of climate change. Laboratory-acquired infection is rare. Transmission has occurred on rare occasions by blood transfusion. There have been no documented cases of RMSF transmitted via organ transplantation, although it is theoretically possible.

RMSF is the most severe and frequently fatal rickettsial illness in the United States. Patients at higher risk for severe illness include those in whom treatment was delayed, children younger than 10 years, and patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency. Children younger than 10 years are 5 times more likely than adults to die of RMSF.

Current national surveillance collects data on spotted fever rickettsioses, including RMSF. They are widespread in the United States, with most cases reported in the south Atlantic, southeastern, and south-central states. The incidence of spotted fever

rickettsioses has increased in the past 2 decades; the reported cases in the southwestern United States are largely believed to be secondary to RMSF.

The **incubation period** is approximately 1 week (typical range, 3–12 days).

DIAGNOSTIC TESTS¹: The diagnosis of RMSF must be made using clinical signs and symptoms and can be confirmed later using diagnostic tests. Treatment should never be delayed while awaiting laboratory confirmation or because of lack of history of tick bite; approximately half of RMSF cases occur in people who do not report a tick bite. The indirect immunofluorescence antibody (IFA) assay using *R. rickettsii* antigen is considered the reference standard serologic assay. Both immunoglobulin (Ig) G and IgM antibodies begin to increase approximately 7 to 10 days after onset of symptoms; IgM is less specific, and IgG is the preferred test. Confirmation requires a fourfold or greater increase in antigen-specific IgG between serum specimens collected during the acute (first 1–2 weeks of illness) and convalescent stage (2–6 weeks following resolution of symptoms). An elevated acute titer may represent prior exposure to RMSF or another spotted fever group rickettsiae rather than acute infection, and a negative serologic test in the acute phase does not rule out diagnosis of RMSF. Low-level elevated antibody titers can be an incidental finding in a significant proportion of the general population in some regions. Cross-reactivity can be observed with antigens of other spotted fever group rickettsiae, including *Rickettsia parkeri* and *Rickettsia africae*. Enzyme-linked immunosorbent assays also can be used for assessing antibody presence in acute and convalescent sera but are less useful for quantifying changes in titer values.

RMSF can be diagnosed by detection of *R. rickettsii* DNA in acute whole blood, tissue, and serum specimens by nucleic acid amplification tests (NAATs). *R. rickettsii* typically does not circulate in large numbers in whole blood until advanced stages of disease; assays relying on detection of DNA can lack sensitivity, and a negative result does not rule out RMSF. Specimens used for NAATs should be obtained before doxycycline administration when possible, but initiation of treatment should not be delayed. Diagnosis can also be confirmed by detection of rickettsial DNA in biopsy or autopsy specimens by NAATs or immunohistochemical (IHC) visualization of rickettsiae in tissues, although these assays have limited availability.

R. rickettsii also can be isolated from acute blood specimens or from infected tissues, but culture requires specialized cell culture techniques and a laboratory with a minimum biosafety level 3 designation. Cell culture cultivation of the organism must be confirmed by molecular methods.

TREATMENT¹: Doxycycline is the drug of choice for treatment of RMSF in patients of any age and should be started as soon as RMSF is suspected. Physicians should treat empirically if RMSF is being considered and should not postpone treatment while awaiting laboratory confirmation. Treatment is most effective if initiated in the first 5 days of symptoms, and treatment started after that time is less likely to prevent death or other adverse outcomes. Antimicrobial treatment should be continued until

¹ Biggs HM, Behravesh CB, Bradley KK, et al. Diagnosis and management of tickborne rickettsial diseases: Rocky Mountain spotted fever and other spotted fever group rickettsioses, ehrlichioses, and anaplasmosis—United States. A practical guide for health care and public health professionals. *MMWR Recomm Rep*. 2016;65(RR-2):1–44

the patient has been afebrile for at least 3 days and has demonstrated clinical improvement; the usual minimum duration of therapy is 5 to 7 days but can be longer in severe cases. Resistance to doxycycline or relapses in symptoms after the completion of the recommended course has not been documented. Use of antimicrobial agents other than doxycycline increases risk of mortality. Chloramphenicol can be found in some references as an alternative treatment; however, its use is associated with a higher risk of fatal outcome. Chloramphenicol carries a risk of serious adverse events and is not available as an oral formulation in the United States. Sulfa-containing drugs are associated with clinical worsening and increase the likelihood of death from RMSF. Other antibiotics are not effective. In the case of severe doxycycline allergy, a specialist should be consulted to discuss risks, benefits, and alternatives. Doxycycline desensitization has been described. Experts at the Centers for Disease Control and Prevention (CDC) are available by telephone for consultation with health care providers at 1-800-CDC-INFO (1-800-232-4636).

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: Limiting exposures to ticks and tick bites is the primary means of prevention (see Prevention of Mosquito-borne and Tick-borne Infections, p 207). Prophylactic use of antimicrobial agents to prevent RMSF is not recommended, even in children with a documented tick bite who are asymptomatic. People who were bitten by a tick in an area with endemic disease should be advised to see a health care provider should they develop signs or symptoms of RMSF. No licensed *R. rickettsii* vaccine is available in the United States. Additional information is available on the Centers for Disease Control and Prevention's Web site (www.cdc.gov/rmsf/).

Rotavirus Infections

CLINICAL MANIFESTATIONS: The clinical manifestations of rotavirus vary and depend on whether it is the first infection or a reinfection. After 3 months of age, the first infection generally is the most severe. Infection begins with acute onset of vomiting followed 24 to 48 hours later by watery diarrhea; up to one third of patients will have high fevers. Symptoms usually last for 3 to 7 days but improve over time. In moderate to severe cases or with prolonged diarrhea, additional sequelae including dehydration, electrolyte abnormalities, and acidosis may occur. More severe cases are seen primarily among unvaccinated children 3 through 35 months of age. In certain immunocompromised children, including children with congenital cellular immunodeficiencies or severe combined immunodeficiency (SCID) and children who are hematopoietic cell or solid organ transplant recipients, severe, prolonged, and sometimes fatal rotavirus diarrhea can occur. Rotavirus RNA in cerebrospinal fluid (CSF) has been detected in children with rotavirus-associated seizures.

ETIOLOGY: Rotaviruses are segmented, nonenveloped, double-stranded RNA viruses belonging to the family *Reoviridae*, with at least 10 distinct groups (A through J). Group A viruses are the major causes of human disease, although rotaviruses of groups B and C have also been associated with acute gastroenteritis. An 11-gene typing system is used for rotavirus where the notations Gx-P[x]-Ix-Rx-Cx-Mx-Ax-Nx-Tx-Ex-Hx indicate the genotypes of the 6 structural viral proteins (VP7, VP4, VP6, VP1, VP2, VP3) and the 6 nonstructural proteins (NSP1, NSP2, NSP3, NSP4, NSP5/6), respectively.

The most prevalent genotypes circulating in the United States are: G1P[8], G2P[4], G3P[8], G4P[8], G9P[8], and G12P[8].

EPIDEMIOLOGY: Rotavirus is present in high titer in stools of infected patients several days before and may continue for at least 10 days after onset of clinical disease. Only a small inoculum (<100 viral particles/g of stool) is needed for transmission or to cause infection in a susceptible person, which occurs via the fecal-oral route. Rotavirus can remain viable for weeks to months on contaminated environmental surfaces and fomites (such as toys), which can also lead to transmission. Airborne droplet transmission has not been proven but may play a minor role in disease transmission. Spread within families and institutions is common. Rarely, common-source outbreaks from contaminated water or food have been reported.

The epidemiology and burden of rotavirus disease in the United States has changed dramatically following the introduction of rotavirus vaccines in 2006 and 2008. Before widespread use of these vaccines, rotavirus was the most common cause of community acquired gastroenteritis and health care-associated diarrhea in young children. Since the introduction of rotavirus vaccines in the United States, a biennial pattern has emerged, with small, short seasons (median 9 weeks) beginning in late winter/early spring in some years, alternating with years with extremely low circulation. Beginning in 2008, annual hospitalizations for rotavirus disease among US children younger than 5 years declined by approximately 75%, with an estimated 40 000 to 50 000 fewer rotavirus hospitalizations nationally each year. In case-control evaluations in the United States, the rotavirus vaccines have been found to be approximately 80% to 90% effective against rotavirus disease resulting in hospitalization. The vaccines also are highly effective in reducing emergency department visits for rotavirus disease. During a 4-year period after vaccine introduction, an estimated 177 000 hospitalizations, 242 000 emergency department visits, and 1.1 million outpatient visits for diarrhea were averted among US children younger than 5 years. A 20% reduction in seizure risk has also been associated with rotavirus vaccination.

The **incubation period** for rotavirus is short, usually less than 48 hours.

DIAGNOSTIC TESTS: It is not possible to diagnose rotavirus infection by clinical presentation or nonspecific laboratory tests. Diagnosis of rotavirus infection depends on direct viral detection from fecal specimens. Diagnostic enzyme immunoassays (EIAs) and rapid chromatographic immunoassays for group A rotavirus antigen detection in stool are available commercially. Given the marked reduction in rotavirus disease prevalence because of vaccine use, the positive predictive value of the immunoassays can be expected to be lower, and the negative predictive value can be expected to be higher, compared with the prevaccine period. Polymerase chain reaction (PCR)-based multipathogen detection systems that test stool for a panel of viral, bacterial, and parasitic gastrointestinal tract pathogens, including rotavirus, are being used more frequently. Although the advantages of such PCR-based systems are high throughput, increased sensitivity, and the ability to test for multiple pathogens in a single sample, the probability of coincidental detection of rotaviruses or other potential pathogens that may not be causing current symptoms complicates test interpretation. The virus from rotavirus vaccines can be detected in stool for at least 10 days after immunization.

Research and reference laboratories may have additional diagnostic assays including electron microscopy, polyacrylamide gel electrophoresis (PAGE) of viral RNA with silver staining, and viral culture. Genotyping and nucleotide sequencing can be used

for surveillance purposes to identify circulating rotavirus G and P genotypes. These tests generally are not used for clinical diagnosis of rotavirus disease.

TREATMENT: No specific antiviral therapy is available. Oral or parenteral fluids and electrolytes are given to prevent or correct dehydration. Breastfeeding should continue through the diarrheal illness. Orally administered human immune globulin, administered as an investigational therapy in immunocompromised patients with prolonged infection, has decreased viral shedding and shortened the duration of diarrhea.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, contact precautions are indicated for diapered or incontinent children for the duration of illness.

CONTROL MEASURES: Breastfeeding is associated with milder rotavirus disease and should be encouraged (see Breastfeeding and Human Milk, p 135).

Child Care. General measures for interrupting enteric transmission in child care centers are available (see Children in Group Child Care and Schools, p 145). Hand washing and cleaning surfaces with soap and water followed by disinfection is recommended. Bleach solutions or other products with confirmed virucidal activity against rotavirus can be used to inactivate rotavirus and may help prevent disease transmission resulting from contact with environmental surfaces (www.cdc.gov/infectioncontrol/guidelines/disinfection/disinfection-methods/chemical.html). Infants and children with rotavirus diarrhea should be excluded from child care centers until stools are contained in the diaper or when toilet-trained children no longer have accidents using the toilet and when stool frequency becomes no more than 2 stools above that child's normal frequency, even if the stools remain loose.

Vaccines. Two rotavirus vaccines are licensed for use among infants in the United States: a live, oral human-bovine reassortant pentavalent rotavirus (RV5 [RotaTeq, Merck & Co Inc]) vaccine, administered as a 3-dose series; and a live, oral human attenuated monovalent rotavirus (RV1 [Rotarix, GlaxoSmithKline]) vaccine, administered as a 2-dose series. The products differ in composition and schedule of administration. The American Academy of Pediatrics and the Centers for Disease Control and Prevention do not express a preference for either vaccine.

The following are recommendations for use of rotavirus vaccines currently licensed in the United States¹ (see Table 3.56):

- Infants in the United States should be immunized routinely with a licensed rotavirus vaccine.
- Breastfeeding infants should be immunized according to the same schedule as non-breastfed infants.
- Immunization should not be initiated for infants 15 weeks, 0 days of age or older. For infants to whom the first dose of rotavirus vaccine is administered inadvertently at 15 weeks, 0 days of age or older, the remainder of the rotavirus immunization series should be completed according to the schedule.
- The maximum age for the last dose of rotavirus vaccine is 8 months, 0 days.
- The rotavirus vaccine series should be completed with the same product whenever possible. However, immunization should not be deferred if the product used for

¹ Centers for Disease Control and Prevention. Prevention of rotavirus gastroenteritis among infants and children. Recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR Recomm Rep*. 2009;58(RR-2):1–25

Table 3.56. Recommended Schedule for Administration of Rotavirus Vaccine

Recommendation	RV5 (RotaTeq)	RV1 (Rotarix)
Number of doses in series	3	2
Recommended ages for doses	2, 4, and 6 months of age	2 and 4 months of age
Minimum age for first dose	6 weeks of age	6 weeks of age
Maximum age for first dose	14 weeks, 6 days of age	14 weeks, 6 days of age
Minimum interval between doses	4 weeks	4 weeks
Maximum age for last dose	8 months, 0 days of age	8 months, 0 days of age

previous doses is not available or is unknown. In this situation, the health care professional should continue or complete the series with the product available.

- If any dose in the series was RV5 vaccine or the product is unknown for any dose in the series, a total of 3 doses of rotavirus vaccine should be administered.
- Rotavirus vaccine can be administered concurrently with other childhood vaccines.
- Rotavirus vaccine may be administered at any time before, concurrent with, or after administration of any blood product, including antibody-containing blood products.
- If an infant regurgitates, spits out, or vomits during or after vaccine administration, the vaccine dose should not be repeated.
- If a recently immunized infant is hospitalized, standard precautions should be followed.

Considerations in special populations:

- Infants with transient, mild illness, with or without low-grade fever, may receive rotavirus vaccine.
- Infants who have had rotavirus gastroenteritis before receiving the full series of rotavirus immunization should begin or complete the schedule following the standard age and interval recommendations.
- Preterm infants may be immunized if the infant is at least 6 weeks of postnatal age and is clinically stable. Preterm infants should be immunized on the same schedule and with the same precautions as recommended for full-term infants. Rotavirus vaccine virus is shed by some infants in the weeks after vaccination. There are limited published studies examining the transmission of vaccine virus in hospital settings, including neonatal intensive care units, but health care-associated transmission has not been documented. Individual institutions may consider administering rotavirus vaccine at the recommended chronologic age to otherwise eligible infants during hospitalization, including in the neonatal intensive care unit. If not administered earlier, the first dose of vaccine should be administered at the time of discharge to eligible infants.
- Rotavirus vaccine should be administered to human immunodeficiency virus (HIV)-exposed and HIV-infected infants, irrespective of CD4+ T-lymphocyte percentage or count, according to the schedule for uninfected infants (see Human Immunodeficiency Virus Infection, p 489). Rotavirus vaccine may be indicated for infants with other acquired immunocompromising conditions if the potential benefit of protection outweighs the risk of adverse reaction.

- Infants living in households with immunocompromised people can be immunized. Highly immunocompromised patients should avoid handling diapers of infants who have been vaccinated with rotavirus vaccine for 4 weeks after vaccination.
- Infants living in households with pregnant people should be immunized.

Contraindications and precautions:

- Rotavirus vaccine should not be administered to infants who have a history of a severe allergic reaction (eg, anaphylaxis) after a previous dose of rotavirus vaccine or to a vaccine component.
- Known SCID or history of intussusception are contraindications for use of both rotavirus vaccines. Gastroenteritis, including severe diarrhea and prolonged shedding of vaccine virus, has been reported in infants who received live, oral rotavirus vaccines and later identified as having SCID.
- Consultation with experts should be sought prior to administering rotavirus vaccine in infants with altered immunocompetence other than SCID (eg, condition that affects the immune system, including cancer or treatment with drugs such as steroids, chemotherapy, or radiation) or with moderate to severe illness, including gastroenteritis and preexisting chronic intestinal tract disease.
- Infants exposed in utero to biologic response modifiers (BRMs) given to the pregnant person can have detectable drug concentrations for many months following delivery, resulting in concern for immunosuppression among infants in the 12 months after the last dose during pregnancy. Data are sparse on the safety of rotavirus vaccines in infants who were exposed to in utero to BRMs administered to the pregnant person. Considering that rotavirus disease is rarely life threatening in the United States, rotavirus vaccines should be avoided in infants for the first 12 months after the last in utero exposure to most BRMs. Exceptions include certolizumab, which is not transferred across the placenta because of its structure as a pegylated Fab fragment, and likely infliximab, although the data are more sparse for it; rotavirus vaccination of infants can be considered when treatment with either of these BRMs was administered to the pregnant person (see *Biologic Response-Modifying Drugs Used to Decrease Inflammation*, p 104). As more data become available for the other BRMs, recommendations are likely to change and consultation with an expert in pediatric infectious diseases is recommended.
- The tip caps of the prefilled oral applicators of the RV1 vaccine may contain natural rubber latex, so infants with a severe (anaphylactic) allergy to latex (eg, some patients with spina bifida or bladder extrophy) should preferentially receive RV5 vaccine, because dosing tubes of RV5 do not contain natural rubber latex.

Adverse Events. Postmarketing surveillance data from the United States, Australia, Mexico, Canada, and Brazil indicate that there is a small risk of intussusception from the currently licensed rotavirus vaccines. In the United States, the available data suggest the attributable risk is between approximately 1 and 5 excess intussusception cases per 100 000 vaccinated infants. The risk appears to be primarily during the first week following the first or second dose; data from Australia suggest some risk may extend up to 21 days following the first dose. In the United States as well as other parts of the world, the benefits of rotavirus vaccination in preventing severe rotavirus disease outweigh the risk of intussusception. Parents should be informed of the risk, the early signs and symptoms of intussusception, and the need for prompt care if these develop.

Postmarketing strain surveillance in the United States and other countries has revealed that RV5 vaccine reassortant strains have been detected occasionally in stool samples of children with diarrhea. In some of the reports, the reassortant virus seemed to cause diarrheal illness. An RV1 vaccine wild-type reassortant strain has also been reported outside the United States.

In 2010, porcine circovirus or porcine circovirus DNA was detected in both rotavirus vaccines. There is no evidence that this virus is a safety risk or causes illness in humans.

Rubella

CLINICAL MANIFESTATIONS:

Postnatal Rubella. Many cases of postnatal rubella are subclinical, with 25% to 50% of adults being asymptomatic. Clinical disease usually is mild and characterized by a generalized erythematous maculopapular rash, lymphadenopathy, and slight fever. The rash starts on the face, becomes generalized in 24 hours, and lasts a median of 3 days. Lymphadenopathy, which may precede rash, often involves posterior auricular or suboccipital lymph nodes, can be generalized, and lasts between 5 and 8 days. In addition, conjunctivitis, cough, headache, coryza, and palatal enanthema may occur 1 to 5 days prior to the rash. Transient polyarthralgia and polyarthritis rarely occur in children but are common in adolescents and adults, especially among females. Encephalitis (1 in 6000 cases) and thrombocytopenia (1 in 3000 cases) are complications.

Congenital Rubella Syndrome. Maternal rubella during pregnancy can result in miscarriage, fetal death, or a constellation of congenital anomalies (congenital rubella syndrome [CRS]). The most commonly described anomalies/manifestations associated with CRS are ophthalmologic (cataracts, pigmentary retinopathy, microphthalmos, congenital glaucoma), cardiac (patent ductus arteriosus, peripheral pulmonary artery stenosis), auditory (sensorineural hearing impairment), or neurologic (behavioral disorders, meningoencephalitis, microcephaly, developmental disabilities). Neonatal manifestations of CRS include growth restriction, interstitial pneumonitis, radiolucent bone disease, hepatosplenomegaly, thrombocytopenia, and dermal erythropoiesis (so-called “blueberry muffin” lesions). Mild forms of the disease can be associated with few or no obvious clinical manifestations at birth. Congenital defects primarily occur in the infants of people infected during the first trimester of pregnancy. CRS is one of the few known causes of autism.

ETIOLOGY: Rubella virus is an enveloped, positive-stranded RNA virus classified as a *Rubivirus* in the *Matonaviridae* family.

EPIDEMIOLOGY: Humans are the only natural host. Postnatal rubella is transmitted primarily through direct or droplet contact from nasopharyngeal secretions. The peak incidence of infection is during late winter and early spring. Immunity from wild-type or vaccine virus usually is lifelong, but reinfection on rare occasions has been demonstrated and rarely has resulted in CRS.

Rubella virus has been recovered from lens aspirates in children with congenital cataracts for several years, and a small proportion of infants with congenital rubella continue to shed virus in nasopharyngeal secretions and urine for 1 year or more, with transmission to susceptible contacts being possible (see Infection Prevention and Control Measures in Health Care Settings and Control Measures).

Persistent infection of rubella virus has been associated with Fuchs' uveitis, encephalitis, and granulomas, sometimes decades after the initial infection and/or vaccination. Both wild-type and vaccine viruses can persist for decades subclinically before disease emerges. Most cases occur among patients with various primary immunodeficiencies.

Before widespread use of rubella vaccine, rubella was an epidemic disease, occurring in 6- to 9-year cycles, with most cases occurring in children. In the postvaccine era, most cases in the mid-1970s and 1980s occurred in young unimmunized adults in outbreaks on college campuses and in occupational settings. More recent outbreaks have occurred in people born outside the United States or among unimmunized populations. The incidence of rubella in the United States has decreased by more than 99% from the prevaccine era (see Table 1.1, p 20).

Rubella was declared eliminated from the United States in 2004, and since 2012 all rubella cases reported in the United States had evidence that the patients contracted virus outside the United States. In addition, mothers of most children with CRS reported since 1998 were born outside the United States. A national serologic survey from 2009–2010 indicated that among children and adolescents 6 through 19 years of age, rubella seroprevalence was >97%. In 2003, the Pan American Health Organization (PAHO) adopted a resolution calling for elimination of rubella and CRS in the Americas by the year 2010. The strategy consisted of achieving high levels of measles-rubella vaccination coverage in the routine immunization program and in the supplemental vaccination campaigns, including adults, to rapidly reduce the number of people in the country susceptible to acute infection. This goal was accomplished while simultaneously strengthening epidemiologic surveillance to monitor impact. The last confirmed endemic rubella case in the Americas was diagnosed in Argentina in February 2009, and the last confirmed endemic CRS case was reported in Brazil in August 2009. In April 2015, the PAHO International Expert Committee for Verification of Measles and Rubella Elimination verified that the region of the Americas had achieved the rubella and CRS elimination goals.

The average **incubation period** of rubella virus is 17 days, with a range of 12 to 23 days. People infected with rubella are most contagious a week before and after the appearance of rash.

DIAGNOSTIC TESTS: Rubella infection can be confirmed by: (1) detection of rubella viral RNA by reverse transcriptase-polymerase chain reaction (RT-PCR); (2) detection of rubella virus-specific immunoglobulin (Ig) M; (3) a fourfold increase in rubella IgG antibody titer in paired acute and convalescent serum specimens (collected at least 10 days apart); or (4) isolation of rubella virus in cell culture. Neonates in whom there is concern for CRS should have both virologic and serologic testing performed.

Currently, the most reliable method of rubella diagnosis is detection of rubella virus RNA by RT-PCR. In most postnatal cases, viral RNA is detectable by RT-PCR within 3 days of rash onset, and in most congenital cases, viral detection is possible at birth and in some cases for up to 12 months. Nasopharyngeal and throat swab specimens are the preferred specimens for detecting rubella RNA in both suspected CRS and postnatal cases. Viral RNA also may be detectable in blood, urine, and cataract specimens, particularly in infants with congenital infection. Collection of 2 or more specimen types, for example nasopharyngeal swab and urine samples, can increase the likelihood of diagnosis. Genotyping, typically only available in public health laboratories, is critical for tracking the source of infection.

Detection of rubella-specific IgM antibody usually indicates primary infection. Most postnatal rubella cases are IgM-positive by 5 days after symptom onset. A second sample collected 10 days following the first is necessary to confirm or rule out rubella if the day 5 serum specimen is negative. For diagnosis of postnatally acquired rubella, a fourfold or greater increase in antibody titer between acute and convalescent periods or seroconversion between acute and convalescent IgG serum titers also indicate infection. Acute serum must be collected as close to rash onset as possible, preferably in the first 3 days after symptom onset. CRS can be confirmed by detection of rubella-specific IgM antibody usually within the first 6 months of life. Congenital infection also can be confirmed by stable or increasing serum concentrations of rubella-specific IgG over the first 7 to 11 months of life. Diagnosis of congenital rubella infection in children older than 1 year is difficult because of routine vaccination with measles, mumps, and rubella (MMR) vaccine.

Rubella virus can be isolated most consistently from throat or nasal swab specimens (and less consistently from urine) by inoculation of appropriate cell culture. Virus isolation is usually conducted to confirm virus shedding from patients. Laboratory personnel should be notified immediately that rubella is suspected, because specialized cell culture methods are required to isolate and identify the virus. Blood, urine, and cataract specimens also may yield virus, particularly in infants with congenital infection.

TREATMENT: Management is supportive.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, for postnatal rubella droplet precautions are recommended for 7 days after onset of the rash. Contact isolation is indicated for children with proven or suspected congenital rubella until they are at least 1 year of age, unless rubella RT-PCR testing of 2 sets of clinical specimens (eg, throat/nasal swab and urine specimen) obtained 1 month apart after 3 months of age do not detect rubella virus RNA. In addition, droplet precautions can be considered if the infant has a respiratory illness or an aerosol-generating procedure is being performed. Infection control precautions should be considered in children with CRS up to 3 years of age who are hospitalized for congenital cataract extraction.

CONTROL MEASURES:

School and Child Care. Children with postnatal rubella should be excluded from school or child care for 7 days after onset of the rash. During an outbreak, children without evidence of immunity should be immunized or excluded for 21 days after onset of rash of the last case in the outbreak. Children with CRS should be considered contagious as indicated in the section above on Infection Prevention and Control Measures in Health Care Settings. When infants with CRS who are still potentially contagious are considered for placement in a group child care setting, public health authorities should be contacted for guidance. Caregivers of these infants should be made aware of the potential hazard of the infants to susceptible pregnant contacts. Rubella is an enveloped virus; alcohol-based hand rubs are generally effective against enveloped viruses. Surfaces and items contaminated with potentially infectious material should be disinfected. A 1% bleach solution or 70% ethanol are effective at inactivating rubella virus.

Care of Exposed People. Evidence of rubella immunity consists of documented receipt of at least 1 dose of rubella-containing vaccine on or after the first birthday or serologic evidence of immunity. People born prior to 1957 can be considered immune. Documented evidence of rubella immunity is especially important for people who

could become pregnant. Prenatal IgG serologic screening for rubella immunity should be performed for all pregnant people. The cutoff value for rubella immunity is set at 10 IU/mL. People whose levels of rubella-specific IgG antibody are ≥ 10 IU/mL can be considered to have adequate evidence of rubella immunity. Those with rubella-specific IgG titer less than 10 IU/mL should receive rubella vaccine during the immediate postpartum period before discharge from the hospital. Vaccinated people capable of becoming pregnant who have received 1 or 2 doses of rubella-containing vaccine with rubella serum IgG titers less than 10 IU/mL should receive 1 additional dose of MMR vaccine (maximum of 3 doses) and do not need to be retested thereafter for serologic evidence of rubella immunity. When a pregnant person with unknown rubella immunity is exposed to rubella, a blood specimen should be obtained as soon as possible and tested for rubella antibody (IgG and IgM). An aliquot of frozen serum should be stored for possible repeated testing at a later time. The presence of rubella-specific IgG antibody at the time of exposure indicates that the person most likely is immune. If antibody is not detectable, a second blood specimen should be obtained 2 to 3 weeks later and tested concurrently with the frozen first specimen. If the second test result is negative, another blood specimen should be obtained 6 weeks after the exposure and also tested concurrently with the frozen first specimen; a negative test result in both the second and third specimens indicates that infection has not occurred, and a positive test result in the second or third specimen but not the first (seroconversion) indicates recent infection.

Immune Globulin. Administration of immune globulin (IG) to susceptible people experimentally exposed to rubella virus can prevent clinical rubella. However, there have also been many reports of the failure of IG to prevent the anomalies of congenital rubella. For this reason, the routine use of immune globulin intramuscular for the prevention of rubella in an exposed pregnant person is not recommended.

Vaccine. Rubella vaccine administered after exposure has not been demonstrated to prevent illness. Immunization of exposed nonpregnant people may be indicated, because if the exposure did not result in infection, then immunization will protect these people in the future. Immunization of a person who is incubating natural rubella or who already is immune is not associated with an increased risk of adverse reactions.

Rubella Vaccine.^{1,2} The only rubella vaccines licensed in the United States are live attenuated strains. Rubella vaccine is only available in the United States as combination formulations, which include MMR (M-M-R II manufactured by Merck, and Priorix manufactured by GSK) and measles, mumps, rubella, and varicella (MMRV) vaccines. Both vaccines contain the rubella RA 27/3 strain. Vaccine can be administered simultaneously with other vaccines (see Simultaneous Administration of Multiple Vaccines, p 63, and Table 1.9, p 60). Serum antibody to rubella is induced in more than 95% of recipients after a single dose at 12 months or older. Clinical efficacy and challenge studies have demonstrated that 1 dose confers long-term immunity against clinical and

¹ Centers for Disease Control and Prevention. Prevention of measles, rubella, congenital rubella syndrome, and mumps, 2013 summary: recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR Recomm Rep*. 2013;62(RR-4):1-34

² Krow-Lucal E, Marin M, Shepersky L, Bahta L, Loehr J, Dooling K. Measles, mumps, rubella vaccine (PRIORIX): recommendations of the Advisory Committee on Immunization Practices—United States, 2022. *MMWR Morb Mortal Wkly Rep*. 2022;71(46):1465–1470

asymptomatic infection in more than 90% of immunized people. However, both symptomatic (rare) and asymptomatic reinfection have occurred in immunized people.

Because of the 2-dose recommendations for measles- and mumps-containing vaccine (as MMR) and varicella vaccine (as MMRV), 2 doses of rubella vaccine are administered routinely. The 2-dose series provides an added safeguard against primary vaccine failures.

Vaccine Recommendations. At least 1 dose of live attenuated rubella-containing vaccine is recommended for people 12 months or older. The first dose is usually given at 12 through 15 months of age, with a second dose of MMR or MMRV at school entry at 4 through 6 years of age or sooner. People who have not received the dose at school entry should receive their second dose as soon as possible but optimally no later than 11 through 12 years of age (see Measles, p 570).

Special emphasis must continue to be placed on the immunization of at-risk post-pubertal individuals, especially college students, military recruits, recent immigrants, health care professionals, teachers, and child care providers. People who were born in 1957 or after and who have not received at least 1 dose of vaccine or who have no serologic evidence of immunity to rubella are considered susceptible and should be immunized with MMR vaccine. Clinical diagnosis of infection is unreliable and should not be accepted as evidence of immunity.

Specific recommendations are as follows:

- People capable of becoming pregnant who lack documentation of presumptive evidence of rubella immunity should be immunized unless they are pregnant. Rubella-containing vaccine recipients should be advised not to become pregnant for 28 days after vaccination (see Precautions and Contraindications, p 740, for further discussion). Routine serologic testing before immunization of people who are capable of becoming pregnant is unnecessary and is a potential impediment to protection against rubella, because it requires 2 visits.
- During annual health care examinations, family planning visits, and visits to sexually transmitted infection clinics, people capable of becoming pregnant should be assessed for rubella susceptibility and, if deemed susceptible, should be immunized with MMR vaccine.
- Routine prenatal IgG screening for rubella immunity should be performed. If a pregnant person is found to be susceptible, rubella vaccine should be administered during the immediate postpartum period before discharge from the hospital.
- People who have rubella-specific IgG titers of ≥ 10 IU/mL can be considered to have adequate evidence of rubella immunity. Except for people capable of becoming pregnant, people who have an equivocal serologic test result should be considered susceptible to rubella unless they have documented receipt of 1 dose of rubella-containing vaccine or subsequent serologic test results indicate rubella immunity.
- Vaccinated people capable of becoming pregnant who have rubella serum IgG less than 10 IU/mL should receive 1 additional dose of MMR vaccine (maximum of 3 doses) and do not need to be retested thereafter for serologic evidence of rubella immunity.
- Breastfeeding is not a contraindication to postpartum immunization of the birthing parent (for additional information, see Breastfeeding and Human Milk, p 135).
- All susceptible health care personnel who may be exposed to patients with rubella or who provide care for pregnant patients, as well as people who work in educational

institutions or provide child care, should be immunized to prevent infection for themselves and to prevent transmission of rubella to pregnant people.¹

Adverse Reactions.

- Of susceptible children who receive MMR or MMRV vaccines, fever develops in 5% to 15% from 6 to 12 days after immunization. Rash occurs in approximately 5% of immunized people. Mild lymphadenopathy occurs commonly. Febrile seizures occur slightly more frequently among children 12 through 23 months of age after administration of MMRV vaccine compared with MMR and varicella administered as separate injections during the same visit (see Measles, p 570).
- Joint pain, usually in small peripheral joints, has been reported in approximately 0.5% of young children following vaccination with a rubella-containing vaccine. Arthralgia and transient arthritis tend to be more common in susceptible postmenarcheal vaccine recipients, occurring in approximately 25% and 10%, respectively. Joint involvement usually begins 7 to 21 days after immunization and generally is transient. The incidence of joint manifestations after immunization is lower than after wild-type virus infection at the corresponding age.
- Transient paresthesia and pain in the arms and legs have rarely been reported.
- Central nervous system manifestations have been reported, but no causal relationship with rubella vaccine has been established.
- Other reactions that occur after immunization with MMR or MMRV are associated with the measles, mumps, and varicella components of the vaccine (see Measles, p 570, Mumps, p 611, and Varicella-Zoster Infections, p 938).

Precautions and Contraindications.

- **Pregnancy.** Rubella vaccine should not be administered to pregnant people. If vaccine is administered to an unknowingly pregnant person or the pregnancy occurs within 28 days of immunization, the patient should be counseled on the theoretical risks to the fetus. The theoretical maximum risk for CRS after vaccine administration is 0.2%, which is considerably lower than the risk with wild rubella virus or risk of non-CRS-induced congenital defects in pregnancy. Of the 2931 people immunized while pregnant who have been followed globally, 3.3% of offspring had subclinical infection, none had congenital defects, and 96.7% were not infected. In view of these observations, receipt of rubella vaccine during pregnancy is not an indication for termination of pregnancy.
- **Children of pregnant people.** Immunizing susceptible children who have a parent or other household contact who is pregnant does not pose a risk. Most immunized people intermittently shed small amounts of virus from the pharynx 7 to 28 days after immunization, but no evidence of transmission of the vaccine virus from immunized children has been found.
- **Febrile illness.** Children with minor illnesses, such as upper respiratory tract infection, may be immunized (see Understanding Vaccine Evaluation and Safety as an Approach to Addressing Parental Concerns, p 27). Fever is not a contraindication to immunization. However, if other manifestations suggest a more serious illness, the child should not be immunized until recovery has occurred.
- **Recent administration of IG.** IG preparations interfere with immune response to measles vaccine and theoretically may interfere with the serologic response to

¹ Centers for Disease Control and Prevention. Immunization of health-care personnel: recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR Recomm Rep*. 2011;60(RR-7):1-45

rubella vaccine (see Table 1.11, p 69). If rubella vaccine is indicated postpartum for a person who has received anti-Rho (D) IG or blood products, suggested intervals are the same as used between IG administration and measles immunization (see Table 1.11, p 69).

- **Altered immunity.** Immunocompromised patients with disorders associated with increased severity of viral infections should not receive live-virus rubella vaccine (see Immunization and Other Considerations in Immunocompromised Children, p 93). Exceptions are patients with human immunodeficiency virus (HIV) infection who are not severely immunocompromised. MMR vaccine is recommended for all people ≥ 12 months of age with HIV who do not have evidence of severe immunosuppression (see Human Immunodeficiency Virus Infection, p 489). For vaccination purposes, severe immunosuppression for people ≤ 5 years of age is defined as a CD4+ T-lymphocyte percentage $< 15\%$, and for people > 5 years of age is defined as a CD4+ T-lymphocyte percentage $< 15\%$ **or** a CD4+ T-lymphocyte count < 200 lymphocytes/mm³. Severely immunocompromised HIV-infected infants, children, adolescents, and young adults should not receive MMR. MMRV vaccine should not be administered to any infant or child with HIV, regardless of degree of immunosuppression, because of lack of safety data in this population. If possible, children receiving biologic response modifiers, such as anti-tumor necrosis factor-alpha (see Biologic Response-Modifying Drugs Used to Decrease Inflammation, p 104), should be immunized before initiating treatment.
- **Household contacts of immunocompromised people.** The risk of rubella exposure for patients with altered immunity is decreased by immunizing susceptible contacts. Although small amounts of vaccine virus may be isolated from the pharynx, no evidence of transmission of rubella vaccine virus from immunized children to immunocompromised contacts has been found. Precautions and contraindications appropriate for the measles, mumps, and varicella components of MMR or MMRV vaccines also should be reviewed before administration (see Measles, p 570, Mumps, p 611, and Varicella-Zoster Infections, p 938).
- **Corticosteroids.** For patients who have received high doses of corticosteroids (2 mg/kg or greater or more than 20 mg/day) for 14 days or more and who otherwise are not immunocompromised, the recommended interval between stopping the steroids and immunization is at least 4 weeks (see Immunization and Other Considerations in Immunocompromised Children, p 93) after steroids have been discontinued.

Tuberculosis. Tuberculin skin testing or interferon gamma release assay (IGRA) testing is not a prerequisite for MMR immunization. Antituberculosis therapy should be initiated before administering MMR vaccine to people with untreated tuberculosis infection or disease. Tuberculin skin or IGRA testing, if otherwise indicated, can be performed on the day of immunization with MMR vaccine. Otherwise, tuberculin skin or IGRA testing should be postponed for 4 to 6 weeks, because measles immunization temporarily may suppress tuberculin skin test reactivity and possibly affect IGRA testing.

Public Health Reporting. Accurate diagnosis and reporting of CRS are extremely important in assessing control of rubella. All birth defects in which rubella infection is suspected etiologically should be investigated thoroughly and reported to the CDC through local or state health departments.

Salmonella Infections

CLINICAL MANIFESTATIONS:

Nontyphoidal Salmonella Infection. Nontyphoidal *Salmonella* (NTS) infection is associated with a spectrum of illness ranging from asymptomatic gastrointestinal tract carriage to gastroenteritis, urinary tract infection, bacteremia, and focal infections, including meningitis, brain abscess, and osteomyelitis (to which people with sickle cell anemia are predisposed). The most common illness associated with NTS infection is gastroenteritis, with manifestations of diarrhea, abdominal cramps, and fever. The site of infection usually is the distal small intestine and colon. Sustained or intermittent bacteremia can occur, and focal infections are recognized in up to 10% of patients with NTS bacteremia. In the United States, the incidence of invasive NTS is highest among infants. Certain NTS serovars (eg, Dublin, Choleraesuis), although rare, are more likely to result in invasive infection than gastroenteritis. Invasive NTS disease in infants and toddlers, manifesting as severe clinical illness and accompanied by high case fatality rates, is prevalent in many parts of sub-Saharan Africa. *Salmonella* Typhimurium, *Salmonella* Enteritidis, and *Salmonella* I:4,[5],12:i:- (and, to a lesser extent, *Salmonella* Dublin) are the most frequent NTS serovars isolated from blood and cerebrospinal fluid. Severe anemia, malaria, human immunodeficiency virus (HIV), and malnutrition are known risk factors that contribute to the high case fatality rate (10%–30%). However, whole genome sequencing has revealed that most of the *Salmonella* Typhimurium and *Salmonella* I:4,[5],12:i:- isolates from infants and toddlers with invasive NTS disease in sub-Saharan Africa exhibit genomic degradation that renders them distinct from NTS associated with gastroenteritis in North America and Europe.

Enteric Fever. *Salmonella enterica* serovars Typhi, Paratyphi A, Paratyphi B, and Paratyphi C (which occurs rarely) can cause a protracted bacteremic illness referred to collectively as enteric fever (and as typhoid fever and paratyphoid fever). In older children, the onset of enteric fever typically is gradual, with manifestations such as fever, constitutional symptoms (eg, headache, malaise, anorexia, cough, and lethargy), abdominal pain, hepatomegaly, splenomegaly, dactylitis, and rose spots (visible in approximately 30% of patients). Change in mental status and shock may ensue. Myocarditis or endocarditis occur rarely. In infants and toddlers, invasive infection with enteric fever serovars can manifest as a mild, nondescript febrile illness accompanied by self-limited bacteremia or as an invasive infection in association with more severe clinical symptoms and signs, sustained bacteremia, and meningitis. Diarrhea (resembling pea soup) or constipation can be early features. Intestinal perforations or hemorrhage occurs in up to 10% of hospitalized adults and children with enteric fever. Prolonged untreated typhoid increases the risk for intestinal perforations. Relative bradycardia (pulse rate slower than would be expected for a given body temperature) has been considered a common feature of typhoid fever in adults but in children is neither a discriminating feature in the assessment of a febrile child from an area where enteric fever is endemic, nor a feature of the disease per se. Chronic carriage of *S* Typhi (excretion longer than 1 year) following acute typhoid infection is associated with cholelithiasis, increased age, and female sex.¹ Chronic carriage in children is uncommon.

¹ The term female refers to sex assigned at birth.

ETIOLOGY: *Salmonella* bacteria are gram-negative bacilli in the *Enterobacterales* order. Current taxonomy recognizes 3 *Salmonella* species: *S enterica* with 6 subspecies, *Salmonella bongori*, and *Salmonella subterranea*. *S enterica* subspecies *enterica* (also called subspecies I) is responsible for most infections in humans and other warm-blooded animals; the other *S enterica* subspecies and *S bongori* are usually isolated from cold-blooded animals. More than 2600 *Salmonella* serovars have been described. During 2017-2021, the most commonly reported human clinical isolates in the United States were *Salmonella* serovars Enteritidis, Newport, Typhimurium, and Javiana; these serovars accounted for approximately 45% of all human clinical *Salmonella* isolates in the United States during this period (www.cdc.gov/ncezid/dfwed/BEAM-dashboard.html). *S Typhi* belongs to O serogroup 9, along with many other common serovars including Enteritidis and Dublin. The relative prevalence of serovars varies by country, state, and county.

EPIDEMIOLOGY:

Nontyphoidal Salmonella Infection. Every year, NTS organisms are among the most common causes of laboratory-confirmed cases of enteric disease reported to the US Foodborne Diseases Active Surveillance Network (wwwn.cdc.gov/foodnetfast). The incidence of NTS infection is highest in children younger than 4 years. In the United States, rates of invasive infections and mortality are higher in infants, elderly people, and people with hemoglobinopathies (including sickle cell disease) and immunocompromising conditions (eg, malignant neoplasms, HIV infection). Most reported cases are sporadic, but widespread outbreaks, including health care-associated and institutional outbreaks, have been reported.

The incidence of foodborne cases of NTS gastroenteritis ranged from 16.6 to 19.6 per 100 000 in the period of 2015-2019, but fell to 13.3 per 100 000 in 2020. The incidence of diarrheal infections attributable to *Campylobacter* species, Shiga toxin-producing *Escherichia coli*, and *Shigella* species also decreased notably in 2020, likely as a result of the COVID-19 pandemic (wwwn.cdc.gov/foodnetfast and www.cdc.gov/foodnet/reports/prelim-data-intro-2018.html).

The principal reservoirs for NTS organisms include birds, mammals, reptiles, and amphibians. The major food vehicles of transmission to humans in industrialized countries include seeded vegetables and other produce as well as food of animal origin (such as poultry, beef, pork, eggs, and dairy products). Multiple other food vehicles (eg, peanut butter, frozen pot pies, powdered infant formula, cereal, and bakery products) have also been implicated in outbreaks in the United States and Europe. Other modes of transmission include ingestion of contaminated water or close contact with infected animals, mainly poultry (eg, chicks, chickens, ducks), reptiles or amphibians (eg, pet turtles, iguanas, geckos, bearded dragons, lizards, snakes, frogs, toads, newts, salamanders), and rodents (eg, hamsters, mice, guinea pigs) or other mammals (eg, hedgehogs). Reptiles and amphibians that live in tanks or aquariums can contaminate the water with bacteria, which can spread to people. Small turtles with a shell length of less than 4 inches are a well-known source of *Salmonella* infections. Because of this risk, the US Food and Drug Administration (FDA) has banned the interstate sale and distribution of these turtles since 1975. Animal-derived pet foods and treats have been linked to *Salmonella* infections as well, especially in young children.

A risk of transmission to others persists for as long as an infected person sheds NTS organisms. Twelve weeks after infection with the most common NTS serovars, approximately 45% of children younger than 5 years shed organisms, compared with 5% of older children and adults; antimicrobial therapy can prolong shedding. Approximately 1% of adults continue to shed NTS organisms for more than 1 year.

Enteric Fever. Although typhoid fever (approximately 300–400 cases annually) and paratyphoid fever (approximately 100 cases annually) are uncommon in the United States, these infections are highly endemic in many resource-limited countries, particularly in Asia. Consequently, most typhoid fever infections in US residents are acquired during international travel. Unlike NTS serovars, the enteric fever serovars (*S* Typhi, *S* Paratyphi A, *S* Paratyphi B, and *S* Paratyphi C) are restricted to human hosts, in whom they cause both clinical and subclinical infections. Chronic human *S* Typhi carriers (mostly involving chronic infection of the gall bladder in persons with cholelithiasis but occasionally involving infection of the urinary tract) constitute the long-term reservoir of typhoidal *Salmonella* in areas with endemic disease. Infection with enteric fever serovars implies ingestion of a food or water vehicle contaminated by a chronic carrier or a person with acute clinical or subclinical typhoidal *Salmonella* infection.

The **incubation period** for NTS gastroenteritis usually is 6 to 48 hours, but incubation periods of a week or more have been reported. For enteric fever, the **incubation period** usually is 7 to 14 days (range 3–60 days).

DIAGNOSTIC TESTS: Isolation of *Salmonella* from cultures of stool, blood, urine, bile (including duodenal fluid containing bile), and material from foci of infection is diagnostic. NTS gastroenteritis is diagnosed by stool culture or molecular testing; stool cultures should be obtained in all children with bloody diarrhea, or unexplained persistent or severe diarrhea. To evaluate for enteric fever, blood cultures (positive in 60% of patients with enteric fever) and stool cultures (positive in up to 30%) should be obtained for all children who present with unexplained fever after travel to resource-limited countries or contact with someone who has traveled internationally. In addition, blood cultures should be considered for patients at risk of severe illness (eg, age <3 months, those who are immunocompromised or have hemolytic anemia) and in patients with evidence of disseminated infection, bacteremia, or septicemia. Optimal recovery of *Salmonella* from stool is achieved with the use of enrichment broth and multiple selective agar plate media. Definitive identification requires confirmation by phenotypic methods (biochemical profiling and preliminary agglutination with high-quality typing sera, if available, in the hospital or state laboratory), molecular methods (such as polymerase chain reaction [PCR]-based assays), or mass spectrometry of cellular components and O serogroup determination. Serovar determination using validated antisera to identify O group and phase 1 and 2 flagella (H) antigens and Vi polysaccharide capsule or serotyping by whole genome sequencing are helpful for epidemiologic purposes and usually performed at public health laboratories.

Diagnostic tests to detect *Salmonella* antigens by enzyme immunoassay, latex agglutination, and monoclonal antibodies have been developed, as have commercial immunoassays that detect antibodies to antigens of enteric fever serovars. These tests are especially important in areas of the world where typhoid fever is endemic.

Several multiplex PCR platforms for detection of multiple viral, parasitic, and bacterial pathogens, including *Salmonella* organisms, directly in stool have been approved for diagnostic use by the FDA and are commercially available. Nevertheless, clinical microbiology laboratories should maintain culture capabilities for *Salmonella* species because antimicrobial susceptibility testing requires an isolate. In addition, isolates are useful for state public health laboratories to conduct genomic characterization of strains for outbreak detection and epidemiologic investigation.

If enteric fever is suspected, multiple cultures may be needed to isolate the pathogen. Blood, bone marrow, and bile (or duodenal fluid containing bile) comprise the highest-yield clinical specimens for culture. Bone marrow cultures are considered the gold standard and may be positive even when blood cultures are negative. *S* Typhi and *S* Paratyphi are often not recovered from stool culture. The sensitivity of blood culture and bone marrow culture in children with enteric fever is approximately 60% and 90%, respectively. The sensitivity of a single blood culture plus culture of bile (collected from a bile-stained duodenal string) is 90% for detecting *S* Typhi infection in children with clinical enteric fever. Collection of large but age-appropriate blood volumes is needed to optimize recovery of organisms from blood cultures.

The Centers for Disease Control and Prevention does not recommend using serologic tests, such as the Widal test, to diagnose acute typhoid, because these tests are difficult to interpret in populations in whom previous *Salmonella* infection or vaccination may result in a false-positive result. Isolate recovery remains important for guiding antimicrobial therapy for enteric fever, given that cases are increasingly caused by multidrug-resistant strains. Serologic testing may be helpful for identification of chronic carriers, who often have very elevated IgG Vi titers. However, Vi serologic testing is not useful if the individual has received a Vi polysaccharide vaccine within the previous year.

TREATMENT:

Nontyphoidal Salmonella Infection.

- Antimicrobial therapy usually is not indicated for patients with either asymptomatic infection or uncomplicated gastroenteritis caused by NTS serovars, because therapy does not shorten the duration of diarrheal disease, can prolong duration of fecal shedding, and increases symptomatic relapse rate.
- Antimicrobial therapy is recommended for gastroenteritis caused by NTS serovars in people at increased risk for invasive disease, including infants younger than 3 months and people with chronic gastrointestinal tract disease, neoplasms, hemoglobinopathies, HIV infection, or other immunocompromising conditions. It should also be considered for those experiencing severe symptoms, such as severe diarrhea or prolonged or high fever.
- If antimicrobial therapy is initiated in patients in the United States with presumed or proven NTS gastroenteritis, a blood and a stool culture should be obtained prior to antibiotic administration and an initial dose of ceftriaxone should be given. The patient who does not appear ill or have evidence of disseminated infection can be discharged on oral azithromycin pending blood culture results. Once susceptibilities are available, ampicillin/amoxicillin or trimethoprim-sulfamethoxazole may be considered for susceptible strains. A fluoroquinolone is an alternative option. For those who appear ill or have evidence of disseminated infection, hospitalization is required.

- For patients with bacteremia caused by NTS, evaluation for disseminated disease (meningitis, osteoarticular infection, endocarditis) should be considered. Blood cultures should be repeated until negative. Initial therapy with ceftriaxone should be administered. Transition from intravenous ceftriaxone to oral azithromycin or a fluoroquinolone to complete a 7- to 10-day course of therapy may be considered after the blood culture has cleared and focal disease has been excluded. Specific antimicrobial, route of administration, and duration of therapy will depend on antimicrobial susceptibilities, patient age and other host factors, clinical response, and geographic region and availability of antibiotics. Aminoglycosides have reduced efficacy and are not recommended for the treatment of any invasive *Salmonella* infections (including those attributable to *S* Typhi) despite in vitro sensitivity of strains.
- Treatment durations should be extended to 4 weeks for meningitis and 4 to 6 weeks for osteomyelitis or other focal metastatic infections. Evaluation for underlying immunodeficiency (eg, asplenia, HIV) should be considered for patients with invasive infection.
- Antibiotic-resistant nontyphoidal *Salmonella* strains are increasing. Ciprofloxacin-nonsusceptible strains increased from 2% in 2009 to 9% in 2020 (www.cdc.gov/drugresistance/pdf/threats-report/2019-ar-threats-report-508.pdf and wwwn.cdc.gov/narmsnow/).

Enteric Fever.

- Travel history and regional antibiotic resistance patterns should be carefully considered when choosing empiric antibiotic therapy for enteric fever. Most typhoid fever infections diagnosed in the United States are fluoroquinolone nonsusceptible; therefore, clinicians should not use fluoroquinolones as empiric therapy.
- Since 2016, Pakistan has had an ongoing large epidemic of extensively drug-resistant (XDR) *S* Typhi disease with resistance to ceftriaxone, ampicillin, ciprofloxacin, and trimethoprim-sulfamethoxazole (TMP-SMX); isolates are susceptible only to azithromycin and carbapenems.¹ XDR *S* Typhi has spread to many regions of Pakistan, and many confirmed cases of XDR typhoid have been documented in travelers returning from Pakistan to the United States, Canada, European countries, Taiwan, and Australia. More recently, XDR *S* Typhi has also been reported in US residents who did not travel internationally. Although the original Hyderabad, Pakistan XDR strain was sensitive to azithromycin, some areas of South Asia have since reported *S* Typhi with diminished sensitivity to azithromycin. Mass vaccination with World Health Organization prequalified Vi conjugate vaccine (Typhbar-TCV, Bharat Biotech International, India) was conducted in Hyderabad, Pakistan, after which the incidence of XDR cases dropped markedly in the vaccinated population.
- For enteric fever caused by *S* Typhi that is known or suspected to be multidrug resistant (but not XDR), empiric therapy with a parenteral third-generation cephalosporin or azithromycin should be initiated. Azithromycin or a carbapenem antibiotic should be considered if the patient has traveled to Pakistan or Iraq in the 30 days before symptom onset because of ceftriaxone-resistant strains in those countries. Drugs of choice, route of administration, and duration of therapy are based on

¹ François Watkins LK, Winstead A, Appiah GD, et al. Update on extensively drug-resistant *Salmonella* serotype Typhi infections among travelers to or from Pakistan and report of ceftriaxone-resistant *Salmonella* serotype Typhi infections among travelers to Iraq—United States, 2018–2019. *MMWR Morb Mortal Wkly Rep*. 2020;69(20):618–622

susceptibility of the organism (or inferred susceptibility if this is not available), severity and site of infection, host characteristics, and clinical response. The optimal duration of therapy is unclear and depends on the antibiotic used. Most experts would treat for at least 7 to 10 days for uncomplicated disease, although in 1 trial of children with uncomplicated typhoid fever, a 5-day course of azithromycin was effective. If amoxicillin, TMP-SMX, or a fluoroquinolone are used on the basis of susceptibility testing, a 10- to 14-day course of therapy should be considered. Consultation with an expert in infectious diseases is recommended for management of severe and complicated cases.

- Relapse of typhoidal *Salmonella* infection can occur in up to 17% of patients within 4 weeks and is a particular risk for immunocompromised patients, who may require longer duration of treatment as well as retreatment. Relapse rates appear to be lower in those treated with oral ciprofloxacin or azithromycin compared with patients treated with oral TMP-SMX, amoxicillin, or parenteral ceftriaxone.
- The chronic typhoidal serovar carrier state may be eradicated by 4 weeks of oral therapy with ciprofloxacin in approximately 80% of people. High-dose parenteral ampicillin can be used if 4 weeks of oral fluoroquinolone therapy is not tolerated and if the strain is susceptible. Cholecystectomy followed by another course of antimicrobial agents may be indicated in some adults if antimicrobial therapy alone fails.
- Corticosteroids may be beneficial in children with severe enteric fever, which is characterized by delirium, obtundation, stupor, coma, or shock. These drugs should be reserved for critically ill patients in whom relief of manifestations of toxemia may be lifesaving. The usual regimen is high-dose dexamethasone, administered intravenously at an initial dose of 3 mg/kg, followed by 1 mg/kg, every 6 hours, for a total course of 48 hours.
- For enteric fever caused by *S* Typhi acquired from overseas travel, a stool culture should be performed on all contacts who traveled with the index case(s). If results are positive, treatment of contacts should be initiated with azithromycin until susceptibilities are known (due to high likelihood of fluoroquinolone nonsusceptibility) and the contact should be monitored for development of any symptoms. Asymptomatic people in the United States who had contact with the index case(s) but did not travel overseas with them, should be evaluated on a case by case basis to determine necessity for culture of stool samples.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, contact precautions should be used for diapered and incontinent children for the duration of illness. In children with enteric fever, precautions should be continued until culture results are negative for 3 consecutive stool specimens obtained at least 48 hours after cessation of antimicrobial therapy. For XDR typhoid, contact precautions should be used throughout the hospital stay.

CONTROL MEASURES: Important measures include proper food hygiene practices; treated water supplies; proper hand hygiene; adequate sanitation to dispose of human fecal waste; exclusion of infected people from handling food or providing health care; education on the risk of *Salmonella* infections from animal contact; prohibiting the sale of pet turtles; limiting exposure of children younger than 5 years and immunocompromised children to reptiles, amphibians, live poultry, and rodents at home, at school,

and in child care and public settings (see Diseases Transmitted by Animals [Zoonoses], p 1157); reporting cases to appropriate health authorities; and investigating outbreaks. Eggs and other foods of animal origin should be cooked thoroughly. People should not eat raw eggs or foods containing raw eggs or consume unpasteurized milk or raw milk products.¹

Child Care. Outbreaks of *Salmonella* illness in child care centers are rare but do occur. Specific strategies for controlling infection in out-of-home child care involve adherence to hygiene practices, including meticulous hand hygiene, and limiting exposure to certain animals. Animals at higher risk of causing salmonellosis, including reptiles, amphibians, and poultry, are not recommended in schools, child care settings, hospitals, or nursing homes (see Children in Group Child Care and Schools, p 145).

When NTS serovars are identified in a symptomatic child care attendee or staff member with enterocolitis, older children and staff members do not need to be excluded unless they are symptomatic. Stool cultures are not required for asymptomatic contacts. Likewise, children or staff members with NTS enterocolitis do not require negative culture results from stool samples; children can return to child care facilities if stools are contained in the diaper or when toilet-trained children are continent and when stool frequency becomes no more than 2 stools above that child's normal frequency for the time the child is in the program, even if the stools remain loose (see Children in Group Child Care and Schools, p 145).

When *S Typhi* infection is identified in a child care staff member, local or state health departments should be consulted regarding regulations for length of exclusion and testing, which may vary by jurisdiction. A directory of state and territorial, city and county, and tribal health departments can be found at www.cdc.gov/publichealthgateway/healthdirectories/index.html. Because typhoid and paratyphoid infections can be severe (with 77% of US pediatric cases resulting in hospitalization), exclusion of an infected child is warranted at least until negative results for 3 stool samples obtained at least 48 hours after cessation of antimicrobial therapy for *S Typhi* or *S Paratyphi* (see Children in Group Child Care and Schools, p 145).

Typhoid Vaccine. Two typhoid vaccines are licensed by the FDA for use in the United States: live, attenuated oral vaccine Ty21a for people 6 years or older, and the intramuscular Vi capsular polysaccharide vaccine (ViCPS) for people 2 years or older (see Table 3.57). The efficacy of these 2 vaccines ranges from 50% to 80%, but the duration of protection differs notably between the vaccines. Vaccine is selected on the basis of age of the child, need for booster doses, and possible contraindications (see Precautions and Contraindications, p 750) and reactions (see Adverse Events, p 750).

Recommended Use. In the United States, immunization is recommended only for the following people:

- **Travelers to areas where risk of exposure to *S Typhi* is recognized.** Risk is greatest for travelers to the Indian subcontinent, South and Southeast Asia, Latin America, the Caribbean, the Middle East, Africa, and parts of Oceania (eg, Samoa, Fiji) who may have prolonged exposure to contaminated food and drink. Travelers need to be cautioned that typhoid vaccine is not a substitute for careful selection of food and drink (see www.cdc.gov/travel).

¹ American Academy of Pediatrics, Committee on Infectious Diseases and Committee on Nutrition. Consumption of raw or unpasteurized milk and milk products by pregnant women and children. *Pediatrics*. 2014;133(1):175-179 (Reaffirmed November 2019)

Table 3.57. Commercially Available Typhoid Vaccines in the United States

Typhoid Vaccine	Type	Route	Minimum Age of Receipt	No. of Doses ^a	Booster Frequency, y
Ty21a	Live attenuated	Oral	6 years	4	5
ViCPS	Polysaccharide	Intramuscular	2 years	1	2

ViCPS: Vi capsular polysaccharide vaccine.

^aPrimary immunization. For further information on dosage, schedules, and adverse events, see text.

- **People with intimate exposure to a documented chronic *S* Typhi carrier,** as occurs with continued household contact.

- **Laboratory workers with frequent or potential contact with *S* Typhi.**

Dosages. For primary immunization, the following dosage is recommended for each vaccine:

- **Typhoid vaccine live oral Ty21a (Vivotif).** Children (6 years and older) and adults should take 1 Ty21a enteric-coated capsule every other day for a total of 4 capsules. Each capsule of Ty21a should be swallowed whole (not chewed) with liquid, no warmer than 37°C (98°F), approximately 1 hour before a meal. Ty21a should be kept refrigerated, and all 4 doses must be taken to achieve maximal efficacy. Immunization should be completed at least 1 week before possible exposure.
- **Typhoid Vi polysaccharide vaccine (Typhim Vi).** Primary immunization of people 2 years and older with unconjugated Vi capsular polysaccharide vaccine (ViCPS) consists of one 0.5-mL (25-µg) dose administered intramuscularly. ViCPS should be administered at least 2 weeks before possible exposure.
- **Vi conjugate vaccine (not currently licensed or available in the United States).** This is a typhoid conjugate vaccine that consists of the Vi capsular polysaccharide of *S* Typhi linked to tetanus toxoid protein that is manufactured and licensed in India (Typbar-TCV). It is the first Vi conjugate to be prequalified by the World Health Organization (WHO). Typbar-TCV has been recommended by the WHO Scientific Advisory Group of Experts for use in infants as young as 6 months of age on the basis of results of clinical trials establishing its tolerability and immunogenicity in children 6 through 23 months of age, as well as in older children and adults. The vaccine is administered as a single intramuscular dose and provides greater protection against typhoid fever than the other available vaccines. Serum IgG Vi antibody appears to endure for several years among children living in areas with endemic infection. Mass vaccination of children in Hyderabad, Pakistan, demonstrated safety and effectiveness of Typbar-TCV in preventing typhoid attributable to the XDR *S* Typhi strain. Typbar-TCV is not licensed in the United States. However, if families with children younger than 2 years of age (and, hence, not able to receive the Typhim Vi vaccine) but older than 6 months are traveling to live in areas of South Asia where XDR *S* Typhi is circulating, parents of infants and toddlers can be advised to contact local pediatricians to have their young children vaccinated with this vaccine.
- **Protection against *S* Paratyphi A and *S* Paratyphi B.** No currently available vaccine provides protection against *S* Paratyphi A. Results of 2 field trials suggest that Ty21a may provide partial cross-protection against *S* Paratyphi B.

Booster Doses. In circumstances of continued or repeated exposure to *S* Typhi, periodic reimmunization is recommended to maintain immunity.

Continued efficacy for 7 years after immunization with Ty21a vaccine has been demonstrated; however, the manufacturer of Ty21a vaccine recommends reimmunization (completing the entire 4-dose series) every 5 years if continued or renewed exposure to *S* Typhi is expected.

ViCPS elicits a T-lymphocyte independent antigen response that does not create immunologic memory to allow boosting of serum Vi antibody titers following an initial immunization. The manufacturer of ViCPS recommends reimmunization every 2 years if continued or renewed exposure is expected.

Ty21a (which does not express Vi antigen) and ViCPS (which protects by stimulating serum IgG Vi antibody) mediate protection by distinct mechanisms. No data have been reported concerning use of one vaccine administered after primary immunization with the other.

Adverse Events. Ty21a vaccine is very well tolerated, but mild adverse reactions may occur; these include abdominal pain, nausea, diarrhea, vomiting, fever, headache, and rash or urticaria. Reported adverse reactions to ViCPS also are minimal and include fever, headache, malaise, myalgia, and local reaction of tenderness and pain, erythema, or induration of 1 cm or greater.

Precautions and Contraindications. A contraindication to administration of ViCPS vaccine is a history of hypersensitivity to any component of the vaccine. No safety data have been reported for typhoid vaccines in pregnant people. Ty21a vaccine is a live attenuated vaccine and should not be administered to immunocompromised people, including people known to be infected with HIV, pregnant people, or people with a phagocytic cell defect or chronic granulomatous disease.¹ The intramuscular ViCPS may be an alternative, although the expected immune response may not be achieved in some hosts. Ty21a should not be administered during acute febrile illness or gastrointestinal tract illness. Antimalarial drugs mefloquine and chloroquine and the combination antimalarials atovaquone/proguanil and pyrimethamine/sulfadoxine, at doses used for prophylaxis, can be administered with Ty21a. The manufacturer advises that other antimalarial agents be administered at least 3 days after the last dose of Ty21a.² Antimicrobial agents should be avoided from 3 days before the first dose through 3 days after the last dose of Ty21a.

Public Health Reporting. Notification of public health authorities, sending isolates (or specimens), and determination of serovar are of primary importance in detection and investigation of outbreaks.

Scabies

CLINICAL MANIFESTATIONS: Scabies is characterized by an intensely pruritic, erythematous eruption that may include papules, nodules, vesicles, or bullae caused by burrowing of adult female mites in upper layers of the epidermis, creating serpiginous

¹ Rubin LG, Levin MJ, Ljungman P, et al. 2013 IDSA clinical practice guideline for vaccination of the immunocompromised host. *Clin Infect Dis*. 2014;58(3):e44-e100

² Jackson BR, Iqbal S, Mahon B. Updated recommendations for the use of typhoid vaccine—Advisory Committee on Immunization Practices, United States, 2015. *MMWR Morb Mortal Wkly Rep*. 2015;64(11):305-308

burrows. Itching is most intense at night. Sites of predilection in older children and adults are the interdigital folds, flexor aspects of wrists, extensor surfaces of elbows, anterior axillary folds, waistline, thighs, navel, genitalia, areolae, abdomen, intergluteal cleft, and buttocks. In children younger than 2 years, the eruption more often is vesicular and often occurs in areas usually spared in older children and adults, such as the scalp, face, neck, palms, and soles. The eruption is caused by a hypersensitivity reaction to the parasite's proteins and products.

Characteristic scabietic burrows appear as thin, gray or white, serpiginous, thread-like lines. Excoriations are common, and most burrows are obliterated by scratching before a patient seeks medical attention. Occasionally, 2- to 5-mm red-brown nodules are present, particularly on covered parts of the body, such as the genitalia, groin, and axilla. These scabies nodules are a granulomatous response to dead mite antigens and feces; the nodules can persist for weeks and even months after effective treatment. Cutaneous secondary bacterial infection is a frequent complication and usually is caused by *Streptococcus pyogenes* or *Staphylococcus aureus*. Studies have demonstrated a rare correlation between scabies and development of poststreptococcal glomerulonephritis.

Crusted (formerly called Norwegian) scabies is an uncommon clinical syndrome characterized by a large number of mites and widespread, crusted, hyperkeratotic lesions. Crusted scabies usually occurs in people with debilitating conditions, people with developmental disabilities, or people who are immunocompromised, including patients receiving biologic response modifiers. Crusted scabies also can occur in otherwise healthy children after long-term use of topical corticosteroid therapy.

Postscabietic pustulosis is a reactive phenomenon that may follow successful treatment of primary infestation with scabies. Affected infants and young children manifest episodic crops of sterile, pruritic papules and pustules predominantly in an acral distribution, but lesions may extend to a lesser degree onto the torso.

ETIOLOGY: The mite *Sarcoptes scabiei* subspecies *hominis* is the cause of scabies. The adult female burrows in the stratum corneum of the skin and lays eggs. Larvae emerge from the eggs in 2 to 4 days and molt to nymphs and then to adults, which mate and produce new eggs. The entire cycle takes approximately 10 to 17 days. *S. scabiei* subspecies *canis*, acquired from dogs with clinical mange, can cause a self-limited and mild infestation in humans, usually involving the area in direct contact with the infested animal.

EPIDEMIOLOGY: Humans are the source of infestation. Transmission usually occurs through prolonged close, personal contact. Even minimal contact with patients with crusted scabies or their immediate environment can result in transmission because of the large number of mites in exfoliating scales. Infestation acquired from dogs and other animals is uncommon, and these mites do not replicate in humans. Scabies of human origin can be transmitted as long as the patient remains infested and untreated, including during the interval before symptoms develop. Scabies is endemic in many countries and occurs worldwide sporadically and in epidemics, which may be cyclical in some settings. Scabies affects people from all socioeconomic levels without regard to age, gender, or standards of personal hygiene. Scabies in adults may be acquired sexually.¹

¹ Centers for Disease Control and Prevention. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(RR-4):1-187

The **incubation period** in people without previous exposure usually is 4 to 6 weeks. People who previously were infested are sensitized and develop symptoms 1 to 4 days after repeated infestation with the mite; reinfestations usually are milder than the original episode.

DIAGNOSTIC TESTS: Diagnosis of scabies typically is made by clinical examination.¹ Diagnosis can be confirmed by identification of the mite, mite eggs, or scybala (feces) from scrapings of papules or intact burrows, preferably from the terminal portion where the mite generally is found. Mineral oil, microscope immersion oil, or water applied to skin facilitates collection of scrapings. A broad-blade scalpel is used to scrape the burrow. Scrapings and oil can be placed on a slide under a glass coverslip and examined microscopically under low power. Adult female mites average 330 to 450 μm in length. Skin scrapings provide definitive evidence of infestation but have low sensitivity. Handheld dermoscopy (epiluminescence microscopy) has been used to identify in vivo the pigmented mite parts or air bubbles corresponding to infesting mites within the stratum corneum. Reflectance in vivo microscopy and polymerase chain reaction assays on swabbed skin material are promising techniques with improved sensitivity and specificity.

TREATMENT: Topical permethrin 5% cream or off-label use of oral ivermectin both are effective agents for treatment of scabies (see Drugs for Parasitic Infections, p 1068). Most experts recommend starting with topical 5% permethrin cream as the drug of choice, particularly for infants (not approved for infants younger than 2 months), young children, and pregnant or nursing people. Permethrin kills the scabies mite and eggs. For children and adults, lotion or cream containing this scabicide should be applied over the entire body below the head and removed by bathing after 8 to 14 hours. Because scabies can affect the face, scalp, and neck in infants and young children, treatment of the entire head, neck, and body in this age group is required. Special attention should be given to trimming fingernails and ensuring application of medication to these areas. Two (or more) applications, each about a week apart, may be necessary to eliminate all mites.

A Cochrane review found that oral ivermectin is as effective as topical permethrin for treating scabies. Because ivermectin is not ovicidal, it is given as 2 doses, 7 to 14 days apart. Ivermectin is not approved for treatment of scabies by the US Food and Drug Administration (FDA). Oral ivermectin should be considered for patients who have failed treatment or who cannot tolerate topical permethrin.

Alternative drugs include 10% crotamiton cream or lotion (not FDA approved for children), 5% to 10% precipitated sulfur compounded into petrolatum, or Spinosad 0.9% suspension (approved by FDA in 2021 for adults and children 4 years and older). Lindane lotion (currently not available in the United States) generally should not be used for treatment of scabies because of safety concerns and availability of other treatments but may be used if all other medications cannot be tolerated or have failed.

Because scabietic lesions are the result of a hypersensitivity reaction to the mite, itching may not subside for several weeks despite successful treatment. Use of oral antihistamines and topical corticosteroids can help relieve itching. Topical or systemic antimicrobial therapy is indicated for secondary bacterial infections of excoriated lesions.

¹ Engelman D, Yoshizumi J, Hay RJ, et al. The 2020 International Alliance for the Control of Scabies consensus criteria for the diagnosis of scabies. *Br J Dermatol*. 2020;183(5):808-820

Treatment of crusted scabies can be difficult and typically requires multiple doses of both topical and oral therapy. The most commonly recommended medications are 5% topical permethrin cream and oral ivermectin. Duration of therapy depends on severity of the disease (www.cdc.gov/parasites/scabies/health_professionals/meds.html).

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, contact precautions are recommended until the patient has been treated with an appropriate scabicide.

CONTROL MEASURES:

- Most experts recommend prophylactic therapy for household members, particularly those who have had prolonged direct skin-to-skin contact. Manifestations of scabies infestation can appear as late as 2 months after exposure, during which time the mite can be transmitted. Household members should be treated at the same time to prevent reinfestation. Bedding and clothing worn next to the skin during the 3 days before initiation of therapy should be laundered in a washer with hot water and dried using a hot cycle. Mites do not survive more than 3 days without skin contact. Clothing that cannot be laundered should be removed from the patient and stored for several days to a week to avoid reinfestation.
- Children should not be excluded or sent home early from school because of scabies (see Table 2.3, p 149). They can be treated at the end of the day and allowed to return to child care or school after the first course of treatment has been completed.
- Epidemics and localized outbreaks may require stringent and consistent measures to treat contacts. Health care workers and other caregivers who have had prolonged skin-to-skin contact with patients with infestation may benefit from prophylactic treatment.
- Environmental disinfection is unnecessary and unwarranted in noncrusted scabies. Thorough vacuuming of environmental surfaces is recommended after use of a room by a patient with noncrusted scabies.
- People with crusted scabies and their close contacts must be treated promptly and aggressively to prevent outbreaks. Information about environmental disinfection for crusted scabies is available from the Centers for Disease Control and Prevention (www.cdc.gov/parasites/scabies/health_professionals/crusted.html).

Schistosomiasis

CLINICAL MANIFESTATIONS: Schistosomiasis (bilharziasis) is acquired by skin penetration of infecting larvae (cercariae, shed by freshwater snails). Initial infections often are asymptomatic. Skin manifestations include pruritus at the penetration site a few hours after water exposure, followed in 5 to 14 days by an intermittent pruritic, sometimes papular, eruption. More intense papular eruptions may occur more quickly and last for 7 to 10 days after exposure in people sensitized previously. Cercarial dermatitis (swimmer's itch) also can be caused by larvae of schistosome parasites of birds or other wildlife. These larvae can penetrate human skin but eventually die in the dermis and do not cause systemic disease.

Parasites capable of causing intestinal and urogenital schistosomiasis enter the bloodstream after penetration of the skin, migrate through the lungs, and eventually mature into adult worms that reside in the venous plexus that drains the intestines

or, in the case of *Schistosoma haematobium*, the urogenital tract. Four to 8 weeks after exposure, worms develop into adults and females begin egg deposition, which can lead to an acute serum sickness-like illness (Katayama syndrome) that manifests as fever, malaise, cough, rash, abdominal pain, hepatosplenomegaly, diarrhea, nausea, lymphadenopathy, and/or eosinophilia. This syndrome is most common among non-immune hosts, such as travelers. Severity of symptoms associated with chronic infection is partially related to worm burden. People with low to moderate worm burdens may have only subclinical disease or relatively mild manifestations, such as growth stunting or anemia. Higher worm burdens are associated with a range of symptoms primarily caused by inflammation and local fibrosis triggered by the immune response to eggs produced by adult worms. Severe forms of chronic intestinal schistosomiasis (*Schistosoma mansoni* and *Schistosoma japonicum* infections) can result in hepatosplenomegaly, abdominal pain, bloody diarrhea, periportal fibrosis, portal hypertension, ascites, esophageal varices, and hematemesis. Urogenital schistosomiasis (*S haematobium* infections) can result in the bladder becoming inflamed and fibrotic. Urinary tract symptoms and signs include dysuria, urgency, microscopic and gross hematuria, secondary urinary tract infections, hydronephrosis, and nonspecific pelvic pain. *S haematobium* is associated with lesions of the lower genital tract (vulva, vagina, and cervix) in women, prostatitis and hematospermia in men, and certain forms of bladder cancer.¹ Other organ systems can be involved—for example, eggs can embolize to the lungs, causing pulmonary hypertension. Less commonly, eggs can lodge in the central nervous system, causing severe neurologic complications.

ETIOLOGY: The trematodes (flukes) *S mansoni*, *S japonicum*, *Schistosoma mekongi*, *Schistosoma guineensis*, and *Schistosoma intercalatum* cause intestinal schistosomiasis, and *S haematobium* causes urogenital disease. All species have similar life cycles.

EPIDEMIOLOGY: Persistence of schistosomiasis in a population depends on the local presence of an appropriate snail as an intermediate host. Eggs excreted in stool (*S mansoni*, *S japonicum*, *S mekongi*, *S intercalatum*, and *S guineensis*) or urine (*S haematobium*) into fresh water hatch into motile miracidia, which infect snails. After development and asexual replication in snails, cercariae emerge and penetrate the skin of humans in contact with water. In areas with endemic schistosomiasis, children are infected first when they accompany their parents to lakes, ponds, and other open fresh water sources. School-aged children typically are the most heavily infected people in the community because of prolonged wading and swimming in infected waters. Children have greater susceptibility to infection than older people because of a lack of high preexisting immunity to these parasites and are important in maintaining transmission through behaviors such as uncontrolled defecation and urination. Animals play an important zoonotic role (as a source of eggs) in maintaining the life cycle of *S japonicum*. Animal reservoirs may also play a role in areas of West Africa, where *S haematobium* has hybridized with the cattle parasite *Schistosoma bovis*. Infection is not transmissible by person-to-person contact or blood transfusion.

Distribution of schistosomiasis is focal and limited by presence of appropriate snail intermediate hosts, infected human reservoirs, and fresh water sources. *S mansoni* occurs throughout tropical Africa, in parts of several Caribbean islands, and in areas of Venezuela, Brazil, Suriname, and the Arabian Peninsula. *S japonicum* is found in

¹ The terms women and men refer to sex assigned at birth.

China, the Philippines, and Indonesia. *S haematobium* occurs in Africa and the Middle East; in 2014, local transmission of *S haematobium*/*S bovis* hybrids was reported in Corsica. *S mekongi* is found in Cambodia and Laos. *S intercalatum* is found in Central Africa, and *S guineensis* is found in West Africa. Adult worms of *S mansoni* usually survive for 5 to 7 years but can live as long as 30 years in the human host. Schistosomiasis can be diagnosed in patients many years after they have left an area with endemic transmission. (See Medical Evaluation for Infectious Diseases for Internationally Adopted, Refugee, and Other Immigrant Children, p 189.) Immunity is incomplete, and reinfection occurs commonly. Swimmer's itch can occur in all regions of the world after exposure to fresh water, brackish water, or salt water.

The **incubation period** is variable but is approximately 4 to 6 weeks for *S japonicum*, 6 to 8 weeks for *S mansoni*, and 10 to 12 weeks for *S haematobium*.

DIAGNOSTIC TESTS: Eosinophilia is common and may be intense in Katayama syndrome (acute schistosomiasis). Infection with *S mansoni* and other intestinal species is diagnosed by microscopic examination of stool specimens to detect characteristic eggs containing fully differentiated larvae, but results may be negative if performed too early in the course of infection. In light infections, several stool specimens examined by a concentration technique may be needed before eggs are found, or eggs may be seen in a biopsy of the rectal mucosa. *S haematobium* is diagnosed by examining urine for eggs; filtration or centrifugation and examination of the urinary sediment is required for optimum sensitivity. Egg excretion in urine often peaks between noon and 3 pm. Biopsy of the bladder or vaginal/cervical mucosa may be used to diagnose *S haematobium* infection. Urine reagent dipsticks commonly will be positive for blood. Serologic tests, available through the Centers for Disease Control and Prevention and some commercial laboratories, may be helpful for detecting light infections; results of these antibody-based tests remain positive for many years and are not useful in differentiating ongoing infection from past infection or reinfection. Serologic test results are negative during acute infection, turn positive 6 to 12 weeks or more after infection, and may be positive before eggs are detectable. Polymerase chain reaction and antigen tests for detection of schistosomes have been developed but are considered to be research tools at present.

Swimmer's itch, which is caused by the cercariae of certain schistosome species whose normal hosts are birds and nonhuman mammals, can be difficult to differentiate from other causes of dermatitis. A skin biopsy may demonstrate larvae, but their absence does not exclude the diagnosis. A history of exposure to water used by waterfowl may be helpful in making the diagnosis.

TREATMENT: The drug of choice for schistosomiasis caused by any species is praziquantel (see Drugs for Parasitic Infections, p 1068). Praziquantel does not kill developing worms, so treatment administered early (eg, 4 to 8 weeks after exposure) should be repeated 2 to 4 weeks later to improve parasitologic cure. Initial management of acute schistosomiasis and neuroschistosomiasis includes reduction of inflammation with steroids, although optimal dose and duration are uncertain. Initial treatment with praziquantel may exacerbate symptoms. The optimal timing of adding praziquantel is unknown; treating with this drug when inflammation has subsided generally is favored. Swimmer's itch is a self-limited disease that may require symptomatic treatment of the rash. More intense reactions may require a course of oral corticosteroids.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended. Schistosomiasis cannot be transmitted from person to person or by the fecal-oral route.

CONTROL MEASURES: Elimination of the intermediate snail host is difficult to achieve in most areas. Mass or selective treatment of infected populations, sanitary disposal of human waste, water sanitation programs, and education about the source of infection are key elements of current control measures. Travelers to areas with endemic schistosomiasis should be advised to avoid any contact with freshwater streams, rivers, ponds, or lakes. Swimming and wading should occur only in chlorinated pools. Human schistosomiasis is not transmitted in sea water.

Shigella Infections

CLINICAL MANIFESTATIONS: *Shigella* species primarily infect the large intestine, resulting in clinical manifestations that range from watery or loose stools with minimal or no constitutional symptoms to more severe symptoms, including high fever or hypothermia, abdominal cramps or tenderness, tenesmus, lethargy, and mucoid stools with or without blood. Infection with *Shigella dysenteriae* serotype 1 often results in a more severe illness than infection with other *Shigella* species, with a higher risk of complications, including septicemia, pseudomembranous colitis, toxic megacolon, intestinal perforation, hemolysis, and hemolytic-uremic syndrome (HUS). Infections attributable to *S dysenteriae* serotype 1 have become less common but continue to be an important etiology of illness in low-resource settings. Generalized seizures have been reported among young children with shigellosis attributable to any serotype, although the pathophysiology and incidence are poorly understood. Seizures associated with shigellosis are self-limited and usually are associated with high fever or electrolyte abnormalities. Septicemia is rare during illness and is caused either by *Shigella* organisms or by translocation of gastrointestinal flora into the bloodstream through compromised intestinal mucosa. Septicemia occurs most often in neonates, malnourished children, and immunocompromised people with *S dysenteriae* serotype 1 infection but may occur in healthy children with non-*S dysenteriae* shigellosis. Septicemia presents a higher risk of death in those ill with shigellosis. Reactive arthritis with extraarticular manifestations is a rare complication that can develop weeks to months after shigellosis, especially in people expressing HLA-B27. Postinfectious irritable bowel syndrome can occur and may last for weeks to months.

ETIOLOGY: *Shigella* species are facultative anaerobic, gram-negative bacilli in the order *Enterobacterales*. Four species (with more than 40 serotypes) have been identified, with *Shigella sonnei* being the most common in the United States. The other species are *Shigella flexneri*, *S dysenteriae*, and *Shigella boydii*. In resource-limited settings, especially in Africa and Asia, *S flexneri* predominates, and *S dysenteriae* serotype 1 is associated with outbreaks. Shiga toxin, a potent cytotoxin produced by *S dysenteriae* serotype 1, enhances the virulence of this serotype at the colonic mucosa resulting in small blood vessel and renal damage, leading to HUS in some individuals. The Shiga toxin genes are phage-encoded and have been found in a small number of strains belonging to other *Shigella* species and serotypes, including *S flexneri* serotype 2a, *S dysenteriae* serotype 4, and *Shigella sonnei*. HUS has been associated with an infection attributable to *S sonnei* in an adult, although the non-*S dysenteriae* species are not commonly associated with HUS.

EPIDEMIOLOGY: Humans are the primary reservoir of *Shigella* species, although non-human primates are also able to be infected. The primary mode of transmission is the fecal-oral route, and transmission can occur via contact with a contaminated inanimate object, ingestion of contaminated food or water, or sexual contact. Houseflies and cockroaches also may be vectors facilitating physical transport of feces with *Shigella*. It is very easy to transmit *Shigella* infection, because ingestion of very few organisms is sufficient for infection to occur. Prolonged organism survival in water (up to 6 months) and food (up to 30 days) can occur. Children 5 years or younger attending child care settings and their caregivers, as well as people living in crowded conditions, are at increased risk of infection. Men who have sex with men are also at increased risk of shigellosis and are particularly at risk for multidrug-resistant strains. Infections attributable to *S flexneri*, *S boydii*, and *S dysenteriae* are slightly more common among adults than among children. Travel to resource-limited settings with inadequate sanitation can place travelers at risk of infection. Even without antimicrobial therapy, the carrier state usually ceases within 1 to 4 weeks after onset of illness; long-term carriage is uncommon and does not correlate with underlying intestinal dysfunction.

Antibiotic resistance is increasing among *Shigella* isolates, especially among international travelers, men who have sex with men, people who lack housing, and people who are immunocompromised. During 2020, a year impacted by the COVID-19 pandemic, preliminary data suggest that 38% of *Shigella* isolates tested in the United States were resistant to ampicillin, 63% were resistant to trimethoprim-sulfamethoxazole, 13% were resistant to azithromycin, 50% were resistant to ciprofloxacin, and 13% were resistant to ceftriaxone.¹ The Centers for Disease Control and Prevention (CDC) has been monitoring *Shigella* isolates that harbor 1 or more quinolone resistance mechanisms (ie, those with a minimum inhibitory concentration [MIC] of ≥ 0.12 $\mu\text{g/mL}$ for ciprofloxacin) but that have in vitro susceptibility to fluoroquinolones (<https://emergency.cdc.gov/han/han00411.asp>). Additional data are needed to determine whether fluoroquinolone treatment outcomes and risk of illness transmission are impacted in patients with such isolates. Data from the National Antimicrobial Resistance Monitoring System (NARMS) indicate that many *Shigella* isolates with a quinolone resistance mechanism are nonsusceptible or resistant to many other commonly used first-line treatment agents. Since 2015, an increase in extensively drug-resistant (XDR) *Shigella* infections, defined as isolates resistant to azithromycin, ciprofloxacin, ceftriaxone, trimethoprim-sulfamethoxazole, and ampicillin, has been reported through national surveillance systems. In 2022, about 5% of *Shigella* infections reported to CDC were caused by XDR strains, compared with 0% in 2015 (<https://emergency.cdc.gov/han/2023/han00486.asp>).

The **incubation period** varies from 1 to 7 days but typically is 1 to 3 days.

DIAGNOSTIC TESTS: Isolation of *Shigella* organisms from feces or rectal swab specimens containing feces is diagnostic; sensitivity is improved by testing stool as soon as possible after it is passed, along with the use of enrichment broth media and selective agar plate media. If specimens cannot be transported to the testing laboratory within 2 hours, they should be transferred to appropriate transport media (eg, Cary-Blair or

¹ Centers for Disease Control and Prevention. National Antimicrobial Resistance Monitoring System (NARMS) Now: Human Data. Centers for Disease Control and Prevention; November 2021. Available at: www.cdc.gov/narmsgnow

similar media) and kept and transported at 4°C. Definitive identification of the organism requires both biochemical profiling and serogrouping to differentiate *Shigella* from *Escherichia*. Identification by mass spectrometry of cellular components should not be used, because this method cannot distinguish between the 2 genera. The presence of fecal lactoferrin demonstrated on a methylene-blue stained stool smear is sensitive for the diagnosis of colitis but is not specific for shigellosis. Although bacteremia is rare, children who are severely ill, immunocompromised, or malnourished should have a blood culture obtained. Multiplex polymerase chain reaction (PCR) platforms for detection of multiple bacterial (including *Shigella*), viral, and parasitic pathogens have high sensitivity but will not distinguish between viable and nonviable organisms nor provide antimicrobial susceptibility results. To guide treatment, if needed, and to enable surveillance and outbreak detection, stool cultures are recommended if shigellosis is diagnosed using multiplex PCR platforms or other nonculture-based diagnostic tests. Other tests for bacterial detection, including qualitative and quantitative PCR assays, are available in research laboratories and some clinical laboratories. Isolates of *Shigella* species (or clinical specimens from positive nonculture diagnostic tests if reflex culturing is not possible) should be submitted as required to local or state public health laboratories.

TREATMENT:

- Although severe dehydration is rare with shigellosis, correction of fluid and electrolyte losses, preferably by oral rehydration solutions, is the mainstay of treatment.
- Most infections with *S. sonnei* are self-limited (48 to 72 hours) and mild episodes do not require antimicrobial therapy.
- Antimicrobial treatment is recommended for patients with severe disease or with underlying immunosuppressive conditions; in these patients, empiric therapy should be given while awaiting culture and susceptibility results. Treatment is also indicated for symptomatic patients with culture-proven *Shigella* who require hospitalization, attend daycare, live in institutions or are involved in food handling. Available evidence suggests that antimicrobial therapy is somewhat effective in shortening duration of diarrhea and hastening eradication of organisms from feces; however, whether antimicrobial treatment reduces transmission is unclear.
- Antimicrobial susceptibility testing of clinical isolates is indicated to guide therapy because resistance to antimicrobial agents is common and increasing. Increasing antimicrobial resistance to azithromycin, ciprofloxacin, and ceftriaxone have been reported in the United States. For situations in which antibiotic treatment is indicated, oral administration is recommended, except for seriously ill patients, those with underlying immunodeficiencies, and patients who are unable to take oral medications. First-line antibiotic therapy generally consists of one of the following antibiotics, guided by antimicrobial susceptibility testing:
 - ♦ Azithromycin for 3 days.
 - ♦ A fluoroquinolone (eg, ciprofloxacin) for 3 days. Fluoroquinolones should be avoided if the *Shigella* strain has an MIC of ≥ 0.12 $\mu\text{g/mL}$ for ciprofloxacin, even if the laboratory indicates that the isolate is “susceptible,” until more is known about the clinical outcomes of ciprofloxacin treatment when MICs are ≥ 0.12 $\mu\text{g/mL}$.
 - ♦ Oral ampicillin or trimethoprim-sulfamethoxazole for 5 days are alternative options; amoxicillin is not effective because of its rapid absorption from the gastrointestinal tract.

- Parenteral ceftriaxone for 2 to 5 days. Oral cephalosporins (eg, cefixime) are of unclear efficacy.
- Longer treatment durations may be indicated in patients with invasive infection such as septicemia.
- Antidiarrheal compounds that inhibit intestinal peristalsis are contraindicated, because they can prolong the clinical and bacteriologic course of disease and can increase the rate of complications.
- Nutritional supplementation, including vitamin A (200 000 IU) and zinc (elemental Zn, orally daily for 10–14 days, 10 mg/day for newborn infants to 6 months of age, and 20 mg/day for those older than 6 months), can be given to hasten clinical resolution in geographic areas where children are at risk of malnutrition.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, contact precautions are indicated for the duration of illness.

CONTROL MEASURES:

General Control Measures. Strict attention to hand hygiene is essential to limit spread. Other important control measures include improved sanitation, appropriately chlorinating water supplies, proper cooking and storage of food, excluding infected people such as food handlers and child care providers, safe diapering practices, and measures to decrease contamination of food and surfaces by houseflies. People should refrain from recreational water venues (eg, swimming pools, water parks) while they have diarrhea; for children who are incontinent, recreational water activities should be avoided for 1 additional week (or as advised by local public health authorities). (See Prevention of Illness Associated With Recreational Water Use, p 214.) Sexually active people should avoid engaging in sexual activity for at least 1 week (ideally 2 weeks) after resolution of diarrhea. Breastfeeding provides some protection for infants.

Child Care Centers. General measures for interrupting enteric transmission in child care centers are recommended (see Children in Group Child Care and Schools, p 145). Meticulous hand hygiene is the single most important measure to decrease transmission. Waterless hand sanitizers may be effective when access to soap or clean water is limited. Eliminating access to shared water-play areas and contaminated diapers also can limit disease spread. Child care staff members should follow all standard infection control recommendations, specifically enhancing hand hygiene and ensuring that those who change diapers are not responsible for food preparation. When *Shigella* infection is identified in a child care attendee or staff member, stool specimens from symptomatic attendees and staff members should be obtained.

Following this, children may return to child care facilities if stools are contained in the diaper or when toilet-trained children are continent and when stool frequency becomes no more than 2 stools above that child's normal baseline, even if the stools remain loose (see Table 2.3, p 149).

Institutional Outbreaks. *Shigella* outbreaks that are most difficult to control are those that involve children who are not yet or only recently toilet-trained, adults who are unable to care for themselves (eg, cognitively impaired people and skilled nursing facility residents), or those that occur in areas with an inadequate supply of chlorinated water. A strong emphasis on hand hygiene, infection control, and appropriate antimicrobial therapy is needed to control disease transmission. In residential

institutions, ill people should be cohorted in separate areas from those who are not ill to reduce disease spread.

Public Health Reporting. *Shigella* infections are generally a reportable disease to state or local public health authorities. A directory of state and territorial, city and county, and tribal health departments can be found at www.cdc.gov/publichealthgateway/healthdirectories/index.html. At the time of notification, the local health department can assist with additional case finding and management of a possible outbreak. Infected people should be excluded from the child care facility until the state or local health department approves return per state or local child care exclusion regulations. Case reporting to appropriate health authorities (eg, hospital infection control personnel and public health departments) is essential to optimize adherence to inclusion and exclusion policies.

Smallpox (Variola)

In 1980, the World Health Assembly declared that smallpox (caused by variola virus) had been eradicated successfully worldwide, and no subsequent human cases have been confirmed. Following eradication, 2 World Health Organization (WHO) reference laboratories were authorized to maintain stocks of variola virus (Centers for Disease Control and Prevention in Atlanta, Georgia, and VECTOR in Novosibirsk, Russia). The United States discontinued routine childhood immunization against smallpox in 1972 and routine immunization of health care professionals in 1976. As a result of the terrorism events on September 11, 2001 and concern that the virus might be used as a weapon of bioterrorism, the smallpox immunization policy was revisited. In 2002, the United States resumed routine immunization of military personnel deployed to certain areas of the world. During 2003, a civilian smallpox immunization program for first responders in the United States was initiated to facilitate preparedness and response to a possible smallpox bioterrorism event. Such a bioterrorism event has not occurred.

CLINICAL MANIFESTATIONS: People infected with variola major strains develop a severe prodromal illness characterized by high fever (102°F–104°F [38.9°C–40.0°C]) and constitutional symptoms, including malaise, severe headache, backache, abdominal pain, and prostration, lasting for 2 to 5 days. Infected children may suffer from vomiting and seizures during this prodromal period. Most patients with smallpox are severely ill and bedridden during the febrile prodrome. The prodromal period is followed by the development of lesions on the mucosa of the mouth or pharynx, which may not be noticed by the patient. This stage occurs less than 24 hours before onset of rash, which usually is the first recognized manifestation of smallpox. With onset of oral lesions, the patient becomes infectious and remains so until all skin crust lesions have separated. The rash typically begins on the face and rapidly progresses to involve the forearms, trunk, and legs, with the greatest concentration of lesions on the face and distal extremities. The majority of patients will have lesions on the palms and soles. With rash onset, fever decreases but does not resolve. Lesions begin as macules that progress to papules, followed by firm vesicles and then deep-seated, hard pustules described as “pearls of pus.” Each stage lasts 1 to 2 days. By the sixth or seventh day of rash, lesions may begin to umbilicate or become confluent. Lesions increase in size for approximately 8 to 10 days, after which they begin to crust. Once all the crusts

have separated and a fresh layer of skin has formed, generally 3 to 4 weeks after the onset of rash, the patient no longer is infectious. Variola major in unimmunized people is associated with case fatality rates of approximately 30% during epidemics of smallpox. The mortality rate is highest in pregnant people, children younger than 1 year, and adults older than 40 years. The potential for improved outcomes because of modern supportive therapy and the availability of new antiviral agents is not known.

Variola minor strains cause a disease that is indistinguishable clinically from variola major, except that it causes less severe systemic symptoms and has more rapid rash evolution, reduced scarring, and fewer fatalities.

In addition to the typical presentation of smallpox (90% of cases or greater), there are 2 uncommon severe forms of variola major: hemorrhagic and malignant smallpox. Hemorrhagic smallpox is characterized either by a hemorrhagic diathesis before onset of the typical smallpox rash (early hemorrhagic smallpox) or by hemorrhage into skin lesions and disseminated intravascular coagulation (late hemorrhagic smallpox). In malignant or flat type smallpox, the skin lesions do not progress to the pustular stage but remain flat and soft. Each variant occurs in approximately 5% of cases and is associated with a 95% to 100% mortality rate. Pregnancy is a risk factor for hemorrhagic variola. Defects in cellular immunity may be responsible for flat type variola major, which is seen more commonly in children than adults.

Varicella (chickenpox) can be mistaken for smallpox. Generally, children with varicella do not have a febrile prodrome, but adults may have a brief, mild prodrome. Although the 2 diseases are confused easily in the first few days of the rash, smallpox lesions develop into pustules that are firm and deeply embedded in the dermis, whereas varicella lesions develop into superficial vesicles. Because varicella erupts in crops of lesions that evolve quickly, lesions on any one part of the body will be in different stages of evolution (papules, vesicles, and crusts), whereas all smallpox lesions on any one part of the body are in the same stage of development. The rash distribution of the 2 diseases differs. Varicella most commonly starts on the trunk and moves peripherally with less involvement of the extremities as compared with the trunk (centripetal). Variola lesions can be found distributed on all parts of the body but are generally found in higher numbers on the face and extremities compared with the trunk (centrifugal). Mpox also can be mistaken for smallpox as it produces a clinically similar but milder illness (see Mpox, p 606). Prominent lymphadenopathy can be a distinguishing feature of mpox.

ETIOLOGY: Variola virus, the virus that causes smallpox, is a member of the *Poxviridae* family (genus *Orthopoxvirus*). Other members of this genus that can infect humans include monkeypox virus, cowpox virus, vaccinia virus, and several putative novel species. Cowpox virus is believed to have been used by Benjamin Jesty in 1774 and by Edward Jenner in 1796 as material for the first smallpox vaccine. Later, cowpox virus was replaced with vaccinia virus.

EPIDEMIOLOGY: Humans are the only natural reservoir for variola virus (smallpox). Smallpox is spread most commonly by large respiratory droplets from the oropharynx of infected people, although rare transmission from aerosol spread has been reported. Infection from direct contact with lesion material or indirectly via fomites, such as clothing and bedding, has also been reported. Because most patients with smallpox are extremely ill and bedridden, spread generally is limited to household contacts, hospital

workers, and other health care professionals. Secondary household attack rates for smallpox were considerably lower than for measles and similar to or lower than rates for varicella.

Novel putative orthopox species with clinical presentations similar to cowpox virus and vaccinia virus have been reported in Alaska, Norway, and the country of Georgia.

The **incubation period** for smallpox is 7 to 17 days (mean, 10–12 days).

DIAGNOSTIC TESTS: If smallpox is suspected, consultation should be made immediately with the state or local health department. An algorithm to guide evaluation of smallpox is available at www.cdc.gov/smallpox/clinicians/algorithm-protocol.html. Diagnostic work-up should include exclusion of varicella-zoster virus and other common conditions that cause a vesicular/pustular rash illness. Caution is required when collecting specimens from patients in whom a diagnosis of smallpox is considered. Detailed guidelines for safe collection of specimens can be obtained through consultation with the Centers for Disease Control and Prevention (CDC; www.cdc.gov/smallpox/; 770-488-7100).

Variola virus can be detected in vesicular or pustular fluid by a number of different methods, including electron microscopy, immunohistochemistry, culture, or nucleic acid amplification test (NAAT). Testing for orthopoxviruses using a NAAT is available through the US Laboratory Response Network, after consultation is made with state or local public health departments. If smallpox is suspected and the orthopoxvirus NAAT result is positive, specimens are sent to CDC for a confirmatory variola-specific NAAT. This is available only at the CDC.

TREATMENT: Tecovirimat (TPOXX or ST-246) was licensed by the US Food and Drug Administration (FDA) in July 2018 as an oral treatment for smallpox for patients weighing 13 kg or more, using the Animal Rule pathway (ie, effectiveness of the drug was based on animal data only). In May 2022, an intravenous formulation was licensed for use in patients weighing 3 kg or more. Dosing information and treatment duration can be found in Table 4.10 (p 1044). Tecovirimat has been shown to be active against monkeypox virus and rabbitpox in animal models. In addition, it was used for mpox treatment in people under an expanded access investigational new drug protocol during the 2022 mpox outbreak. Tecovirimat effectiveness against variola in humans is unknown. It inhibits the function of an envelope protein required for spread of the virus from cell to cell. Tecovirimat is included in the US Strategic National Stockpile that is managed by the US Department of Health and Human Services, Office of the Assistant Secretary for Preparedness and Response.

Brincidofovir is a lipophilic derivative of cidofovir that is administered orally and does not appear to have renal toxicity. It was also approved under the Animal Rule for treatment of smallpox in June 2021. Dosing information can be found in Table 4.10 (p 1044). Brincidofovir has been shown to be active against rabbitpox and mousepox in animal models, although effectiveness against variola virus in humans is unknown. It inhibits viral DNA polymerase-mediated synthesis of viral DNA. Cidofovir inhibits the growth of variola virus in laboratory studies but has not been clinically evaluated in humans for the treatment of smallpox. It is not approved by the FDA for the treatment of smallpox but might be recommended for use during an outbreak using an investigational new drug protocol or emergency use authorization.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

At the time of admission, a patient suspected of having smallpox should be placed in a private, airborne infection isolation room equipped with negative-pressure ventilation with high-efficiency particulate air filtration. Standard, contact, and airborne precautions plus eye protection should be implemented promptly, and hospital infection control personnel and the state (and/or local) health department should be alerted immediately, even if alternative diagnoses are being evaluated concurrently.

CONTROL MEASURES:

Vaccines. Information on vaccination for orthopoxviruses can be found on the CDC website (www.cdc.gov/smallpox/clinicians/index.html). Two vaccines, ACAM2000 and JYNNEOS, are licensed to prevent orthopoxvirus infections, including smallpox. Both are part of the National Strategic Stockpile and are intended for emergency use during a smallpox event. They also are available through CDC for pre-exposure prophylaxis for select laboratory and health care personnel who are at risk for exposure to orthopoxviruses. In the absence of a smallpox outbreak, preexposure vaccination for smallpox is not recommended for the general US population. Postexposure immunization for smallpox provides some protection against disease and significant protection against a fatal outcome; it should ideally be administered within 3 to 4 days of exposure but may be given later.

ACAM2000 is a live, **replicating** vaccinia virus vaccine licensed to prevent smallpox. The lyophilized vaccine does not contain variola virus but rather the related vaccinia virus. ACAM2000 is grown in tissue culture and elicits an immune response similar to Dryvax, a previously licensed vaccinia virus vaccine (no longer available) that was highly effective in preventing smallpox. Vaccine protection wanes with time, but substantial protection has been observed up to 15 to 20 years after immunization. Administration involves a specialized multiple-puncture technique with a bifurcated needle, but any health care provider can be trained to administer ACAM2000. Inadvertent transmission of the vaccine virus may occur from vaccine recipients to their household contacts. Immunocompromised people and those with atopic skin disease are at increased risk of serious complications following contact transmission including progressive vaccinia and eczema vaccinatum. Detailed information, including information on contraindications and adverse effects, can be found in the ACAM2000 package insert and medication guide (www.fda.gov/BiologicsBloodVaccines/Vaccines/ApprovedProducts/ucm180810.htm).

A live, **nonreplicating** vaccinia virus vaccine (JYNNEOS) was approved by the FDA in 2019 for prevention of smallpox and mpox in people 18 years and older who are at high risk for smallpox or mpox infection. Two doses are administered 4 weeks apart. JYNNEOS may be considered for persons with contraindications for receiving ACAM2000 (including individuals with immunocompromising conditions, atopic skin disease, eczema or other exfoliative skin disease, or allergy to a component of ACAM2000). ACIP guidance for JYNNEOS for occupational preexposure prophylaxis has been published.¹

¹ Rao AK, Petersen BW, Whitehill F, et al. Use of JYNNEOS (smallpox and monkeypox vaccine, live, non-replicating) for preexposure vaccination of persons at risk for occupational exposure to orthopoxviruses: recommendations of the Advisory Committee on Immunization Practices—United States, 2022. *MMWR Morb Mortal Wkly Rep*. 2022;71(22):734–742

An investigational vaccinia vaccine similar to ACAM2000 (APSV) is also part of the strategic national stockpile for emergency use during a smallpox event. Guidelines on the use of these vaccines in a smallpox event have been published.¹

Treatment of Complications of Smallpox Vaccine. Vaccinia immune globulin (VIG) is licensed for certain complications of vaccination with replication competent vaccinia. VIG has no role in treatment of smallpox (www.cdc.gov/smallpox/clinicians/vaccine-medical-management6.html). Tecovirimat and brincidofovir have been used for the treatment of disseminated vaccinia through individual patient expanded access requests. Physicians should consult with their state or local health departments for diagnosis and management of patients with complications of vaccinia vaccination. CDC medical staff can be reached through the CDC emergency operations center at 770-488-7100. The CDC smallpox vaccine adverse events clinical consultation team can discuss need for treatment with VIG or antivirals and arrange shipment when indicated. Physicians at military medical facilities (or physicians treating a US Department of Defense health care beneficiary) can call the Defense Health Agency's 24/7 Immunization Healthcare Support Center at 877-GETVACC (877-438-8222) and select option #1.

Public Health Reporting. Smallpox is a nationally and immediately notifiable condition. Cases of febrile rash illness for which smallpox is considered in the differential diagnosis should be reported immediately to state or local health departments.

Sporotrichosis

CLINICAL MANIFESTATIONS: Three **cutaneous** patterns are described for sporotrichosis. The classic lymphocutaneous process with multiple nodules is seen more commonly in adults. Inoculation occurs at a site of minor trauma, causing a painless papule that enlarges slowly to become a firm, slightly tender, subcutaneous nodule that can develop a violaceous hue or ulcerate. Secondary lesions follow the same evolution and develop along the lymphatic distribution proximal to the initial lesion. A localized cutaneous form of sporotrichosis, also called fixed cutaneous form, is seen more commonly in children and presents as a solitary crusted papule or papuloulcerative or nodular lesion in which lymphatic spread is not observed. The extremities and face are the most common sites of infection. A disseminated cutaneous form with multiple lesions is rare, usually occurring in immunocompromised patients.

Extracutaneous sporotrichosis accounts for 20% of all cases and usually occurs in the setting of unusual areas of trauma or in immunocompromised patients. Osteoarticular infection results from hematogenous spread or local inoculation. The most commonly affected joints are the knees, elbows, wrists, and ankles. Pulmonary sporotrichosis clinically resembles tuberculosis and occurs after inhalation or aspiration of aerosolized conidia. Disseminated disease generally occurs after hematogenous spread from primary skin or lung infection. Disseminated sporotrichosis can involve multiple foci (eg, eyes, pericardium, genitourinary tract, central nervous system) and occurs predominantly in immunocompromised patients. Pulmonary and disseminated forms of sporotrichosis are uncommon in children.

¹ Peterson BW, Damon IK, Pertowski CA, et al. Clinical guidance for smallpox vaccine use in a postevent vaccination program. *MMWR Recomm Rep*. 2015;64(RR-2):1-26

ETIOLOGY: *Sporothrix schenckii* is a thermally dimorphic fungus that grows as a mold or mycelial form at room temperature and as a budding yeast at 35°C to 37°C and in host tissues. *S schenckii* is a complex of at least 6 species. Within this complex, *S schenckii sensu stricto* is responsible for most infections, followed by *Sporothrix globosa*; in South America, *Sporothrix brasiliensis* is a major cause of infection.

EPIDEMIOLOGY: *S schenckii* is a ubiquitous organism that has worldwide distribution but is most common in tropical and subtropical regions of Central and South America and parts of North America and Asia. The fungus has been isolated from soil and plant material, including hay, straw, sphagnum moss, and decaying vegetation. Thorny plants such as rose bushes and pine trees commonly are implicated, because pricks from their thorns or needles inoculate the organism from the soil or moss around the bush or tree. *S brasiliensis* is responsible for hyperendemic cutaneous sporotrichosis in Rio de Janeiro. Primarily zoonotic, it is transmitted by direct inoculation through bites or scratches or mucosal exposure to secretions from infected cats.

The **incubation period** is 7 to 30 days after cutaneous inoculation but can be as long as 6 months.

DIAGNOSTIC TESTS: Culture of *Sporothrix* species from a tissue, wound drainage, or sputum specimen is diagnostic. The mold phase of the organism can be isolated on a variety of fungal media, including Sabouraud dextrose agar at 25°C to 30°C. Filamentous colonies generally appear within 1 week. Definitive identification requires conversion to the yeast phase by subculture to enriched media, such as brain-heart infusion agar with 5% blood and incubation at 35°C to 37°C. In some cases, repeated subcultures are required for conversion. Culture of *Sporothrix* species from a blood specimen is definite evidence for disseminated infection, which is associated with immunodeficiency. Histopathologic examination of tissue often is not helpful, because the organism is seldom abundant, but may be useful to exclude clinically similar infections such as cutaneous leishmaniasis. Fungal stains including periodic acid-Schiff or Gomori methenamine silver to visualize this distinctive oval or cigar-shaped organism are required. Antibody tests offered by some reference laboratories have been useful in a few cases of extracutaneous sporotrichosis. Molecular testing on tissue samples is available only in a few reference laboratories and is not standardized.

TREATMENT^{1,2}: Sporotrichosis usually does not resolve without treatment. Itraconazole is the drug of choice for children with lymphocutaneous and localized cutaneous disease. See Recommended Doses of Parenteral and Oral Antifungal Drugs (p 1026) for dosing. Duration of therapy is 2 to 4 weeks after all lesions have resolved, usually for a total duration of 3 to 6 months. Serum trough concentrations of itraconazole should be 1 to 2 µg/mL. A trough level should be checked 10 days or later following initiation to ensure adequate drug exposure. When measured by high-pressure liquid chromatography, both itraconazole and its bioactive hydroxyitraconazole metabolite are reported, the sum of which should be considered in assessing the trough concentration.

¹ Kauffman CA, Bustamante B, Chapman SW, Pappas PG; Infectious Diseases Society of America. Clinical practice guidelines for the management of sporotrichosis: 2007 update by the Infectious Diseases Society of America. *Clin Infect Dis*. 2007;45(10):1255-1265

² Thompson GR III, Le T, Chindamporn A, et al. Global guideline for the diagnosis and management of the endemic mycoses: an initiative of the European Confederation of Medical Mycology in cooperation with the International Society for Human and Animal Mycology. *Lancet Infect Dis*. 2021;21(12):e364-e374

The itraconazole oral solution formulation is preferred over the capsule formulation because of improved absorption and should be taken on an empty stomach. However, a super bioavailable (SUBA) itraconazole is now approved by the Food and Drug Administration for the treatment of pulmonary and extrapulmonary blastomycosis in individuals 18 years or older, with pharmacokinetic studies of this formulation demonstrating less variable absorption than conventional itraconazole capsules and a similar side effect profile; data in children are lacking. Saturated solution of potassium iodide (1 drop taken orally, 3 times daily, increasing as tolerated to a maximum of 1 drop/kg of body weight or 40 to 50 drops, 3 times daily, whichever is lowest) is an alternative therapy for nonsevere forms.

Amphotericin B, preferably as a lipid formulation, is recommended as initial therapy for visceral or disseminated sporotrichosis in children (see Recommended Doses of Parenteral and Oral Antifungal Drugs, p 1026). After clinical response to amphotericin B therapy is documented, itraconazole can be substituted and should be continued for at least 12 months. Itraconazole may be required for lifelong therapy in children with human immunodeficiency virus infection. Pulmonary and disseminated infections respond less well than cutaneous infection, despite prolonged therapy.

Local hyperthermia can be effective in treating cutaneous lesions, as *S schenckii* growth is impaired when temperatures exceed 42°C. Hyperthermia may be considered especially when patients cannot take recommended drugs safely (eg, pregnancy) but may not be well-tolerated by young children.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are indicated.

CONTROL MEASURES: Use of protective gloves and clothing for occupational and recreational activities that could lead to exposure to *S schenckii* can decrease risk of disease. Interaction with stray cats should be minimized in areas where *S brasiliensis* is endemic or hyperendemic; gloves, clothing, and face shields should be used in these locales if handling a cat with suspected sporotrichosis.

Staphylococcal Food Poisoning

CLINICAL MANIFESTATIONS: Staphylococcal foodborne illness is characterized by abrupt and sometimes violent onset of severe nausea, abdominal cramps, vomiting, and prostration, often accompanied by diarrhea. Low-grade fever or mild hypothermia can occur. The illness typically lasts no longer than 1 day, but symptoms are intense and can require hospitalization. The short incubation period, brevity of illness, and usual lack of fever help distinguish staphylococcal from other infectious causes of food poisoning, with the exception of the vomiting syndrome caused by *Bacillus cereus*. *Clostridium perfringens* food poisoning usually has a longer incubation period, and chemical food poisoning usually has a shorter incubation period. Patients with foodborne *Salmonella*, *Campylobacter*, or *Shigella* infection are more likely to have fever and a longer incubation period (see Appendix VI: Clinical Syndromes Associated With Foodborne Diseases, p 1150).

ETIOLOGY: Enterotoxins produced by strains of *Staphylococcus aureus* and, rarely, *Staphylococcus epidermidis* and *Staphylococcus intermedius* cause the symptoms of staphylococcal food poisoning. More than 20 such enterotoxins have been identified. These are stable in the face of many environmental conditions (freezing, drying, heat treatment,

low pH) and resistant to intestinal tract proteolysis. The degree and type of symptoms may vary by toxin type and dose.

EPIDEMIOLOGY: Illness is caused by ingestion of food containing staphylococcal enterotoxins. The most commonly implicated foods are meats, most often pork (including sliced ham) and poultry served after inadequate heating. Food handlers may contaminate foods with enterotoxigenic strains of *S aureus*. When contaminated food remains at room temperature for several hours, the staphylococcal organisms multiply and produce toxins that are heat-stable (ie, not inactivated by reheating). The number of reported outbreaks caused by *S aureus* decreased in the 2000s. Possible reasons include less contamination of raw meat, improved food handling practices, and fewer investigations because of resource constraints.

The **incubation period** is typically 2 to 4 hours (range 30 minutes to 8 hours) after ingestion.

DIAGNOSTIC TESTS: In most cases, given the short duration of illness and rapid recovery with supportive care, diagnostic testing to confirm the diagnosis is not necessary. However, tests for enterotoxin are commercially available. In an outbreak, recovery of large numbers of staphylococci ($\geq 10^5$ *S aureus* organisms/g) from stool or vomitus or detection of enterotoxin in an implicated food can confirm the diagnosis, as can identification of the same subtype of *S aureus* from the stool or vomitus of 2 or more ill people. Guidance for confirming outbreaks of staphylococcal food poisoning can be found online (www.cdc.gov/foodsafety/outbreaks/investigating-outbreaks/confirming_diagnosis.html). To aid in outbreak investigations, public health laboratories can determine whether strains are similar using molecular methods. Local public health authorities should be notified about possible outbreaks because they can often determine the source and institute control measures to prevent similar outbreaks.

TREATMENT: Treatment is supportive. Antimicrobial agents are not indicated.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Staphylococcal food poisoning is not spread from person to person. Standard precautions are recommended.

CONTROL MEASURES: Strict hand hygiene should be enforced for all food handlers. People with boils, abscesses, or other purulent lesions that could be from staphylococcal skin infection should be especially careful to wash hands thoroughly and use gloves or other protective equipment while handling food. Prepared foods should be refrigerated in wide, shallow containers within 2 hours after cooking (within 1 hour if the ambient temperature is higher than 90°F). Information on good food handling practices, including time and temperature recommendations for cooking, storage, and reheating, is available online (www.foodsafety.gov).

Staphylococcus aureus

CLINICAL MANIFESTATIONS: *Staphylococcus aureus* causes a variety of localized and invasive suppurative infections and 3 toxin-mediated syndromes: toxic shock syndrome, scalded skin syndrome, and food poisoning (discussed in Staphylococcal Food Poisoning, p 766). Localized infections include cellulitis, skin and soft tissue abscesses, furuncles, carbuncles, pustulosis, impetigo (bullous and nonbullous), paronychia, mastitis, omphalitis, hordeola, orbital cellulitis/abscess, sinusitis, peritonsillar

abscesses (Quinsy), parotitis, lymphadenitis, and wound infections. Bacteremia can be associated with focal complications including osteomyelitis; septic arthritis; endocarditis; pneumonia; pleural empyema; septic pulmonary emboli; pericarditis; soft tissue, muscle, or visceral abscesses; and septic thrombophlebitis of small and large vessels. In patients with neutropenia, ecthyma gangrenosum may occur. Primary *S aureus* pneumonia also can occur after aspiration of organisms from the upper respiratory tract and can occur in the context of concurrent or antecedent viral infections from the community (eg, influenza) or in ventilated patients. Meningitis may occur in preterm infants but otherwise is rare unless accompanied by a foreign body (eg, ventriculoperitoneal shunt) or a congenital or acquired defect in the dura. *S aureus* causes a variety of infections with and without bacteremia associated with foreign bodies, including intravascular catheters or grafts, peritoneal catheters, spinal instrumentation or intramedullary rods, pressure equalization tubes, pacemakers and other intracardiac devices, vagal nerve stimulators, and prosthetic joints. *S aureus* infections can be fulminant. Certain chronic diseases, conditions, and events, such as diabetes mellitus, malignancy, prematurity, immunodeficiency, kidney disease, nutritional disorders, dialysis, surgery, and transplantation, increase the risk for severe *S aureus* infections. Metastatic foci and abscesses need to be drained and foreign bodies should be removed when possible. Prolonged antimicrobial therapy for invasive infection often is necessary to achieve cure.

Staphylococcal toxic shock syndrome (TSS), a toxin-mediated disease, usually is caused by strains producing TSS toxin-1 or possibly other related staphylococcal enterotoxins. Characterized by acute onset of fever, generalized erythroderma, rapid-onset hypotension, and signs of multisystem organ involvement, including profuse watery diarrhea, vomiting, conjunctival injection, and severe myalgia (see Table 3.58 for clinical case definition). TSS can occur in menstruating persons using tampons or following childbirth or abortion. TSS also can occur after surgical procedures, in association with cutaneous lesions, or without a readily identifiable focus of infection, and blood cultures are often negative. People with TSS, especially menses-associated illness, are at risk of a recurrent episode.

Prevailing strains (eg, USA300) of methicillin-resistant *S aureus* (MRSA) rarely produce TSS toxin but readily produce other extracellular toxins (eg, leukocidins and enterotoxins) that may lead to clinical presentations that resemble, but do not meet clinical criteria for, TSS. These clinical phenotypes are often referred to as toxin-mediated disease.

Staphylococcal scalded skin syndrome (SSSS) is a toxin-mediated disease caused by circulation of exfoliative toxins A and B. The manifestations of SSSS are age related and include Ritter disease (generalized exfoliation) in the neonate, a tender scarlatiniform eruption and localized bullous impetigo in older children, or a combination of these with thick white/brown flaky desquamation of the entire skin, especially on the face and neck, in older infants and toddlers. The hallmark of SSSS is the toxin-mediated cleavage of the stratum granulosum layer of the epidermis (ie, Nikolsky sign). Proper pain management is a mainstay of therapy for SSSS. Healing occurs without scarring. Bacteremia is rare, but dehydration and superinfection can occur with extensive exfoliation.

ETIOLOGY: Staphylococci are catalase-positive, gram-positive cocci that appear microscopically as grape-like clusters. Staphylococci are ubiquitous and can survive extreme

Table 3.58. *Staphylococcus aureus* Toxic Shock Syndrome: Clinical Case Definition^a

Clinical Findings

- Fever: temperature 38.9°C (102.0°F) or greater
- Rash: diffuse macular erythroderma
- Desquamation: 1–2 weeks after onset of rash, particularly on palms, soles, fingers, and toes
- Hypotension: systolic pressure 90 mm Hg or less for adults; lower than fifth percentile for age for children younger than 16 years
- Multisystem organ involvement: 3 or more of the following:
 1. Gastrointestinal tract: vomiting or diarrhea at onset of illness
 2. Muscular: severe myalgia or creatinine phosphokinase concentration greater than twice the upper limit of normal
 3. Mucous membrane: vaginal, oropharyngeal, or conjunctival hyperemia
 4. Renal: serum urea nitrogen or serum creatinine concentration greater than twice the upper limit of normal or urinary sediment with 5 white blood cells/high-power field or greater in the absence of urinary tract infection
 5. Hepatic: total bilirubin, aspartate aminotransferase, or alanine aminotransferase concentration greater than twice the upper limit of normal
 6. Hematologic: platelet count 100 000/mm³ or less
 7. Central nervous system: disorientation or alterations in consciousness without focal neurologic signs when fever and hypotension are absent

Laboratory Criteria

- *Negative* results on the following tests, if obtained:
 1. Blood or cerebrospinal fluid cultures; blood culture rarely may be positive for *S aureus*
 2. Serologic tests for Rocky Mountain spotted fever, leptospirosis, or measles

Case Classification

- **Probable:** a case that meets the laboratory criteria and in which 4 of 5 clinical findings are present
- **Confirmed:** a case that meets laboratory criteria and all 5 of the clinical findings, including desquamation, unless the patient dies before desquamation occurs.

^aAdapted from <https://ndc.services.cdc.gov/case-definitions/toxic-shock-syndrome-2011/>.

conditions of drying, heat, and low-oxygen and high-salt environments. *S aureus* has many surface proteins, including the microbial surface components recognizing adhesive matrix molecule (MSCRAMM) receptors, which allow the organism to bind to tissues and foreign bodies coated with fibronectin, fibrinogen, and collagen. This permits a low inoculum of organisms to adhere to sutures, catheters, prosthetic valves, and other devices. They also secrete a robust arsenal of extracellular proteins aimed at nutrient acquisition, host cell destruction, and immune evasion.

EPIDEMIOLOGY: *S aureus* is the most common cause of skin and soft tissue infections and musculoskeletal infections in otherwise healthy children. *S aureus* colonizes the skin and mucous membranes of 30% to 50% of healthy adults and children. The anterior nares, throat, axilla, perineum, vagina, and rectum are usual sites of colonization. *S aureus* is one of the most common causes of health care-associated bacteremia in all age groups and health care-associated pneumonia in children and is the most common pathogen responsible for surgical site infections. Patients with neutrophil dysfunction, such as those with chronic granulomatous disease (CGD), are at increased risk for *S aureus* infections.

S aureus-mediated TSS was first recognized in 1978 by Dr. Jim Todd, and many early cases were associated with tampon use. Although changes in tampon composition and use have resulted in a decreased proportion of cases associated with menses, menstrual and nonmenstrual cases of TSS continue to occur and are reported with similar frequency. Risk factors for TSS include absence of antibody to TSS toxin-1 and focal *S aureus* infection with a TSS toxin-1-producing strain. TSS toxin-1-producing strains can be part of normal flora of the anterior nares or vagina, and colonization at these sites is believed to result in protective antibody in more than 90% of adults.

Transmission of *S aureus*. Rates of skin carriage of more than 50% occur in children with desquamating skin disorders or burns and in people with frequent needle use (eg, people who have diabetes mellitus, are on hemodialysis, inject drugs, or receive allergy shots). Although domestic animals can be colonized, data suggest that colonization is acquired from other humans. Hospitalized children who are colonized with MRSA on admission or acquire MRSA colonization in the hospital are at increased risk for subsequent MRSA infection compared with noncolonized children.

S aureus is transmitted most often by direct contact in community settings and indirectly from patient to patient via transiently colonized hands of health care professionals in health care settings. Health care professionals and family members who are colonized with *S aureus* in the nares or on skin also can serve as a reservoir for transmission. Contaminated environmental surfaces and objects also can play a role in transmission of *S aureus*. Although not transmitted by the droplet route routinely, *S aureus* can be dispersed into the air over short distances. Dissemination of *S aureus* from people with nasal carriage, including infants, is related to density of colonization, and increased dissemination occurs during viral upper respiratory tract infections. Parental *S aureus* colonization at a variety of body sites has been associated with neonatal colonization.

Health Care-Associated MRSA. MRSA has been endemic in most US hospitals since the 1980s. Risk factors for health care-associated MRSA infections include hospitalization, surgery, dialysis, long-term care stay within the previous year, presence of an indwelling device, presence of wounds, and history of prior MRSA infection or colonization. The incidence of invasive health care-associated MRSA infections has decreased in many communities since the mid-2000s.

Health care-associated MRSA strains (ie, those that historically were responsible for most health care-associated MRSA infections) have often been resistant to more antibiotic classes (including clindamycin) than community-associated strains.

Community-Associated MRSA. Community-associated MRSA infections attributable to strains different from traditional health care-associated MRSA emerged in the 1990s. These strains most commonly cause skin and soft tissue abscesses, although they can also cause more severe infections. Clinical infections are more common in settings where there is crowding; frequent skin-to-skin contact; sharing of personal items, such as towels and clothing; poor personal hygiene; and among those with nonintact skin, including body piercings. Outbreaks have been reported among athletic teams, in correctional facilities, and in military training facilities. Community-associated MRSA strains can also circulate in hospitals and cause health care-associated MRSA

infections. Community-associated MRSA strains have tended to be susceptible to a variety of non- β -lactam antibiotics.

Vancomycin-Intermediately Susceptible *S aureus*. Vancomycin-intermediately susceptible *S aureus* (VISA) strains (minimum inhibitory concentration [MIC], 4–8 $\mu\text{g/mL}$) have been isolated from people (historically, dialysis patients) who have received multiple courses of vancomycin. Strains of MRSA can be heterogeneous for vancomycin resistance (see Diagnostic Tests). Extensive vancomycin use allows VISA strains to develop during therapy. Control measures recommended by the Centers for Disease Control and Prevention (CDC) have included using proper methods to detect VISA, using appropriate infection-control measures, and adopting measures to ensure appropriate vancomycin use.

Vancomycin-Resistant *S aureus*. Vancomycin-resistant *S aureus* (VRSA) infections (MIC >8 $\mu\text{g/mL}$) are very rare, and in all confirmed cases, reported patients had underlying medical conditions, a history of MRSA infections, and prolonged exposure to vancomycin.

The **incubation period** is variable for staphylococcal disease. A long delay can occur between acquisition of the organism and onset of disease. For SSSS, the **incubation period** usually is 1 to 10 days; for postoperative TSS, the **incubation period** can be as short as 12 hours. Menses-related cases can develop at any time during menstruation.

DIAGNOSTIC TESTS: Gram stains of specimens from skin lesions or pyogenic foci showing gram-positive cocci in clusters can provide presumptive evidence of staphylococcal infection. Isolation of organisms from culture of otherwise sterile body fluid is the method for definitive diagnosis. *S aureus* is almost never a contaminant when isolated from a blood culture or other sterile site.

Molecular assays have been approved by the US Food and Drug Administration for detection of *S aureus* from blood cultures growing gram-positive organisms. These assays include nonamplified molecular assays, such as peptide nucleic acid fluorescent in situ hybridization (PNA-FISH) and Verigene, as well as nucleic acid amplification tests, such as BD GenOhm Staph SR, Xpert MRSA/SA BC, the FilmArray Blood Culture Identification Panel (BCID), and the polymerase chain reaction (PCR)-T2 magnetic resonance sepsis panel. Matrix-assisted laser desorption/ionization–time-of-flight (MALDI-TOF) mass spectrometry can rapidly identify *S aureus* colonies on culture plates or from growth in blood cultures.

S aureus-mediated TSS is a clinical diagnosis (Table 3.58); *S aureus* is isolated from blood cultures in fewer than 5% of patients with TSS. Specimens for culture should be obtained from an identified focus of infection, because these sites usually will yield the organism. Because approximately one third of isolates of *S aureus* from nonmenstrual cases produce toxins other than TSS toxin-1, and TSS toxin-1–producing organisms can be present as normal flora, TSS toxin-1 production by an isolate is not a useful diagnostic test.

Antimicrobial susceptibility testing should be performed for all *S aureus* specimens isolated from normally sterile sites. Laboratory practice includes routine screening (D-testing) to exclude inducible clindamycin resistance. Another phenomenon that has been described is heteroresistance to antibiotics, in which the heterogeneous or heterotypic strains appear susceptible by disk diffusion but contain resistant subpopulations

that are only apparent when cultured with antibiotic-containing media. When these resistant subpopulations are cultured on antibiotic-free media, they can continue as stable resistant mutants or revert to susceptible strains (heterogeneous resistance). Bacteria expressing heteroresistance grow more slowly than the susceptible bacteria and can be missed at growth conditions greater than 35°C (95°F). The clinical significance of heteroresistance is not clear, but some have suggested that it could be a cause of some vancomycin treatment failures.

S aureus strain genotyping, in conjunction with epidemiologic information, can facilitate identification of the source, extent, and mechanism of transmission in an outbreak. Several molecular typing methods are available for *S aureus*, including pulsed-field gel electrophoresis, spa typing, multilocus sequence typing, and whole genome sequencing. Choice of method should consider purpose of typing and available resources.

TREATMENT:

Skin and Soft Tissue Infection. Skin and soft tissue infections, such as diffuse impetigo or cellulitis attributable to methicillin-susceptible *S aureus* (MSSA), optimally are treated with oral penicillinase-resistant beta-lactam drugs, such as a first- or second-generation cephalosporin. For the patient with penicillin allergy and in cases in which MRSA is considered, trimethoprim-sulfamethoxazole, doxycycline, or clindamycin can be used if the isolate is susceptible. Topical mupirocin is recommended for localized impetigo.

The most frequent manifestation of community-associated MRSA infection is skin and soft tissue infection, which can range from mild to severe. Drainage is an important component of managing these infections. A randomized placebo-controlled study evaluating treatment strategies for uncomplicated skin infections included children with simple abscesses ≤ 3 cm (6–11 months of age), ≤ 4 cm (1–8 years of age), or ≤ 5 cm (>8 years of age) in diameter and found that drainage plus systemic oral therapy with either clindamycin or trimethoprim-sulfamethoxazole was associated with better outcomes compared with drainage alone.

Invasive Staphylococcal Infections. Empiric therapy for suspected invasive or severe staphylococcal infection, including pneumonia, osteoarticular infection, visceral abscesses, and foreign body-associated infection with bacteremia, is vancomycin plus an anti-staphylococcal beta lactam (eg, nafcillin, oxacillin, cefazolin). For children with mild to moderate illness for suspected osteomyelitis attributable to *S aureus*, empiric therapy may be informed by local susceptibility of *S aureus* isolates. When rates of community-associated MRSA are low ($<10\%$), oxacillin, nafcillin, or cefazolin may be initiated; when rates of resistance are higher, empiric therapy should include clindamycin or vancomycin. Subsequent therapy should be based on antimicrobial susceptibility results.

Serious MSSA infections require intravenous therapy with an antistaphylococcal beta-lactam antimicrobial agent, such as nafcillin, oxacillin, or cefazolin, because most *S aureus* strains produce beta-lactamase enzymes and are resistant to penicillin and ampicillin (see Table 3.59). The addition of rifampin may be considered for those with invasive disease associated with an indwelling foreign body, especially if removal of the infected implant or device is not feasible. **Vancomycin is not recommended for treatment of serious MSSA infections (including endocarditis), because outcomes are inferior with vancomycin compared with antistaphylococcal beta lactams.** First- or second-generation cephalosporins (eg, cefazolin) or vancomycin are less effective than nafcillin or oxacillin for treatment of MSSA meningitis.

Table 3.59. Parenteral Antimicrobial Agent(s) for Treatment of Bacteremia and Other Serious *Staphylococcus aureus* Infections

Antimicrobial Agents		Comments
I. Initial empiric therapy (organism of unknown susceptibility)		
Drugs of choice:	Vancomycin (15 mg/kg, every 6 h) + nafcillin or oxacillin ^{a,b}	For life-threatening infections (eg, septicemia, pneumonia, endocarditis, CNS infection); ceftaroline or linezolid are alternatives to vancomycin, but there are limited efficacy data in children
	Vancomycin (15 mg/kg, every 6–8 h) ^b	For non-life-threatening infection without signs of sepsis (eg, skin infection, cellulitis, osteomyelitis, septic arthritis) when rates of MRSA colonization and infection in the community are substantial; ceftaroline ^c or linezolid ^c or daptomycin ^d (if no pneumonia) are alternatives
	Clindamycin	For non-life-threatening infection without signs of sepsis when rates of MRSA colonization and infection in the community are substantial and prevalence of clindamycin resistance is <15%
II. Methicillin-susceptible <i>S aureus</i> (MSSA)		
Drugs of choice:	Nafcillin or oxacillin ^e	Preferred for meningitis (cefazolin does not penetrate well into central nervous system)
	Cefazolin	
Alternatives:	Clindamycin	Only for patients with a serious penicillin allergy and clindamycin-susceptible strain (not for endovascular infections or meningitis)
	Vancomycin ^{a,b,e}	Only for patients with a serious penicillin and cephalosporin allergy infected with a clindamycin-resistant strain (or if there is a serious beta-lactam allergy and endovascular infection or meningitis)
	Ampicillin + sulbactam	For patients with polymicrobial infections caused by susceptible isolates

Table 3.59. Parenteral Antimicrobial Agent(s) for Treatment of Bacteremia and Other Serious *Staphylococcus aureus* Infections, continued

Antimicrobial Agents		Comments
III. Methicillin-resistant <i>S aureus</i> (MRSA; oxacillin MIC ≥ 4 $\mu\text{g/mL}$)		
Drugs of choice:	Vancomycin ^{a,b,e}	For life-threatening infections, including meningitis or endovascular infections including those complicated by venous thrombosis
	Clindamycin (if strain susceptible)	For pneumonia, ^a septic arthritis, osteomyelitis, skin or soft tissue infections (not for endovascular infections or meningitis)
	Trimethoprim-sulfamethoxazole	For skin or soft tissue infections
Alternative (check susceptibility prior to use):	Linezolid ^c	For serious infections caused by clindamycin resistant isolates in patients with renal dysfunction or those intolerant of vancomycin
	Ceftaroline ^c	For skin infections, pneumonia, alternative for severe infections
	Daptomycin ^d	Bloodstream infections, skin and soft tissue infections, infections other than pneumonia
	Dalbavancin ^c	For skin or soft tissue infections
	Tedizolid ^c	For skin or soft tissue infections for patients 12 years and over

Table 3.59. Parenteral Antimicrobial Agent(s) for Treatment of Bacteremia and Other Serious *Staphylococcus aureus* Infections, continued

Antimicrobial Agents		Comments
IV. Vancomycin-intermediately susceptible <i>S aureus</i> (VISA; MIC 4 to 16 µg/mL)		
Drugs of choice:	Optimal therapy is not known ^c	Consult with an expert in infectious disease; therapy dependent on in vitro susceptibility test results
	Linezolid ^c	
	Ceftaroline ^c	
	Daptomycin ^d	
	Quinupristin-dalfopristin ^c	
	Tigecycline ^c	
Alternatives:	Vancomycin ^b + linezolid ± gentamicin	
	Vancomycin ^b + trimethoprim-sulfamethoxazole	

CNS indicates central nervous system; MIC, minimum inhibitory concentration.

^aFor suspected MRSA pneumonia complicating influenza in critically ill children, add clindamycin, ceftaroline, or linezolid to vancomycin empiric treatment. Empiric selection of antibiotics is highly dependent on the local/regional susceptibility data.

^bThe area-under-the-curve to minimum inhibitory concentration (AUC/MIC) has been identified as the most appropriate pharmacokinetic/pharmacodynamic (PK/PD) target for vancomycin in adult patients with MRSA. Although there are limitations in prospective outcomes data in pediatric patients with serious MRSA infections, the most recent consensus guideline from the American Society of Health-System Pharmacists, the Infectious Diseases Society of America, the Pediatric Infectious Diseases Society, and the Society of Infectious Diseases Pharmacists recommend AUC guided therapeutic monitoring, preferably with Bayesian estimation, for all pediatric age groups receiving vancomycin.^{f,g,h} This estimation accounts for developmental changes of vancomycin clearance from newborn to adolescent. Dosing in children should be designed to achieve an AUC of 400 to 600 µg-hour/L (assuming MIC of 1) and/or trough levels <15 µg/mL to minimize acute kidney injury risks. Bayesian estimation can be completed with 2 levels, with 1 level being recommended 1 to 2 hours after end of vancomycin infusion, and the second level being drawn 4 to 6 hours after end of infusion. Levels can be obtained as early as after the second dose. Software to assist with these calculations is available online and for purchase. It is recommended to avoid AUC >800 µg-hour/L and trough levels >15 µg/mL. Most children younger than 12 years will require higher doses to achieve optimal AUC/MIC compared with older children. Consultation with an infectious diseases specialist should be considered to determine which agent to use and duration of use.

Table 3.59. Parenteral Antimicrobial Agent(s) for Treatment of Bacteremia and Other Serious *Staphylococcus aureus* Infections, continued

Antimicrobial Agents	Comments
^cLinezolid, ceftaroline, dalbavancin, tedizolid, quinupristin-dalfopristin, and tigecycline are agents with activity in vitro and efficacy in adults with multidrug-resistant, gram-positive organisms, including <i>S aureus</i>. Because experience with these agents in children is limited, consultation with a specialist in infectious diseases should be considered before use. Further, tigecycline should not be used in children younger than 8 years if there are effective alternatives, because there may be reversible inhibition of bone growth and adverse effects on tooth development. Tigecycline also has a black box warning for an increase in all-cause mortality and should be reserved for situations where alternative agents are not suitable. Tedizolid has not been adequately evaluated in patients with severe neutropenia (neutrophil counts <1000 cells/mm³). ^dDaptomycin is active in vitro against multidrug-resistant, gram-positive organisms, including <i>S aureus</i>. Daptomycin is approved by the US Food and Drug Administration only for treatment of complicated skin and skin structure infections and for <i>S aureus</i> bloodstream infections for patients 1 year and older. Daptomycin is ineffective for treatment of pneumonia. Because experience with these agents in children is limited, consultation with a specialist in infectious diseases should be considered before use. ^eGentamicin and rifampin for the first 2 weeks should be added for endocarditis of a prosthetic device. Addition of rifampin is recommended for other device-related infections (spinal instrumentation, prosthetic joint). ^fRybak MJ, Le J, Lodise TP, et al. Therapeutic monitoring of vancomycin for serious methicillin-resistant <i>Staphylococcus aureus</i> infections: a revised consensus guideline and review by the American Society of Health-System Pharmacists, the Infectious Diseases Society of America, the Pediatric Infectious Diseases Society, and the Society of Infectious Diseases Pharmacists. <i>Am J Health Syst Pharm</i>. 2020;77(11):835–864 ^gRybak MJ, Le J, Lodise TP, et al. Executive summary: Therapeutic monitoring of vancomycin for serious methicillin-resistant <i>Staphylococcus aureus</i> infections: a revised consensus guideline and review by the American Society of Health-System Pharmacists, the Infectious Diseases Society of America, the Pediatric Infectious Diseases Society, and the Society of Infectious Diseases Pharmacists. <i>J Pediatr Infect Dis Soc</i>. 2020;9(3):281–284 ^hHeil EL, Claeys KC, Mynatt RP, et al. Making the change to area under the curve-based vancomycin dosing. <i>Am J Health Syst Pharm</i>. 2018;75(24):1986–1995	

Observational data suggest that clindamycin should not be used as the only treatment of persistent bacteremia or endovascular infection.

Guidelines for management of serious skin/soft tissue infection, complicated pneumonia/empyema, central nervous system (CNS) infection, osteomyelitis, and endocarditis caused by MRSA are available.¹ For MRSA pneumonia complicating influenza in children, vancomycin monotherapy in the first 24 hours of treatment was associated with higher mortality compared with vancomycin combined with a second antibiotic (clindamycin, linezolid, or ceftaroline) in a retrospective, multicenter study. Thus, a combination of vancomycin plus one of these agents is recommended for empiric treatment of children with life-threatening pneumonia complicating influenza. Antibiotic therapy can be de-escalated to a single agent if there is clinical improvement and antibiotic susceptibility information to guide treatment.

VISA infection is rare in children. If there is concern for inadequate clinical response or reduced susceptibility to vancomycin, consultation with an infectious disease specialist is recommended. Data on the optimal treatment for VISA infection are limited.

Duration of therapy for serious MSSA or MRSA infections depends on the site and severity of infection but usually is 4 weeks or more for endocarditis, necrotizing pneumonia, or disseminated infection, assuming a documented clinical and microbiologic response. For children with uncomplicated staphylococcal osteoarticular infection, particularly those attributable to MSSA, a 3- to 4-week course of therapy may be adequate.^{2,3} For uncomplicated bacteremia, 14 days of therapy is recommended. Overall, in assessing whether modification of therapy is necessary, clinicians should consider whether the patient is improving clinically, should identify and drain sequestered foci of infection and remove foreign material (such as a central catheter) when possible, and for MRSA strains, should consider consultation with an infectious diseases specialist or infection control expert.

Completion of the treatment course with an oral drug can be considered in non-neonates if an endovascular infection (ie, endocarditis or infected thrombus) or CNS infection is not a concern. For endovascular and CNS infections, parenteral therapy is recommended for the entire treatment course. Drainage of large abscesses, often more than once, and removal of foreign bodies are almost always required in addition to medical therapy. In some cases, multiple débridement procedures are necessary for children with complicated *S aureus* osteoarticular infection.

Duration of therapy for *S aureus* central line-associated bloodstream infections is controversial and depends on several factors—the type and location of the catheter, the site of infection (exit site vs tunnel vs line), the feasibility of using an alternative vascular access site at a later date, the presence or absence of a catheter-related

thrombus, and host immunity. Infections are more difficult to treat when associated with a thrombus, thrombophlebitis, or intra-atrial thrombus, and a longer course is suggested if the patient is immunocompromised. Expert opinion differs on recommended treatment duration, but many suggest a minimum of 14 days provided there is no evidence of a metastatic focus, and the patient responds to antimicrobial therapy with rapid sterilization of the blood cultures. If the patient needs a new central line, waiting at least 48 to 72 hours after bacteremia has resolved before insertion, is optimal. If a tunneled catheter is needed for ongoing care, treatment of the infection without removal of the catheter can be attempted but may not always be successful. Vegetations or a thrombus in the heart or great vessels always should be considered when a central line becomes infected and should be suspected more strongly if blood cultures remain positive for more than 2 days on appropriate antimicrobial therapy following removal of the central line or if there are other clinical manifestations associated with endocarditis. Transesophageal echocardiography is the most sensitive technique for identifying vegetations, but transthoracic echocardiography generally is adequate for children younger than 10 years and/or weighing <60 kg.

Management of *S aureus* Toxin-Mediated Diseases. The principles of therapy for TSS include aggressive fluid management (and vasoactive agents, as needed) to maintain adequate venous return and cardiac filling to prevent end organ damage, source control that includes prompt identification and removal of any indwelling foreign body (eg, tampon) or drainable focus, and anticipation and management of the commonly observed multiorgan complications of TSS (eg, acute respiratory distress syndrome, renal dysfunction). Consultation with an expert in infectious diseases is recommended. Initial antimicrobial therapy should include a parentally administered antistaphylococcal beta-lactam antimicrobial agent and a protein synthesis-inhibiting drug, such as clindamycin, at maximum dosages. Vancomycin should be added to the beta-lactam agent in regions where MRSA infections are common, although MRSA-associated TSS is rare in the United States (see Table 3.59, p 773). For TSS with a clindamycin-resistant strain, linezolid may be used as the protein synthesis-inhibiting portion of the therapy. Empiric antibiotic therapy should be modified to targeted therapy once antibiotic susceptibilities are known. Active antimicrobial therapy should be continued for 10 to 14 days. Administration of antimicrobial agents can be changed to the oral route once the patient is tolerating oral alimentation. The total duration of therapy is based on the usual duration for established foci of infection (eg, pneumonia, osteomyelitis). Immune globulin intravenous (IGIV) can be considered in patients with severe staphylococcal TSS unresponsive to other therapeutic measures, because IGIV may neutralize circulating toxin. Although data on the use of IGIV are not robust, it may be considered for critically ill children with shock that is unresponsive to fluid resuscitation, with an undrainable focus of infection, or with persistent oliguria with pulmonary edema. The optimal IGIV regimen is unknown, but 150 to 400 mg/kg per day for 5 days or a single dose of 1 to 2 g/kg has been used. SSSS in infants should be treated with a parenteral antistaphylococcal beta-lactam antimicrobial agent or clindamycin, depending on local susceptibility patterns and the severity of the disease. If MRSA is a consideration, vancomycin or clindamycin (depending on local susceptibility patterns) can be used. Transition to an oral agent is appropriate in nonneonates who have demonstrated excellent clinical response to parenteral therapy.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Contact precautions should be added to standard precautions for patients with abscesses or draining wounds that cannot be covered, regardless of staphylococcal strain (MSSA versus MRSA), and should be maintained until wound drainage ceases or can be contained by a dressing. Infants and young children with staphylococcal furunculosis and patients with SSSS should be placed on contact precautions for the duration of their illness. Although there has been debate about the practice, the CDC continues to recommend contact precautions for patients known to be infected or colonized with MRSA (www.cdc.gov/hai/prevent/staph-prevention-strategies.html).

To prevent transmission of VRSA, the CDC has issued specific infection control recommendations that should be followed (www.cdc.gov/hai/pdfs/VRSA-Investigation-Guide-05_12_2015.pdf).

CONTROL MEASURES: Measures to prevent and control *S aureus* infections can be considered separately for individual patients and for health care facilities.

Individual Patient. Community-associated *S aureus* infections in immunocompetent hosts are difficult to prevent in the absence of clearly apparent risk factors or an outbreak, because the organism is ubiquitous and there is no effective vaccine. Strategies focusing on hand hygiene, environmental disinfection, and wound care have been effective at limiting transmission of *S aureus* and preventing spread of infections in community settings. Specific strategies include appropriate wound care, minimizing skin trauma and keeping abrasions and cuts covered, optimizing hand hygiene and personal hygiene practices (eg, shower after activities involving skin-to-skin contact), avoiding sharing of personal items (eg, towels, razors, clothing), cleaning shared equipment between uses, and regular cleaning of frequently touched environmental surfaces. For patients who experience recurrent *S aureus* infections or who are predisposed to *S aureus* infections because of disorders of neutrophil function, chronic skin conditions, or obesity, a variety of techniques have been used to prevent infection, including scrupulous attention to skin hygiene, dilute bleach baths, and the use of clothing and bed linens that minimize sweating, but none have shown definitive effectiveness in preventing recurrent infections with community-associated MRSA. Household contacts of people with *S aureus* infections generally do not need to be tested for colonization. For patients with multiple recurrent staphylococcal infections, applying mupirocin to the nares and bathing using chlorhexidine for 5 consecutive days for all family members have been associated with decreased recurrences (www.cdc.gov/drugresistance/microbial-ecology/decolonization.html).

Measures to prevent health care-associated *S aureus* infections in individual patients include strict adherence to recommended infection control precautions and appropriate intraoperative antimicrobial prophylaxis, and in some circumstances, use of preoperative antimicrobial regimens to attempt to eradicate nasal carriage; use of chlorhexidine in certain patients also can be considered. Guidelines for prevention of surgical site infections can be found at www.cdc.gov/infectioncontrol/guidelines/ssi/index.html.

Child Care or School Settings. Children with *S aureus* colonization or infection should not be excluded routinely from child care or school settings. Children with draining or open abrasions or wounds should have these covered with a clean, dry dressing. Routine hand hygiene should be emphasized for personnel and children in these facilities.

General Measures. Published recommendations of the CDC Healthcare Infection Control Practices Advisory Committee (HICPAC)¹ for prevention of health care-associated pneumonia should be effective for decreasing the incidence of *S aureus* pneumonia. CDC/HICPAC guidelines for preventing intravascular catheter-related infections include careful preparation of the skin before surgery, including cleansing of skin before placement of intravascular catheters using barrier methods (www.cdc.gov/infectioncontrol/guidelines/bsi/updates.html). Meticulous surgical technique with minimal trauma to tissues, maintenance of good oxygenation, and minimal hematoma and dead space formation will minimize risk of surgical site infection. Appropriate hand hygiene, including before and after use of gloves, by health care professionals and strict adherence to contact precautions are of paramount importance.

Intraoperative Antimicrobial Prophylaxis. Most clean surgical procedures do not require antimicrobial prophylaxis. However, antimicrobial prophylaxis is used in surgeries associated with significant rates of infection and in surgeries in which there are severe consequences of infection (eg, insertion of a major prosthetic device, such as a ventriculoperitoneal shunt or a heart valve), or for a known MRSA carrier undergoing a major surgical procedure (see Antimicrobial Prophylaxis in Pediatric Surgical Patients, p 1117). If antimicrobial prophylaxis is used, the agent, usually cefazolin, is administered 30 to 60 minutes before the operation (vancomycin should be administered over a longer period, approximately 60–120 minutes before skin incision, generally as a single dose), and prophylaxis may be stopped at the conclusion of the procedure in most cases. Administering a single preoperative dose of vancomycin in addition to cefazolin is reasonable for patients known to be colonized with MRSA for whom antibiotic prophylaxis is indicated.

Eradication of Nasal Carriage. The combination of preoperative chlorhexidine baths and intranasal mupirocin has been demonstrated to be beneficial in reducing deep surgical site infections in adult MRSA carriers, but data are limited in children. Use of intermittent or continuous intranasal mupirocin for eradication of nasal carriage also has been shown to decrease the incidence of invasive *S aureus* infections in adult patients undergoing long-term hemodialysis or ambulatory peritoneal dialysis. However, long-lasting eradication of nasal carriage of *S aureus* is difficult, and the practice has not been widely adopted for outpatient dialysis because mupirocin-resistant strains can emerge with repeated or widespread use. A controlled trial in high-risk neonates demonstrated that a regimen of 5 days of mupirocin (intranasal, periumbilical, and perianal) was well-tolerated and led to primary *S aureus* decolonization in 94% of active drug recipients (compared with <5% for placebo recipients); however, >50% of infants who remained hospitalized were recolonized after 2 to 3 weeks.² Intranasal mupirocin treatment is not recommended for routine use but is considered for those with recurrent skin abscesses or during institutional outbreaks of *S aureus* infection.

Institutions. Measures to control spread of *S aureus* within health care facilities involve use and careful monitoring of adherence to HICPAC guidelines.¹⁻³ The CDC also recommends strategies for controlling spread of MRSA (www.cdc.gov/drugresistance/index.html). These strategies focus on administrative issues; engagement, education, and training of personnel; judicious use of antimicrobial agents; monitoring of prevalence trends over time; use of standard precautions for all patients; and use of contact precautions when appropriate. The CDC has also published a collection of strategies to prevent hospital-onset *S aureus* bloodstream infections (www.cdc.gov/hai/prevent/staph-prevention-strategies.html), which focuses on prevention of device and procedure-associated infections, source control strategies for high-risk patients during high-risk periods, interventions to prevent transmission of MRSA in acute care hospitals, and infrastructure needed for prevention. In addition to those contained in HICPAC guidelines for specific device or procedure associated infections, strategies also include intranasal antistaphylococcal antibiotic/antiseptic in conjunction with chlorhexidine wash or wipes before high-risk surgery (eg, cardiothoracic, orthopedic, neurologic, especially those with implantable devices). To reduce the risk of central line-associated bloodstream infections, daily chlorhexidine bathing is recommended for intensive care patients who are at least 2 months of age. Some centers use chlorhexidine wash for younger patients being cared for in the pediatric intensive care unit (the package insert recommends using with care in infants younger than 2 months and preterm infants because of concerns about burns). When rates of endemicity are not decreasing despite adherence to these measures, additional interventions, such as use of active surveillance cultures to identify colonized patients and to place them in contact precautions, may be warranted. Decolonization of a health care professional can be considered if the health care professional has been found to be a carrier of *S aureus* and has been epidemiologically linked as a likely source of ongoing transmission to patients. In this situation, attempts to eradicate carriage with topical nasal mupirocin therapy often are made. Both low-level (MIC 8–256 µg/mL) and high-level (MIC ≥512 µg/mL) resistance to mupirocin have been identified in *S aureus*, with high-level resistance associated with failure of decolonization.

Recommendations for investigation and control of VRSA have been published by the CDC (www.cdc.gov/hai/pdfs/VRSA-Investigation-Guide-05_12_2015.pdf). The CDC should be contacted for confirmatory testing if *S aureus* isolates with vancomycin MIC of ≥8 µg/mL are identified (generally, notification to the local or state health department should occur first; some initial testing can be performed at

many public health laboratories). Ongoing review and restriction of vancomycin use is critical in attempts to control the emergence of VISA and VRSA (see Antimicrobial Resistance and Antimicrobial Stewardship: Appropriate and Judicious Use of Antimicrobial Agents, p 978). To date, the use of catheters impregnated with various antimicrobial agents or metals to prevent health care-associated infections has not been evaluated adequately in children.

Nurseries and Neonatal Intensive Care Units. Outbreaks of *S aureus* infections in newborn nurseries require unique measures of control. Hand hygiene should be emphasized to all personnel and visitors. Standard umbilical cord care currently does not include use of topical products (eg, triple dye). Measures recommended during outbreaks include reinforcement of hand hygiene, alleviating overcrowding and understaffing, surveillance of *S aureus* colonization of newborn infants at admission and periodically thereafter, use of contact precautions for colonized or infected infants, and cohorting of colonized or infected infants and their caregivers. During an outbreak, decolonization measures for infants can be considered. The optimal approach for decolonization of neonates is not yet clear, and some products, such as chlorhexidine, may be associated with risk of caustic cutaneous effects and systemic absorption. A randomized controlled trial of decolonization of high-risk neonates using a mupirocin regimen was well tolerated and was associated with short-term decolonization, although recolonization occurred after 2 to 3 weeks in many neonates who were still hospitalized (see Eradication of Nasal Carriage, p 780). Decolonization of colonized health care professionals who are epidemiologically implicated in *S aureus* transmission can be attempted but may not be successful. The CDC has issued guidance on the prevention and control of *S aureus* infections in neonatal intensive care units (www.cdc.gov/infectioncontrol/guidelines/NICU-saureus/), and the Society for Healthcare Epidemiology of America has issued a white paper on this subject (<https://doi.org/10.1017/ice.2022.53>).

Coagulase-Negative Staphylococcal Infections

CLINICAL MANIFESTATIONS: Coagulase-negative staphylococci (CoNS) are part of normal skin flora and isolates from patient specimens often result from contamination of culture material from skin sites (see Diagnostic Tests). Differentiation between colonization and true infection may be difficult. Of the isolates that do not represent contamination, most come from infections associated with medical devices used in health care, or in patients with obvious disruptions of host defenses caused by surgery, immunosuppression, or prematurity (eg, very low birth weight infants). CoNS cause about 30% of health care-associated bloodstream infections. These organisms are a common cause of late-onset bacteremia and septicemia among preterm infants, typically infants weighing less than 1500 g at birth, and of episodes of health care-associated bacteremia in all age groups. CoNS cause bacteremia in children with intravascular catheters, vascular grafts, intracardiac patches, prosthetic cardiac valves, or pacemaker wires. Infection may also be associated with other indwelling foreign bodies, including cerebrospinal fluid shunts, peritoneal catheters, spinal instrumentation, baclofen pumps, pacemakers, left ventricular assist devices, or prosthetic joints. Mediastinitis after open-heart surgery, endophthalmitis after intraocular trauma, and

omphalitis and scalp abscesses in preterm neonates have occurred. CoNS also can enter the bloodstream from the respiratory tract of mechanically ventilated preterm infants or from the gastrointestinal tract of infants with necrotizing enterocolitis. Some species of CoNS are associated with urinary tract infection, including *Staphylococcus saprophyticus* in adolescent and young adult females, often after sexual intercourse, and *Staphylococcus epidermidis* and *Staphylococcus haemolyticus* in hospitalized patients with urinary catheters. *Staphylococcus lugdunensis* is particularly virulent, resulting in infections resembling those caused by *Staphylococcus aureus*, including skin and soft tissue infection and bacteremia with or without endocarditis. *Staphylococcus schleiferi*, like *S. lugdunensis*, is a virulent species and has caused pacemaker and osteoarticular infections.

ETIOLOGY: There are more than 50 recognized coagulase-negative *Staphylococcus* species. *Staphylococcus epidermidis*, *S. haemolyticus*, *S. saprophyticus*, *S. schleiferi* (subspecies *schleiferi*), *S. lugdunensis*, *Staphylococcus capitis*, *Staphylococcus hominis*, and *Staphylococcus simulans* are the CoNS species most frequently associated with human infections. *Staphylococcus saccharolyticus*, the only anaerobic CoNS, has been implicated in a variety of human infections. More recently identified species that have been implicated rarely in clinical disease include *Staphylococcus borealis*, *Staphylococcus massiliensis*, and *Staphylococcus petrasii* sp. nov. Many CoNS produce an exopolysaccharide slime biofilm that enables these organisms to bind to medical devices (eg, catheters) and makes them relatively inaccessible to host defenses and antimicrobial agents.

EPIDEMIOLOGY: CoNS are ubiquitous inhabitants of the skin and mucous membranes. Virtually all neonates are colonized with CoNS at multiple sites by 2 to 4 days of age. The most frequently isolated CoNS organism is *S. epidermidis*, which is found widely in most areas of skin. Different species colonize specific areas of the body. *S. haemolyticus* is found on areas of skin with numerous apocrine glands, *S. capitis* is often isolated from the scalp and forehead, and *S. lugdunensis* has a predilection for colonization of the inguinal and groin areas. *S. schleiferi* colonizes the mouth of carnivores, can be transferred from pets to owners, and has also been found as a colonizing organism in the preaxillary skin. Infants and children in intensive care units, including neonatal intensive care units, have the highest incidence of CoNS bloodstream infections. CoNS can be introduced at the time of medical device placement, through mucous membrane or skin breaks, through loss of bowel wall integrity (eg, necrotizing enterocolitis in very low birth weight neonates), or during catheter manipulation. Less often, health care professionals with environmental CoNS colonization on their hands transmit the organism.

The **incubation period** is variable for CoNS disease. A long delay can occur between acquisition of the organism and onset of disease.

DIAGNOSTICS TESTS: CoNS are readily isolated in culture using the same media and incubation conditions used for *S. aureus*. Tests for coagulase by traditional methods or by latex agglutination are the same as used for *S. aureus*. CoNS isolated from a single blood culture are commonly classified as skin contaminants, especially in the absence of risk factors for invasive disease. In this situation, full identification and antimicrobial susceptibility testing are generally not performed in most clinical laboratories. Fluorescent in situ hybridization (FISH) probes or multiplex polymerase chain reaction (PCR) panel assays can rapidly differentiate CoNS and *S. aureus* isolated in blood cultures. In a very preterm neonate, an immunocompromised person, or a patient with

an indwelling catheter or prosthetic device, repeated isolation of the same species of CoNS from blood cultures or another normally sterile body fluid suggests true infection. When a central line-associated bloodstream infection is present, blood cultures drawn from the catheter generally become positive 2 or more hours before cultures obtained from a peripheral venipuncture. This type of analysis requires that both a peripheral and catheter blood culture be performed at the same time using equal volumes of blood. Typing methods, such as pulsed-field gel electrophoresis or whole genome sequencing may be utilized to define clonality and identify the significance of isolates in outbreak settings or complex clinical scenarios.

Criteria that suggest CoNS as bloodstream pathogens, rather than contaminants, include the following:

- Two or more positive blood cultures with the same *Staphylococcus* species from different collection sites;
- A positive culture from blood and from another sterile site (eg, cerebrospinal fluid, joint) with the same *Staphylococcus* species and identical antimicrobial susceptibility patterns for each isolate;
- Growth in a continuously monitored blood culture system within 15 hours of incubation;
- Clinical findings of infection;
- Presence of an intravascular catheter that has been in place for 3 days or more; and
- Similar or identical genotypes among all isolates collected from the same patient.

TREATMENT: More than 90% of health care-associated CoNS strains are methicillin resistant. Methicillin-resistant strains are resistant to all beta-lactam drugs, including cephalosporins (except ceftaroline), and usually several other drug classes. Intravenous vancomycin is recommended for the treatment of serious infections caused by CoNS strains resistant to beta-lactam antimicrobial agents. Ceftaroline, daptomycin, and linezolid are alternative agents when vancomycin cannot be used. Dalbavancin has received US Food and Drug Administration approval for use in infants and children; other lipoglycopeptides including telavancin and oritavancin have limited data on use in the pediatric population. In noncritical localized infection, antimicrobials such as trimethoprim-sulfamethoxazole, clindamycin, and doxycycline can be considered based on susceptibility data. Unlike most other CoNS species, *S. lugdunensis* often is methicillin susceptible, and antistaphylococcal beta lactams can be used as first-line therapy when susceptibility is confirmed. See Tables 4.2 (p 988) and 4.3 (p 993) for dosing and drug monitoring information for neonates and non-neonates, respectively.

Treatment of foreign bodies infected with CoNS often involves removal of the device, in addition to antibiotic therapy. Consultation with an expert in pediatric infectious diseases is advised to assist in the management of these infections. The addition of rifampin to vancomycin or daptomycin therapy in prosthetic joint infections is supported by limited studies. Rifampin and gentamicin are generally added to the primary antistaphylococcal agent in the treatment of prosthetic endocarditis (gentamicin typically for the first 2 weeks). Prolonged therapy is likely necessary when there is endocarditis or if the infected device (eg, spinal hardware) cannot be removed entirely. Adjunctive antimicrobial lock therapy of tunneled central lines may result in a higher rate of catheter salvage in adults with CoNS infections, but experience with this approach is limited in children. If blood cultures remain positive for more than 3 to 5 days after initiation of appropriate antimicrobial therapy for CoNS or if the patient

fails to improve, the central line should be removed, parenteral therapy should be continued, and the patient should be evaluated for metastatic foci of infection.

A 5-day course of therapy is generally appropriate for CoNS central line associated blood stream infections in immunocompetent hosts, if the central line is removed, there is no demonstrable thrombus, and bacteremia resolves promptly. If the catheter is retained, a treatment duration of 10 to 14 days is appropriate. For non-neonates, observation without antibiotics could be considered in uncomplicated central line infections if patients are immunocompetent, have no other intravascular device or orthopedic hardware, and there is prompt clearance of bacteremia after the line is removed. The exception is *S lugdunensis*, which should be managed similarly to *S aureus* catheter-related infections regardless of patient age; endocarditis with valvular destruction may require urgent surgical intervention (see *Staphylococcus aureus*, p 767).

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are used.

CONTROL MEASURES: Prevention and control of CoNS infections involves prevention of intraoperative contamination by skin flora and sterile insertion of intravascular and intraperitoneal catheters and other prosthetic devices. Catheter-related blood-stream infections can be markedly reduced with a “bundled” prevention approach, which should include catheter removal as soon as it is no longer needed.

Group A Streptococcal Infections

CLINICAL MANIFESTATIONS: The most common group A streptococcal (GAS) infection is acute pharyngotonsillitis (pharyngitis), which manifests as sore throat with tonsillar inflammation and often tender anterior cervical lymphadenopathy, palatal petechiae, or a strawberry tongue. Purulent complications of pharyngitis include peritonsillar or retropharyngeal abscesses, suppurative cervical adenitis, and rarely, sinusitis and otitis media. Nonsuppurative complications include acute rheumatic fever (ARF) and acute glomerulonephritis (AGN). The goals of antimicrobial therapy for GAS pharyngitis are to reduce acute morbidity, suppurative and nonsuppurative (ARF) complications, and transmission to close contacts. There is insufficient evidence to determine effectiveness of antimicrobials to prevent AGN after pyoderma or pharyngitis.

Scarlet fever occurs most often with pharyngitis and, rarely, with pyoderma or an infected wound. Scarlet fever involves a characteristic confluent erythematous sandpaper-like rash caused by one or more GAS erythrogenic exotoxins. Other than rash, the epidemiologic features, symptoms, signs, sequelae, and treatment of scarlet fever are the same as those of streptococcal pharyngitis.

Acute streptococcal pharyngitis is uncommon in children younger than 3 years. Instead, they may present with rhinitis and a more protracted illness with moderate fever, irritability, and anorexia (streptococcal fever or streptococcosis).

The second most common site of GAS infection is the skin. Streptococcal skin infections (eg, pyoderma or impetigo) can be followed by AGN, occasionally in epidemics. Historically, GAS skin infection has not been proven to lead to ARF; however, emerging evidence from Australia and New Zealand support that ARF can be a complication of GAS skin infection.

Other GAS infections include erysipelas, cellulitis (including perianal), vaginitis, bacteremia, sepsis, pneumonia, endocarditis, pericarditis, septic arthritis, necrotizing fasciitis, purpura fulminans, osteomyelitis, myositis, puerperal sepsis, surgical wound infection, mastoiditis, and neonatal omphalitis. Invasive GAS infections often encompass bacteremia with or without a specific focus of infection and can present as streptococcal toxic shock syndrome (STSS), sepsis, or necrotizing fasciitis. Necrotizing fasciitis can follow minor or unrecognized trauma and uncommonly pharyngitis, often involves an extremity, and manifests as pain out of proportion to examination findings.

STSS is caused by infection with a toxin-producing GAS strain, manifesting as a severe acute illness, which usually has rapid onset. The case definition of STSS (see Table 3.60) requires detection of the GAS organism in a patient with rapid onset of hypotension and signs of multiorgan involvement characterized by 2 or more of the following: acute kidney injury, coagulopathy, liver involvement, acute respiratory distress syndrome, generalized erythematous macular rash, or soft tissue necrosis. Local soft tissue infection (eg, cellulitis, myositis, or necrotizing fasciitis) associated with severe, rapidly increasing pain is common, although STSS can occur without an identifiable focus of infection.

Table 3.60. Streptococcal Toxic Shock Syndrome: Clinical Case Definition^a

-
- I. Isolation of group A *Streptococcus* (*Streptococcus pyogenes*)
- A. From a normally sterile site (eg, blood, cerebrospinal fluid, peritoneal, joint, pleural, or pericardial fluid)
 - B. From a nonsterile site (eg, throat, sputum, vagina, open surgical wound, or superficial skin lesion)
- II. Clinical signs of severity
- A. Hypotension: systolic pressure 90 mm Hg or less in adults or lower than the fifth percentile for age in children <16 years of age
- AND**
- B. Two or more of the following signs of multiorgan involvement:
 - Renal impairment: creatinine concentration 177 $\mu\text{mol/L}$ (2 mg/dL) or greater for adults or at least 2 times the upper limit of normal for age^b
 - Coagulopathy: platelet count 100 000/ mm^3 or less and/or disseminated intravascular coagulation defined by prolonged clotting times, low fibrinogen, and presence of fibrin degradation products
 - Hepatic involvement: elevated alanine aminotransferase, aspartate aminotransferase, or total bilirubin concentrations at least 2 times the upper limit of normal for age^b
 - Acute respiratory distress syndrome defined by acute onset of diffuse pulmonary infiltrates and hypoxemia in absence of cardiac failure or by evidence of diffuse capillary leak
 - A generalized erythematous macular rash that may desquamate
 - Soft tissue necrosis, including necrotizing fasciitis or myositis, or gangrene
-

Adapted from the 2010 Case Definition from the Council of State and Territorial Epidemiologists (<https://ndc.services.cdc.gov/case-definitions/streptococcal-toxic-shock-syndrome-2010/>) and from: The Working Group on Severe Streptococcal Infections. Defining the group A streptococcal toxic shock syndrome: rationale and consensus definition. *JAMA*. 1993;269(3):390–391

^aAn illness fulfilling criteria IA and IIA and IIB can be defined as a *confirmed* case. An illness fulfilling criteria IB and IIA and IIB can be defined as a *probable* case if no other cause for the illness is identified. Manifestations need not be detected within the first 48 hours of illness or hospitalization.

^bIn patients with preexisting renal or hepatic disease, concentrations twofold or greater over patient's baseline.

An association between GAS infection and sudden onset of obsessive-compulsive behavior, tic disorders, or other unexplained acute neurologic changes—called pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS)—has been proposed. The American Academy of Pediatrics is reviewing PANDAS; it will not be covered in this chapter.

ETIOLOGY: More than 240 distinct serotypes or genotypes of group A streptococci (*Streptococcus pyogenes*) have been identified based on M-protein serotype or M-protein gene sequence (*emm* types). In general, *emm* typing is more discriminating than M-protein serotyping. Epidemiologic studies indicate an association between certain *emm* types (eg, types 1, 3, 5, 6, 14, 18, 19, and 24) and rheumatic fever, but a specific rheumatogenic factor remains unidentified. Several *emm* types (eg, types 2, 49, 55, 57, 59, 60, and 61) are more commonly associated with pyoderma and acute glomerulonephritis. Other serotypes (eg, types 1, 6, and 12) are associated with pharyngitis and acute glomerulonephritis. Although many *emm* types can cause STSS, most cases are caused by *emm* 1 and *emm* 3 strains producing at least 1 pyrogenic exotoxin, most commonly streptococcal pyrogenic exotoxin A (*speA*). These toxins are superantigens, stimulating production of tumor necrosis factor and other inflammatory mediators causing capillary leak and other physiologic changes including hypotension and multiorgan damage. In the United Kingdom, an increase in scarlet fever cases since 2016 has been associated with a new strain of *emm* 1 (M1UK lineage).

EPIDEMIOLOGY: Pharyngitis usually results from respiratory droplet transmission but can also occur through contact with respiratory secretions or wound discharge from an infected person. Although environmental transmission via surfaces and fomites was historically not believed to occur, evidence from outbreak investigations indicates that environmental transmission of GAS can occur. Household pets, such as dogs, are not vectors. Pharyngitis and impetigo (and their nonsuppurative complications) can be associated with crowding and often are present in socioeconomically disadvantaged populations. Close contact in schools, child care centers, contact sports (eg, wrestling), boarding schools, and military installations facilitates transmission. Rare foodborne outbreaks of pharyngitis are a consequence of human contamination of food with improper food preparation or refrigeration.

GAS pharyngitis is most common among school-aged children and adolescents, peaking at 7 to 8 years of age. GAS pharyngitis and pyoderma are substantially less common in adults than children.

Geographically, GAS pharyngitis and pyoderma are ubiquitous. Pyoderma is more common in tropical climates and warm seasons, in part because of antecedent insect bites and other minor skin trauma. Streptococcal pharyngitis is more common during late fall, winter, and spring in temperate climates in part because of close contact in schools. Communicability of streptococcal pharyngitis peaks during acute infection and when untreated, then gradually diminishes over a period of weeks.

Throat culture surveys of healthy asymptomatic children during the streptococcal season and during school outbreaks of pharyngitis yield GAS carriage prevalence rates as high as 25%. GAS carriage can persist for many months, but the risks of postinfectious or infectious complications and of transmission are low.

In streptococcal impetigo/pyoderma, the organism usually is acquired by direct contact from another person. GAS colonization of healthy skin usually precedes impetigo.

Impetiginous lesions occur at the site of breaks in skin (eg, insect bites, burns, traumatic wounds, varicella lesions). After development of impetiginous lesions, the upper respiratory tract can become colonized with GAS organisms. Infection of surgical wounds and postpartum (puerperal) sepsis usually result from transmission through direct contact. Health care workers who are pharyngeal, anal, or vaginal GAS carriers and those with skin infection or skin colonization can transmit GAS infection to patients, particularly surgical and obstetrical patients, and long-term care facility residents, sometimes resulting in health care-associated outbreaks. Infections in neonates, uncommon in the United States but common in many low-income countries, result from intrapartum or contact transmission; the latter infection can begin as omphalitis, cellulitis, or necrotizing fasciitis. In the United States, the incidence of invasive GAS infections is highest in the elderly and lowest among children and adolescents. Pregnant people and those in the postpartum period are at increased risk of invasive GAS infection. Fatal cases in children are not common, but they can progress very rapidly (eg, overwhelming sepsis). Before varicella vaccine, varicella infection (chickenpox) was the most commonly identified predisposing factor for invasive GAS infection in children. Other risk factors include exposure to other children and household crowding. The portal of entry is unknown in most invasive GAS infections but presumably relates to skin or mucous membranes. Such infections very rarely follow symptomatic GAS pharyngitis.

STSS can occur at any age. Fewer than 5% of invasive streptococcal infections in children are associated with STSS. Childhood STSS has been reported with focal lesions (eg, varicella, cellulitis, trauma, osteomyelitis, pneumonia), and with bacteremia without a defined focus. Mortality rates are substantially lower for children than for adults with STSS.

ARF is endemic in parts of Africa, Asia, and the Pacific, including the Australian and New Zealand indigenous populations. The United States, Canada, and most of Europe are considered ARF low-risk populations, although sporadic cases continue to occur. During GAS epidemics on military bases in the 1950s, ARF developed in up to 3% of untreated acute GAS pharyngitis. Very rare cases have occurred in treated patients. The current incidence in the United States is not precisely known but is believed to be <0.5%, with much higher rates reported among people of Samoan or Polynesian ancestry living in Hawaii or in residents of American Samoa. Focal outbreaks of ARF in school-aged children occurred in several areas in the United States in the 1990s, and small clusters are reported periodically, most likely related to circulation of particularly rheumatogenic GAS strains.

Poststreptococcal AGN is more common in resource-limited regions, in male individuals, and in children 5 to 12 years of age.¹

The **incubation period** for streptococcal pharyngitis is 2 to 5 days. For impetigo, a 7- to 10-day period between GAS acquisition on healthy skin and the development of lesions has been demonstrated. The **incubation period** for STSS is not known but can be as short as 14 hours when associated with subcutaneous inoculation of organisms (eg, puerperal sepsis, penetrating trauma). The **incubation period** for ARF is generally 1 to 5 weeks following pharyngitis; chorea occurs 1 to 8 months following pharyngitis. The **incubation period** for poststreptococcal AGN is generally 10 days following pharyngitis and up to 3 weeks following GAS skin infections.

¹ The term male refers to sex assigned at birth.

DIAGNOSTIC TESTS¹:

Testing for Group A Streptococci in Pharyngitis. Children with acute onset of sore throat and clinical signs and symptoms such as pharyngeal exudate, enlarged tonsils, pain on swallowing, fever, and enlarged tender anterior cervical nodes are more likely to have GAS infection and should be tested. Children with pharyngitis and obvious viral features (eg, rhinorrhea, cough, hoarseness, oral ulcers) should not be tested or treated for GAS infection. Testing also is generally not recommended for children younger than 3 years, although testing and treatment may be considered for some symptomatic children younger than 3 years who have other risk factors, such as an older sibling with GAS infection. Laboratory confirmation of GAS before initiation of antimicrobial treatment is required for children with pharyngitis without viral symptoms, because many will not have GAS pharyngitis. A specimen should be obtained by vigorously swabbing both tonsils and the posterior pharynx for rapid antigen testing or other diagnostic test, as discussed below. A second backup swab specimen from a child with a negative rapid antigen test should be submitted for culture or molecular testing. Culture on sheep blood agar can confirm GAS infection, with latex agglutination differentiating group A streptococci from other beta-hemolytic streptococci (eg, group C or G). False-negative culture results occur in <10% of symptomatic patients when an adequate throat swab specimen is obtained and cultured by trained personnel. Recovery of GAS organisms from the pharynx or assessing the density of colonies does not distinguish those patients with acute streptococcal infection from streptococcal carriers with intercurrent viral pharyngitis. Cultures negative for GAS organisms after 18 to 24 hours incubation should be reincubated for a second day to optimize recovery of GAS bacteria.

Several rapid tests for GAS pharyngitis are available. The specificity of these tests generally is high (very few false-positive results), but reported sensitivities vary considerably and generally are 75% to 85% (ie, false-negatives occur). As with throat cultures, the sensitivity of these tests is highly dependent on the quality of the throat swab specimen and the experience of the test performer. Because of the very high specificity of rapid antigen-based tests, a positive result does not require culture confirmation, but a negative result requires a confirmatory test in children. Other diagnostic tests using techniques such as polymerase chain reaction (PCR), chemiluminescent DNA probes, and isothermal nucleic acid amplification tests (NAATs) have been developed. The US Food and Drug Administration has approved some NAATs for detection of group A streptococci from throat swab specimens as stand-alone tests that, because of very high sensitivity, do not require routine culture confirmation of negative test results. Some studies suggest that in addition to providing more timely results, these tests may be even more sensitive than standard cultures of throat swab specimens on sheep blood agar. Additional studies are ongoing to establish the benefits and limitations of these tests.

Testing Contacts for GAS Infection. Indications for testing contacts for GAS infection are few, outside of outbreak investigations. Testing asymptomatic household contacts is not recommended, except when the contacts are at increased risk for sequelae of GAS infection, such as with established ARF or AGN; if test results are positive, contacts should be treated.

¹ Shulman ST, Bisno AL, Clegg HW, et al. Clinical practice guideline for the diagnosis and management of group A streptococcal pharyngitis: 2012 update by the Infectious Diseases Society of America. *Clin Infect Dis*. 2012;55(10):e86-e102

In schools, child care centers, or other environments where many people are in close contact, the prevalence of GAS pharyngeal carriage in healthy children can reach 25%, even in the absence of an outbreak of streptococcal disease. Therefore, classroom or more widespread testing generally is not indicated.

Testing asymptomatic household contacts usually is not helpful. However, if multiple household members have pharyngitis or other GAS infections, simultaneous cultures of all household members and treatment of all with positive test results may be of value.

Follow-up Throat Cultures. Post-treatment throat cultures are indicated only for those at particularly high risk of ARF (eg, with previous history of ARF).

Testing for Group A Streptococci in Nonpharyngitis Infections. Cultures of impetigo lesions often yield both streptococci and staphylococci, and determination of the primary pathogen is generally difficult. Culture can be used to determine *S aureus* susceptibility; however, it is generally unnecessary in routine clinical practice. In suspected invasive GAS infections, cultures of blood and focal sites of possible infection are indicated. In necrotizing fasciitis, although imaging studies may be helpful in establishing the diagnosis, surgical exploration should never be delayed for imaging studies. Clinical suspicion of necrotizing fasciitis should prompt urgent surgical evaluation with possible urgent débridement of affected tissues, with Gram stain and culture of surgical specimens. STSS is diagnosed on the basis of clinical findings, laboratory findings, and isolation of GAS organisms (Table 3.60); more than 50% of patients with STSS have blood cultures positive for GAS organisms. Cultures of focal sites of infection are also usually positive and can remain positive for several days after initiation of appropriate antimicrobial agents.

Acute Rheumatic Fever. The Jones criteria for diagnosis of ARF were established in 1944 and revised and modified several times, most recently in 2015.¹ The 2015 Jones criteria revision (Table 3.61) differentiates major and minor criteria on the basis of whether the child is from an area at low or moderate/high risk for ARF. Laboratory evidence of antecedent GAS infection should be confirmed in suspected ARF and includes an elevated or increasing antistreptolysin O or anti-DNAase B titer, a positive rapid antigen test result, or positive streptococcal throat culture (this revision was made prior to widespread availability of molecular tests). Because of the long latency between GAS infection and chorea, laboratory evidence may be lacking when chorea is the only major criterion. See Table 3.61 for the major and minor criteria.

Poststreptococcal Glomerulonephritis. Diagnosis is based on clinical findings of acute nephritis and evidence of a recent GAS infection in the throat or skin, generally by culture or serologic testing.

TREATMENT²:

S pyogenes is uniformly susceptible to all beta-lactam antibiotics (penicillins and cephalosporins); thus, susceptibility testing is needed only for non-beta-lactam agents, such as a macrolide or clindamycin, to which some strains of *S pyogenes* are resistant.

¹ Gewitz MH, Baltimore RS, Tani LY, et al. Revision of the Jones criteria for the diagnosis of acute rheumatic fever in the era of Doppler echocardiography. *Circulation*. 2015;131(20):1806-1818

² Shulman ST, Bisno AL, Clegg HW, et al. Clinical practice guideline for the diagnosis and management of group A streptococcal pharyngitis: 2012 update by the Infectious Diseases Society of America. *Clin Infect Dis*. 2012;55(10):e86-e102

Table 3.61. Revised Jones Criteria (2015)

1. All patients require evidence of antecedent GAS infection for diagnosis of ARF (except in case of isolated chorea, in which evidence of antecedent GAS infection is not required).
2. To confirm an initial diagnosis of ARF, need 2 major OR 1 major and 2 minor criteria.
3. To confirm recurrent ARF diagnosis, need 2 major OR 1 major and 2 minor OR 3 minor criteria.
4. Criteria for diagnosis are dependent on whether patient is from a low-risk or a moderate-/high-risk population. Moderate- and high-risk populations include countries where ARF remains endemic (Africa, Asia-Pacific, indigenous population of Australia and New Zealand). The United States, Canada, and most of western Europe are examples of low-risk areas.
5. Major and minor criteria are listed below, by risk categorization; differences for moderate-/high-risk populations are **bolded**.

Low-Risk Population

Major Criteria

- Carditis (clinical or subclinical)
- Arthritis (polyarthritis only)
- Chorea
- Subcutaneous nodules
- Erythema marginatum

Minor Criteria

- Polyarthralgia (unless arthritis is a major criteria)
- Fever $\geq 38.5^{\circ}\text{C}$
- ESR ≥ 60 mm/h and/or CRP ≥ 3 mg/dL
- Prolonged PR interval (in absence of carditis)

Moderate- and High-Risk Population

Major Criteria

- Carditis (clinical or subclinical)
- Arthritis (polyarthritis or **monoarthritis, or polyarthralgia**)
- Chorea
- Subcutaneous nodules
- Erythema marginatum

Minor Criteria

- **Monoarthralgia** (unless arthritis is a major criteria)
- **Fever $\geq 38^{\circ}\text{C}$**
- **ESR ≥ 30 mm/h** and/or CRP ≥ 3 mg/dL
- Prolonged PR interval (in absence of carditis)

ARF indicates acute rheumatic fever; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; GAS, group A streptococcal.

Modified from Table 7 in Gewitz MH, Baltimore RS, Tani LY, et al. Revision of the Jones criteria for the diagnosis of acute rheumatic fever in the era of Doppler echocardiography: a scientific statement from the American Heart Association. *Circulation*. 2015;131(20):1806-1818.

Pharyngitis.

- Penicillin V, amoxicillin, or penicillin G benzathine are 3 options for first-line regimens for GAS pharyngitis.
- Administration of penicillin shortens the clinical course (if administered promptly), decreases the risk of transmission and suppurative sequelae, and prevents ARF, even when administered up to 9 days after illness onset. All patients with ARF should receive a complete course of penicillin or another appropriate antimicrobial agent for GAS pharyngitis, even if group A streptococci are not recovered from the throat.
- Amoxicillin, orally as a single daily dose (50 mg/kg; maximum, 1000–1200 mg) for 10 days, is as effective as penicillin V or amoxicillin administered orally multiple times per day for 10 days and is a more palatable suspension than penicillin V. This

regimen is endorsed by the American Heart Association and the Infectious Disease Society of America in their guidelines for the treatment of GAS pharyngitis and the prevention of ARF.¹ Adherence is particularly important for once-daily dosing regimens.

- The dose of oral penicillin V is 400 000 U (250 mg), 2 to 3 times per day, for 10 days for children weighing <27 kg and 800 000 U (500 mg), 2 to 3 times per day, for those weighing ≥27 kg, including adolescents and adults. To prevent ARF, oral penicillin or amoxicillin should be taken for 10 full days, regardless of the promptness of clinical recovery. Treatment failures occur more often with oral penicillin than with intramuscular penicillin G benzathine because of inadequate adherence. Notably, short-course treatment (<10 days) for GAS pharyngitis, particularly with penicillin V, is associated with inferior bacteriologic eradication rates.
- Intramuscular penicillin G benzathine is appropriate therapy, ensuring adequate blood concentrations and avoiding adherence issues, but administration may be painful. See Tables of Antibacterial Drug Dosages (p 987) for dosing. Discomfort is decreased if the preparation of penicillin G benzathine is brought to room temperature before intramuscular injection. Mixtures containing shorter-acting penicillins (eg, penicillin G procaine) in addition to penicillin G benzathine are not more effective than penicillin G benzathine alone but are less painful. Although supporting data are limited, the combination of 900 000 U (562.5 mg) of penicillin G benzathine and 300 000 U (187.5 mg) of penicillin G procaine is satisfactory for most children; however, the efficacy of this combination for heavier patients has not been documented.
- For patients who have a history of nonanaphylactic allergy to penicillin or amoxicillin, a 10-day course of a narrow-spectrum (first-generation) oral cephalosporin (eg, cephalexin) is indicated. Patients with immediate (anaphylactic) or type I hypersensitivity to penicillin or amoxicillin should receive oral clindamycin (20 mg/kg per day in 3 divided doses; maximum, 900 mg/day for 10 days) rather than a cephalosporin.
- An oral macrolide (eg, erythromycin, azithromycin, or clarithromycin) also is acceptable for penicillin-allergic patients. This medication should not be used in patients who can take a beta-lactam agent. Therapy for 10 days is indicated, except for azithromycin, which is given for 5 days. GAS strains resistant to macrolides have resulted in treatment failures.
- In the United States, macrolide and clindamycin (inducible and constitutive) resistance rates of close to 30% have been reported among invasive GAS isolates (www.cdc.gov/abcs/bact-facts-interactive-dashboard.html). Testing for macrolide and clindamycin resistance may help in deciding the best antimicrobial agent for a specific patient with penicillin allergy.
- Tetracyclines, sulfonamides, and fluoroquinolones should not be used for treating GAS pharyngitis.
- Children with recurrent GAS pharyngitis shortly after a full course of a recommended oral agent can be retreated with the same antimicrobial agent (if it is a

¹ Gerber MA, Baltimore RS, Eaton CB, et al. Prevention of rheumatic fever and diagnosis and treatment of acute streptococcal pharyngitis. A scientific statement from the American Heart Association, Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee, Council on Cardiovascular Disease in the Young, and the Quality of Care and Outcomes Research Interdisciplinary Working Group and endorsed by the American Academy of Pediatrics. *Circulation*. 2009;119(11):1541-1551

beta-lactam), an alternative beta-lactam oral drug (such as cephalexin or amoxicillin-clavulanate), or an intramuscular dose of penicillin G benzathine. Susceptibility testing should be performed when considering a macrolide or clindamycin.

Frequent Acute Pharyngitis With Positive GAS Testing. Patients with repeated episodes of acute pharyngitis at short intervals in whom GAS infection is documented by culture or rapid antigen or NAAT present a special problem. Most often, they are GAS carriers experiencing frequent viral illnesses for whom repeated testing and antimicrobials are unnecessary. In assessing these patients, inadequate adherence to oral treatment also should be considered. To determine whether the patient is a long-term streptococcal pharyngeal carrier who is experiencing repeated episodes of intercurrent viral pharyngitis (the most common situation), it should be determined: (1) whether clinical findings are more suggestive of GAS or viral infection; (2) whether household or community epidemiologic factors support GAS or viral etiology; (3) the nature of the clinical response to antimicrobial therapy (in GAS pharyngitis, response to therapy usually is <24 hours); and (4) whether test results are positive for GAS between episodes of acute pharyngitis (suggesting the patient is a carrier). Measurement of serologic response to GAS extracellular antigens (eg, antistreptolysin O) is discouraged, because interpretation can be very difficult. Typing (M or *emm* typing) of GAS isolates generally is available only in research or public health laboratories, but if performed, repeated isolation of the same type suggests carriage, while isolation of differing types indicates repeated infections.

Pharyngeal Carriers. Antimicrobial therapy is not indicated for most GAS pharyngeal carriers. The few specific situations in which eradication of carriage may be indicated include the following: (1) a local outbreak of ARF, poststreptococcal glomerulonephritis, or severe or invasive GAS disease; (2) an outbreak of GAS pharyngitis in a closed or semiclosed community; (3) a family history of ARF; (4) multiple (“ping-pong”) episodes of documented symptomatic GAS pharyngitis occurring within a family for many weeks despite appropriate therapy; or (5) when a patient is being seriously considered for tonsillectomy solely because of frequent GAS isolations.

GAS carriage is difficult to eradicate with conventional antimicrobial therapy. Several agents, including clindamycin, cephalosporins, amoxicillin-clavulanate, azithromycin, or a combination that includes either 10 days of penicillin V or IM penicillin G benzathine with rifampin for the last 4 days of treatment are more effective than penicillin alone in terminating chronic streptococcal carriage. Of these drugs, oral clindamycin, 20 to 30 mg/kg per day in 3 doses (maximum, 900 mg/day) for 10 days, has been reported to be the most effective, although clindamycin resistance is increasingly common in the United States. Documented eradication of carriage is helpful in evaluation of subsequent episodes of acute pharyngitis; however, carriage can recur after reacquisition of GAS infection, as some individuals are “carrier prone.”

Nonbullous Impetigo. Topical mupirocin or retapamulin ointment may be useful for limiting person-to-person spread of nonbullous impetigo and for eradicating localized disease. With multiple lesions or nonbullous impetigo in multiple family members, child care groups, or athletic teams, treatment should include oral agents active against both GAS and *S aureus*.

Toxic Shock Syndrome. As outlined in Tables 3.62 and 3.63, most aspects of management are the same for TSS caused by GAS or by *S aureus*. Paramount are prompt

Table 3.62. Management of Streptococcal Toxic Shock Syndrome Without Necrotizing Fasciitis

- Fluid management to maintain adequate venous return and cardiac filling pressures to prevent end-organ damage
- Anticipatory management of multisystem organ failure
- Parenteral antimicrobial therapy at maximum doses with the capacity to:
 - Kill organism with bactericidal cell wall inhibitor (eg, penicillin when group A *Streptococcus* is confirmed)
 - Decrease enzyme, toxin, or cytokine production with protein synthesis inhibitor (eg, clindamycin, or linezolid if clindamycin resistant)
- IGIV often is used as an adjunct, typically at 1 g/kg on day 1, followed by 0.5 g/kg on 1–2 subsequent days

IGIV indicates immune globulin intravenous.

aggressive fluid resuscitation, management of respiratory and cardiac failure, if present, and prompt surgical débridement of any deep-seated infection. Because *S pyogenes* and *S aureus* TSS are difficult to distinguish clinically, initial therapy should include vancomycin, a beta-lactam active *against S aureus*, and a protein synthesis-inhibiting agent, such as clindamycin. The addition of clindamycin is recommended for serious GAS infections, because its antimicrobial activity is unaffected by inoculum size (does not manifest the Eagle effect, the phenomenon in which bacteria exposed to concentrations of antibiotic higher than an optimal bactericidal concentration have paradoxically improved levels of survival, that occurs with beta-lactam antibiotics), it has a long postantimicrobial effect, and it inhibits bacterial protein synthesis, which results in suppression of synthesis of *S pyogenes* antiphagocytic M-protein and bacterial toxins. Clindamycin **should not be used alone** as initial antimicrobial therapy in life-threatening situations because of the potential for resistance, and susceptibility testing should be performed to assess inducible as well as constitutive resistance. In 2020, 29% of invasive GAS case isolates from the Active Bacterial Core surveillance system in the United States were resistant to clindamycin (www.cdc.gov/abcs/bact-facts-interactive-dashboard.html).

Once GAS infection is confirmed, antimicrobial therapy should be tailored to penicillin and clindamycin. If the isolate is resistant to clindamycin, linezolid can be used along with penicillin. Intravenous therapy should be continued at least until the patient is afebrile and stable hemodynamically and blood is documented to be sterile. Clindamycin (or linezolid) may be discontinued after a few days if there is adequate source control and clinical improvement, with continuation of the penicillin therapy. The total duration of therapy is based on duration established for the primary site of infection.

Table 3.63. Management of Streptococcal Toxic Shock Syndrome With Necrotizing Fasciitis

- Principles outlined in Table 3.62
- Immediate surgical evaluation
 - Exploration or incisional biopsy for diagnosis and culture
 - Resection of all necrotic tissue
- Repeated resection of tissue may be needed if infection persists or progresses

Aggressive drainage and irrigation of accessible sites of infection should be performed as soon as possible. If necrotizing fasciitis is suspected, immediate surgical exploration or biopsy is crucial to identify and débride deep soft tissue infection.

Immune globulin intravenous (IGIV) should be strongly considered as adjunctive therapy for STSS or necrotizing fasciitis if the patient is moderately to severely ill, although its use is supported by limited data.

Other Infections. Parenteral antimicrobial therapy is required for severe GAS infections, such as endocarditis, pneumonia, empyema, deep abscess, septicemia, meningitis, arthritis, osteomyelitis, erysipelas, necrotizing fasciitis, and neonatal omphalitis. Treatment often is prolonged (2–6 weeks).

Acute Rheumatic Fever. Treatment for ARF includes eradication of GAS with a standard pharyngitis regimen, treatment of acute inflammatory manifestations (eg, arthritis or valvulitis-associated heart failure), education for parents and patient, and initiation of secondary prophylaxis to prevent future GAS infection. Following initial treatment of ARF with a 10-day course of treatment-dose penicillin V or amoxicillin, patients with well-documented history of ARF (including cases manifested solely as Sydenham chorea) and patients with documented rheumatic heart disease (RHD) should be given continuous antimicrobial prophylaxis to prevent recurrent ARF attacks (secondary prophylaxis), because asymptomatic and symptomatic GAS infections can trigger recurrence of ARF. Continuous secondary prophylaxis should be initiated as soon as the diagnosis of ARF or rheumatic heart disease is made, and initial antibiotic therapy is complete. It should be long-term, perhaps for life, for patients with RHD (even after prosthetic valve replacement), because they remain at risk of ARF recurrence. Risk of recurrence decreases as the interval from the most recent acute episode increases, and patients without RHD are at lower risk of recurrence than patients with residual cardiac involvement. These considerations and the estimate of future exposure to GAS infection all influence the duration of secondary prophylaxis in adults but should not alter the duration of secondary prophylaxis for children and adolescents. Secondary prophylaxis for all who have had ARF should be continued for at least 5 years or until the person is 21 years of age, whichever is longer (see Table 3.64). Prophylaxis also should be continued if the risk of contact with people with GAS infection is high (eg, for parents with school-aged children, teachers, and others in frequent contact with children).

The antibiotic regimens in Table 3.65 are effective for secondary prophylaxis. The intramuscular regimen is the most reliable because success of oral prophylaxis depends primarily on patient adherence; however, inconvenience and pain of injection may cause some patients to discontinue intramuscular prophylaxis. In non-US populations in whom risk of ARF is particularly high, administration of penicillin G benzathine every 3 weeks is justified and recommended, because serum penicillin concentrations can decrease below a protective level in the fourth week after a dose. In the United States, administration every 4 weeks is likely adequate, except for those who have developed recurrent ARF despite adherence to an every-4-week regimen. For penicillin-allergic individuals, oral sulfadiazine is as effective as oral penicillin for secondary prophylaxis but may not be as readily available in the United States. By extrapolating from sulfadiazine, sulfisoxazole has been deemed an appropriate alternative; it is available in combination with erythromycin as a generic version.

Allergic reactions to oral penicillin are less common and usually less severe than reactions to parenteral penicillin and occur much more often in adults than in

Table 3.64. Duration of Prophylaxis for People Who Have Had Acute Rheumatic Fever (ARF): Recommendations of the American Heart Association^a

Category	Duration
Rheumatic fever without carditis	5 years since last episode of ARF or until 21 years of age, whichever is longer
Rheumatic fever with carditis but without residual heart disease (no valvular disease ^b)	10 years since last episode of ARF or until 21 years of age, whichever is longer
Rheumatic fever with carditis and residual heart disease (persistent valvular disease ^b)	10 years since last episode of ARF or until 40 years of age, whichever is longer; consider lifelong prophylaxis for people with severe valvular disease or likelihood of ongoing exposure to group A streptococcal infection

^aModified from Gerber M, Baltimore R, Eaton C, et al. Prevention of rheumatic fever and diagnosis and treatment of acute streptococcal pharyngitis. A scientific statement from the American Heart Association, Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee, Council on Cardiovascular Disease in the Young, and the Quality of Care and Outcomes Research Interdisciplinary Working Group. *Circulation*. 2009;119(11):1541-1551.

^bIn particularly high-risk situations (usually non-US sites), administration every 3 weeks is recommended.

children. Severe allergic reactions rarely occur with intramuscular penicillin G benzathine prophylaxis, but the incidence may be higher in patients older than 12 years with severe RHD. Most severe reactions seem to be vasovagal responses rather than anaphylaxis. A serum sickness-like reaction characterized by fever and joint pains can occur in those receiving prophylaxis and can be mistaken for recurrence of ARF.

Reactions to continuous sulfadiazine or sulfisoxazole prophylaxis are rare and are usually minor; evaluation of blood cell counts may be advisable after 2 weeks of prophylaxis, because leukopenia has been reported. Prophylaxis with a sulfonamide during late pregnancy is contraindicated because of interference with fetal bilirubin metabolism. Febrile mucocutaneous syndromes (erythema multiforme, Stevens-Johnson syndrome, or toxic epidermal necrolysis) rarely have been associated with penicillin and sulfonamides.

When an adverse event occurs with any prophylactic regimen, the drug should be stopped immediately and an alternative drug selected. For the rare patient allergic to both penicillins and sulfonamides, erythromycin is recommended. Other macrolides with less risk of gastrointestinal tract intolerance, such as azithromycin or clarithromycin, are also acceptable.

Poststreptococcal Reactive Arthritis. After an episode of acute GAS pharyngitis, reactive arthritis may develop without sufficient clinical and laboratory findings to fulfill the Jones criteria for diagnosis of ARF. This syndrome has been termed poststreptococcal reactive arthritis (PSRA). The precise relationship of PSRA to ARF is unclear. In contrast to the arthritis of ARF, PSRA does not respond dramatically to nonsteroidal anti-inflammatory agents. Because a very small proportion of patients with PSRA have been reported to develop late valvular heart disease, they should be observed carefully for 1 to 2 years for evidence of cardiac involvement, and some experts recommend secondary prophylaxis during the observation period. If valvular involvement develops, the patient should be considered to have had ARF, and secondary prophylaxis should be initiated (see above).

Poststreptococcal AGN. In addition to management of AGN, the patient should be treated to eradicate the nephritogenic strain with a standard pharyngitis regimen.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, droplet precautions are recommended for those with GAS pharyngitis or pneumonia until 24 hours after initiation of appropriate antimicrobial therapy. For burns with secondary GAS infection and extensive or draining cutaneous infections that cannot be covered or contained adequately by dressings, contact precautions should be used until at least 24 hours after initiation of appropriate therapy.

CONTROL MEASURES: The most important means of controlling GAS disease and its sequelae is prompt identification and treatment of infections.

School and Child Care. Children with GAS pharyngitis or skin infections should not return to school or child care until well appearing and at least 12 hours after beginning appropriate antimicrobial therapy. In the setting of an outbreak, exclusion for at least 24 hours after treatment has been initiated should be considered, and consultation with the state or local public health department is recommended. Close contact with other children during this time should be avoided if possible.

Care of Exposed People. Symptomatic contacts of a child with documented GAS infection with recent or current clinical evidence of a GAS infection should undergo appropriate laboratory tests and treated if test results are positive. Rates of GAS carriage are higher among sibling contacts of children with GAS pharyngitis than among parent contacts in nonepidemic settings; carriage rates as high as 50% for sibling contacts and 20% for parent contacts are reported during epidemics. Asymptomatic acquisition of GAS infection may pose some low risk of nonsuppurative complications; as many as one third of patients with ARF have no history of recent streptococcal infection and another third have minor respiratory tract symptoms not brought to medical attention. However, routine laboratory evaluation of asymptomatic household contacts is not indicated except during outbreaks or when contacts are at increased risk of developing sequelae of infection. In rare circumstances, such as a large family with documented, repeated, intrafamilial transmission resulting in frequent episodes of GAS pharyngitis over a prolonged period, physicians may elect to treat all family members identified by laboratory tests as harboring GAS organisms.

Household contacts of patients with severe invasive GAS disease, including STSS, are at some increased risk of developing severe invasive GAS disease compared with the general population. However, the risk is not sufficiently high to warrant routine testing for GAS colonization, and a clearly effective regimen has not been identified to justify routine chemoprophylaxis of all household contacts. Because of increased risk of sporadic, invasive GAS disease among certain populations (eg, people with human immunodeficiency virus [HIV] infection) and because of increased risk of death in those 65 years and older who develop invasive GAS disease, physicians may choose to offer targeted chemoprophylaxis to household contacts 65 years and older or to members of other high-risk populations (eg, people with HIV infection, varicella, or diabetes mellitus). Because of the rarity of secondary cases and the low risk of invasive GAS infections in children, chemoprophylaxis is generally not recommended in schools or child care facilities.

Bacterial Endocarditis Prophylaxis.¹ The American Heart Association (AHA) has reaffirmed its 2007 recommendations regarding use of antimicrobial agents to prevent infective endocarditis (see Prevention of Bacterial Endocarditis, p 1127). The AHA no longer recommends prophylaxis for patients with RHD without a prosthetic valve. However, use of oral antiseptic solutions and maintenance of optimal oral health through daily oral hygiene and regular dental visits remain important components of an overall health care program. For individuals with a prosthetic valve, infective endocarditis prophylaxis still is recommended, and current AHA recommendations should be followed. If penicillin is being used for secondary ARF prevention, an agent other than penicillin or amoxicillin should be used for infective endocarditis prophylaxis, because penicillin-resistant alpha-hemolytic streptococci are likely to be present in the mouth.

¹ Wilson W, Taubert KA, Gewitz M, et al. Prevention of infective endocarditis. Recommendations by the American Heart Association. A guideline from the American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee, Council on Cardiovascular Disease in the Young, and the Council on Clinical Cardiology, Council on Cardiovascular Surgery and Anesthesia, and the Quality of Care and Outcomes Research Interdisciplinary Working Group. *Circulation*. 2007;116(15):1736–1754

Group B Streptococcal Infections

CLINICAL MANIFESTATIONS: Group B streptococci are a major cause of perinatal infections, including urinary tract infection, bacteremia, intra-amniotic infection (formerly called chorioamnionitis), and endometritis in pregnant and postpartum people, as well as systemic and focal infections in neonates and young infants. In newborn infants, early-onset disease (EOD) usually occurs within the first 24 hours after birth (range, 0 through 6 days), presenting with respiratory distress, apnea, pneumonia, shock and less often, meningitis (5%–10% of cases). Late-onset disease (LOD), which typically occurs at 3 to 4 weeks of age (range, 7 through 89 days), commonly manifests as bacteremia without a focus (60%–65% of cases) or meningitis (approximately 30% of cases); other focal infections, often with concomitant bacteremia, include osteomyelitis, septic arthritis, necrotizing fasciitis, pneumonia, adenitis, and cellulitis. Cases among infants 90 days and older are reported less commonly and typically occur among very preterm infants or infants with immunodeficiency syndromes. Survivors of invasive GBS, particularly cases involving meningitis are at increased risk for neurodevelopmental impairment. A recent study estimated a twofold higher risk for moderate to severe neurodevelopmental impairment by age 10 years for children with invasive neonatal GBS disease in Denmark and a twofold higher risk for the need for educational support compared with uninfected children in the Netherlands.

ETIOLOGY: Group B streptococci (*Streptococcus agalactiae*) are gram-positive diplococci that typically produce a narrow zone of beta hemolysis on 5% sheep blood agar. These organisms are divided into 10 types on the basis of capsular polysaccharides structures. Types Ia, Ib, II, III, IV, and V account for approximately 99% of cases in infants in the United States. Type III causes approximately 30% to 60% of EOD and LOD, respectively.

EPIDEMIOLOGY: Group B streptococci colonize the human gastrointestinal and genitourinary tracts and less commonly the pharynx. The vaginal/rectal colonization rate in pregnant people ranges from 15% to 35% and can be persistent or intermittent. In the 1990s, recommendations were made for prevention of early-onset group B streptococcal (GBS) disease through intrapartum antibiotic prophylaxis (IAP) administered to pregnant people who were found to be colonized or had risk factors for having an infant with EOD (see Control Measures, p 801). As a result of widespread implementation of IAP, the incidence of EOD has decreased by approximately 80% to an estimated 0.22 cases per 1000 live births in 2020. The use of IAP has had no measurable effect on late-onset GBS disease incidence. In 2020, LOD incidence exceeded that of EOD at 0.29 cases per 1000 live births. The case fatality rate for group B streptococcal disease in term infants ranges from 1% to 3% but is higher in preterm neonates (estimated to be 20% for EOD and 8% for LOD). Approximately 70% of EOD and 50% of LOD afflict term neonates.

Transmission from a pregnant person to the infant generally occurs shortly before or during delivery in those who are colonized with GBS organisms. Less commonly, GBS infection may be transmitted in the nursery from health care professionals or visitors or in the community via colonized family members or caregivers. The risk of EOD is increased in preterm infants, infants born 18 hours or more after membrane rupture, and infants born to people with intrapartum fever (temperature $\geq 38^{\circ}\text{C}$ [$\geq 100.4^{\circ}\text{F}$]), intra-amniotic infection, GBS bacteriuria during the current pregnancy, or a history of a previous infant with invasive GBS disease. A higher incidence of

EOD has also been associated with delivering parents who are younger (age <20 years) and Black. However, the independent contribution of these factors is unclear because each of these has been associated with higher rates of both GBS colonization and preterm birth. Infants can remain colonized for several months despite treatment for systemic infection. Recurrent GBS disease affects an estimated 1% to 3% of appropriately treated infants.

The **incubation period** of EOD is fewer than 7 days. In LOD, the **incubation period** is unknown.

DIAGNOSTIC TESTS: Visualization of gram-positive cocci in pairs or short chains from a normally sterile body fluid provides presumptive evidence of infection, but growth of the organism in culture establishes the diagnosis. Multiplex polymerase chain reaction (PCR) assays are available in many clinical laboratories for direct testing of cerebrospinal fluid (CSF) for GBS and may expedite the diagnosis.

For prenatal GBS screening, swab specimens from lower vaginal and rectal sites are collected (vaginal swab specimens alone underestimate GBS colonization by up to 10%–15%). Culture yield can be increased with the use of commercially available selective broth enrichment media for 18 to 24 hours of incubation before being plated on tryptic soy blood agar or other selective agars for an additional 24 to 48 hours. Alternatively, DNA probe assays, latex agglutination assays, and nucleic acid amplification tests (NAATs) are available to detect GBS in enriched broth specimens. Several NAATs are approved for antepartum or intrapartum detection of GBS organisms from vaginal/rectal swab specimens collected from pregnant people. However, the sensitivity of NAATs may be significantly decreased when used for rapid intrapartum testing, because a preanalysis enrichment incubation step cannot be included in those situations. Cases of neonatal GBS disease have occurred in neonates born to people whose screens were negative during pregnancy.

TREATMENT¹:

- Ampicillin plus an aminoglycoside is the empiric treatment of choice for a **new-born infant ≤7 days of age** with presumptive early-onset GBS infection; this reflects the need for coverage of other pathogens, such as *Escherichia coli*, which is the second-most common cause of EOD. In a critically ill neonate, particularly one with low birth weight, broader-spectrum empiric therapy should be considered when there is concern about non-GBS ampicillin-resistant infection.
- For empiric therapy of late-onset GBS disease in **infants 8 through 28 days of age** who are being admitted from the community and are not critically ill and do not have evidence of meningitis, ampicillin plus either gentamicin or an extended-spectrum cephalosporin (eg, cefotaxime, ceftazidime, cefepime) are recommended. If meningitis is suspected, ampicillin plus an extended-spectrum cephalosporin (eg, cefotaxime, ceftazidime, cefepime) should be used (see also Serious Neonatal Bacterial Infections Caused by *Enterobacterales*, p 365).
- For **infants 29 through 89 days of age**, ceftriaxone is recommended. If there is evidence of meningitis or critical illness, vancomycin should be added to expand empiric coverage.

FIG 3.17. RISK ASSESSMENT FOR EARLY-ONSET GROUP B STREPTOCOCCAL DISEASE AMONG INFANTS BORN AT ≤ 34 WEEKS' GESTATION

Adapted from Puopolo KM, Lynfield R, Cummings JJ; American Academy of Pediatrics, Committee on Fetus and Newborn, Committee on Infectious Diseases. Management of infants at risk for group B streptococcal disease. *Pediatrics*. 2019;144(2):e20191881

^aIntraamniotic infection should be considered when a pregnant person presents with unexplained decreased fetal movement and/or there is sudden and unexplained poor fetal testing.

^bLumbar puncture should be performed for culture and analysis of CSF when there is a high suspicion for early onset GBS disease, unless the procedure will compromise the neonate's clinical condition. Antibiotics should be administered promptly and not deferred because of procedural delays.

^cAdequate GBS IAP is defined as the administration of penicillin G, ampicillin, or cefazolin ≥ 4 hours before delivery.

^dFor infants who do not improve after initial stabilization and/or those who have severe systemic instability, the administration of empiric antibiotics may be reasonable but is not mandatory.

- For a **preterm infant hospitalized beyond 72 hours**, empiric treatment for sepsis should take into account the potential for health care-associated pathogens as well as coverage for pathogens associated with neonatal sepsis, including group B streptococci.
- When GBS infection is identified definitively, penicillin G or ampicillin is recommended. See Table 4.2 (p 988) in Tables of Antibacterial Drug Dosages for dosing recommendations.
- For meningitis, especially in the neonate, some experts recommend that a second lumbar puncture be performed approximately 24 to 48 hours after initiation of therapy to assist in management and prognosis. If CSF sterility is not achieved or if increasing protein concentration is noted, a complication (eg, cerebral infarcts, cerebritis, ventriculitis, subdural empyema, ventricular obstruction) is more likely. Additional lumbar punctures and intracranial imaging are indicated if neurologic abnormalities persist, or focal neurological deficits occur. A failed hearing screen or abnormal neurologic examination at discharge mandates careful clinical follow-up.
- For infants with **bacteremia without a defined focus** or with an **isolated urinary tract infection** without bacteremia, treatment typically is 10 days of intravenous therapy. On the basis of observational data suggesting that transition to oral therapy for the latter few days of treatment after clinical improvement on intravenous therapy (to complete a total of 10 days) may be effective, some pediatric infectious diseases experts have provided oral antibiotics for the last few days of treatment for low-risk patients with uncomplicated late-onset GBS bacteremia who had rapid clearance and clinical improvement and can be followed closely. For infants with uncomplicated **meningitis**, 14 days of intravenous therapy is recommended, with longer courses of treatment for infants with prolonged or complicated courses. **Septic arthritis or osteomyelitis** requires treatment for 3 to 4 weeks. Patients who have **endocarditis or ventriculitis** require intravenous treatment for at least 4 weeks. Consultation with a specialist in pediatric infectious diseases is recommended for complicated infections.
- Because of the reported increased risk of infection, the birth mates of a multiple-birth index case with EOD or LOD should be observed carefully for signs of infection and evaluated and treated empirically for suspected systemic infection if signs of illness occur. There is no evidence to support full antibiotic treatment courses in the absence of confirmed GBS disease.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended. Routine cultures to determine whether infants are colonized with group B streptococci are not recommended.

CONTROL MEASURES:

Intrapartum Antibiotic Prophylaxis. Recommendations from the American Academy of Pediatrics¹ (<https://pediatrics.aappublications.org/content/144/2/e20191881>) and the American College of Obstetricians and Gynecology² (ACOG)

¹ Puopolo KM, Lynfield R, Cummings JJ; American Academy of Pediatrics, Committee on Fetus and Newborn, Committee on Infectious Diseases. Management of infants at risk for group B streptococcal disease. *Pediatrics*. 2019;144(2):e20191881

² American College of Obstetricians and Gynecologists. Prevention of group B streptococcal early-onset disease in newborns: ACOG Committee Opinion Number 797. *Obstet Gynecol*. 2020;135(2):e51-e72

(www.acog.org/clinical/clinical-guidance/committee-opinion/articles/2020/02/prevention-of-group-b-streptococcal-early-onset-disease-in-newborns) were published in 2019-2020. Components that are directly germane to the management of neonates at risk for GBS include the following:

- All pregnant people should have culture-based screening from vaginal and rectal sites at 36 0/7 to 37 6/7 weeks' gestation unless intrapartum antibiotic prophylaxis (IAP) for GBS infection is already planned because of predelivery risk factors in the pregnant person. For those who are at increased risk for a planned preterm delivery for medical indications, GBS screening within 5 weeks of anticipated delivery can be considered.
- For those who present with preterm labor, baseline GBS screening should be performed before intravenous GBS IAP is initiated.
- Intravenous penicillin G (5 million U initially, then 2.5 to 3.0 million U, every 4 hours, until delivery) is the preferred agent for GBS IAP because of its efficacy and narrow spectrum of antimicrobial activity. Intravenous ampicillin (2 g initially, then 1 g every 4 hours until delivery) can be used as an alternative when penicillin is unavailable. Oral or intramuscular antimicrobial agents should *not* be used as IAP. Pregnant people who report a mild or unknown penicillin allergy should receive intravenous cefazolin for IAP. Those who report penicillin allergies placing them at high risk for anaphylaxis should receive either intravenous clindamycin or vancomycin for IAP, depending on organism susceptibilities, with dosing detailed in the ACOG guidelines (www.acog.org/clinical/clinical-guidance/committee-opinion/articles/2020/02/prevention-of-group-b-streptococcal-early-onset-disease-in-newborns).
- Penicillin allergy testing is safe during pregnancy and can be considered for people with a history of allergy to penicillin to optimize the antibiotic choice for GBS IAP.
- For the purpose of newborn evaluation regardless of gestational age, "adequate" GBS IAP is defined as the administration of at least 1 dose of penicillin G, ampicillin, or cefazolin 4 or more hours prior to delivery. Available evidence suggests that administration of penicillin G, ampicillin, or cefazolin for periods of time <4 hours prior to delivery confers some level of protection from GBS EOD. Of note, in the Neonatal Early-Onset Sepsis Risk calculator, "GBS specific antibiotics >2 hours prior to birth" is one of the calculator variables. The 2-hour timing is used because multiple factors in addition to GBS IAP are considered when using these multivariate models.
- The ACOG recommendations updated in 2020 detail the indications for IAP, management of people with penicillin allergy, use of alternative agents, and management of people with preterm prelabor rupture of membranes, taking into account gestational age, presence of labor, and availability of GBS test results. See www.acog.org/clinical/clinical-guidance/committee-opinion/articles/2020/02/prevention-of-group-b-streptococcal-early-onset-disease-in-newborns for full discussion.

Management of Neonates at Risk for Early-Onset GBS Disease. Please refer to the AAP clinical report "Management of Infants at Risk for GBS Disease"¹ for detailed discussion. Recommendations include the following:

- Antimicrobial therapy is appropriate only for infants with suspected systemic infection.

¹ Puopolo KM, Lynfield R, Cummings JJ; American Academy of Pediatrics, Committee on Fetus and Newborn, Committee on Infectious Diseases. Management of infants at risk for group B streptococcal disease. *Pediatrics*. 2019;144(2):e20191881

FIG 3.16. RISK ASSESSMENT FOR EARLY-ONSET GROUP B STREPTOCOCCAL DISEASE AMONG INFANTS BORN AT ≥ 35 WEEKS OF GESTATION

Reproduced from Puopolo KM, Lynfield R, Cummings JJ; American Academy of Pediatrics, Committee on Fetus and Newborn, Committee on Infectious Diseases. Management of infants at risk for group B streptococcal disease. *Pediatrics*. 2019;144(2):e20191881. The screenshot of the Neonatal Early-Onset Sepsis Calculator (<https://neonatalesepsiscalculator.kaiserpermanente.org/>) was used with permission from Kaiser-Permanente Division of Research.

^aPerform lumbar puncture and CSF culture before initiation of empiric antibiotics for infants who are at the highest risk of infection, especially those with critical illness. Lumbar puncture can be deferred if the infant's clinical condition would be compromised, and antibiotics should be administered promptly and not deferred because of procedure delays.

^bAdequate GBS IAP is defined as the administration of penicillin G, ampicillin, or cefazolin ≥ 4 hours before delivery.

- Routine use of antimicrobial chemoprophylaxis for neonates born to people who have received adequate IAP is *not* recommended. Early-onset GBS disease is diagnosed by blood or CSF culture. Lumbar puncture should be performed for culture and analysis of CSF when there is a high suspicion for early onset GBS disease. All cultures should include testing for antibiotic susceptibility. Complete blood cell counts and measurement of C-reactive protein are not accurate enough to reliably identify infected infants. Chest radiography and other studies should be performed as clinically indicated.
- Infants born at ≥ 35 weeks' gestation can be assessed for risk of early-onset sepsis using 1 of 3 methods: (1) a categorical algorithm, (2) a multivariate risk assessment, or (3) enhanced clinical observation (see Fig 3.16).
 - ♦ A categorical approach (Fig 3.16A) uses threshold values to identify infants at increased risk for GBS disease. Because thresholds are used, the risk will vary greatly among newborn infants recommended to undergo laboratory evaluation and receive empiric treatment, and it will include relatively low-risk newborn infants.
 - ♦ Multivariate risk assessment (Fig 3.16B, Neonatal Early-Onset Sepsis Calculator; and as an example: <https://neonatalesepsiscalculator.kaiserpermanente.org>) uses the individual infant's combination of risk factors for early-onset sepsis

(including maternal components) and the infant's clinical status to estimate the risk of early-onset sepsis, including risk for GBS disease. It provides recommended clinical actions, such as enhanced clinical observation or laboratory evaluation and empiric antibiotics, on the basis of predicted risk estimates. This tool has been prospectively validated in large newborn cohorts.

- ♦ Enhanced clinical observation (Fig 3.16C) is a risk assessment based on newborn clinical conditions. Good clinical condition at birth in term infants is associated with an approximately 60% to 70% reduction in risk for EOD of all infections, including GBS infection. Infants who appear ill at birth and those who develop signs of illness over the first 48 hours after birth will undergo laboratory evaluation and receive empiric antibiotics. This approach can be combined with a categorical or multivariate assessment for risk factors or used on its own for infants born at ≥ 35 weeks' gestation. Use of this approach requires processes to ensure serial and structured physical assessments and clear criteria for additional evaluation and empiric antibiotic administration.
- Infants born at ≤ 34 weeks' gestation are at higher risk for early-onset sepsis, including GBS sepsis, than are full-term infants. However, the risk varies and is dependent on several maternal, peripartum, and neonatal factors. Management is outlined in Fig 3.17, with additional summary provided in the bullets below.
 - ♦ Infants born preterm because of cervical insufficiency, preterm labor, prelabor rupture of membranes, intra-amniotic infection, and/or acute and otherwise unexplained onset of concerning fetal status are at the highest risk of early-onset sepsis, including from group B streptococci. The administration of GBS IAP can decrease this risk; however, these infants remain at high risk and a laboratory evaluation should be done and empiric antibiotics for pathogens causing early-onset sepsis, including group B streptococci, should be given. The most reasonable approach to these infants is to obtain a blood culture and start empiric antibiotic treatment. Lumbar puncture should be performed for culture and analysis of CSF when there is a high suspicion for early-onset GBS disease, unless the procedure will compromise the neonate's clinical condition.
 - ♦ Some infants born at ≤ 34 weeks' gestation are at much lower risk for early onset sepsis, including GBS sepsis, if they have *all* of the following: (1) delivery for indications in the birthing person (such as pre-eclampsia, other noninfectious medical illness, or placental insufficiency); (2) birthing parent not in labor; (3) no efforts to induce labor occurred; (4) rupture of membranes did not occur prior to delivery, and (5) delivery occurs by cesarean section. Acceptable initial approaches to these infants include (a) no laboratory evaluation and no empiric antibiotic therapy, or (b) blood culture and clinical monitoring. For infants who do not receive empiric antibiotics and do not improve after initial stabilization and/or those who have severe systemic instability, the administration of empiric antibiotics may be reasonable but is not mandatory, because infants can develop instability attributable to noninfectious factors.
 - ♦ Infants born at ≤ 34 weeks' gestation who are delivered for indications in the birthing person but who are ultimately born by vaginal or cesarean delivery after efforts to induce labor and/or with rupture of membranes before delivery are subject to factors associated with the pathogenesis of GBS EOD. If the birthing parent has an indication for GBS IAP, including a positive screen, and adequate IAP is

not given or if any other concerns for infection occur during delivery, the infant should be managed as recommended for infants born at ≤ 34 weeks' gestation who are at highest risk for early-onset sepsis (see first bullet under "Infants born at ≤ 34 weeks' gestation"). If there are no concerns for infection based on birthing parent or delivery factors and these preterm infants are clinically well at birth, an acceptable approach is close observation, escalating to laboratory evaluation and empiric antibiotic therapy for infants with respiratory and/or cardiovascular instability after birth.

Late-Onset GBS Disease and Human Milk. Although there are case reports of human milk being a potential source of late-onset GBS disease, a recent multicenter case control study found no increased risk for late onset GBS with breastfeeding. The AAP does not recommend culturing human milk in an infant with late-onset GBS disease.

Non-Group A or B Streptococcal and Enterococcal Infections

CLINICAL MANIFESTATIONS: Streptococci other than Lancefield groups A or B can be associated with invasive disease in infants, children, adolescents, and adults. The principal clinical syndromes of groups C and G streptococci (most belong to the *Streptococcus dysgalactiae* group) are bacteremia, septicemia, upper and lower respiratory tract infections (eg, pharyngitis, sinusitis, and pneumonia), skin and soft tissue infections, septic arthritis, osteomyelitis, meningitis with a parameningeal focus, brain abscess, toxic shock syndrome, pericarditis, and endocarditis with various clinical manifestations. Viridans streptococci are the most common cause of bacterial endocarditis in children, especially children with congenital or valvular heart disease. Viridans streptococci are a common cause of bacteremia in neutropenic patients with cancer, especially following intensive induction chemotherapy for acute myeloid leukemia, after hematopoietic cell transplantation, and as a cause of central line-associated bacteremia. Among the viridans streptococci, group F streptococci (most belong to the *Streptococcus anginosus* group) are implicated in complicated sinus infections but are an infrequent cause of invasive infection. More serious *S anginosus* group infections include brain or dental abscesses or abscesses in other sites, including lymph nodes, liver, pelvis, and lung. These organisms may also cause sinusitis and other head and neck infections, meningitis, spondylodiskitis, spinal epidural abscesses, subdural empyema, peritonitis, complicated intra-abdominal infections, and cholangitis. Enterococci are associated with bacteremia in neonates and immunocompromised hosts, device-associated infections, intra-abdominal abscesses, and urinary tract infections in patients with anatomical anomalies.

ETIOLOGY: Changes in taxonomy and nomenclature of the *Streptococcus* genus have evolved with advances in molecular technology (see Table 3.66). Among gram-positive organisms that are catalase negative and display chains by Gram stain, the genera associated most often with human disease are *Streptococcus* and *Enterococcus*.

With the advent of genome sequencing, the genus *Streptococcus* has been divided, evolutionarily, into 2 major clades (Mitis-Suis and Pyogenes-Equinus-Mutans) and 14 subclades. Members of this genus that are beta-hemolytic on blood agar plates include *Streptococcus pyogenes* (see Group A Streptococcal Infections, p 785), *Streptococcus agalactiae* (see Group B Streptococcal Infections, p 799), groups C and G streptococci (*S dysgalactiae* subspecies *equisimilis* is the group C subspecies most often associated with human

Table 3.66. Classification of Streptococci Most Commonly Associated With Disease, by Lancefield Group and by Hemolysis

Species	Lancefield Group	Hemolysis
<i>Streptococcus pyogenes</i>	A	β
<i>Streptococcus agalactiae</i>	B	β
<i>Streptococcus dysgalactiae</i> subspecies <i>equisimilis</i> , <i>Streptococcus equi</i> subspecies <i>zooepidemicus</i>	C	β
<i>Enterococcus faecalis</i> , <i>Enterococcus faecium</i> , <i>Streptococcus galloyticus</i>	D	α or γ^a
<i>Streptococcus canis</i>	G	β
<i>Streptococcus pneumoniae</i> , viridans streptococci	Not groupable ^b	α

^aSome *E. faecalis* are β -hemolytic on horse blood agar but not sheep (the latter is more commonly used in clinical laboratories).

^bOccasional viridans streptococci have variable hemolysis and can display Lancefield group A, C, F, or G antigens.

infections), and some members of Groups F and H streptococci. Streptococci that are non-beta-hemolytic (alpha-hemolytic or nonhemolytic) on blood agar plates include: (1) *Streptococcus pneumoniae* (see *Streptococcus pneumoniae* [Pneumococcal] Infections, p 810); (2) the *Streptococcus galloyticus* (formerly *Streptococcus bovis*) group; and (3) viridans streptococci clinically relevant in humans, which include *S. anginosus* group, *Streptococcus mitis* group, *Streptococcus sanguinis* group, *Streptococcus salivarius* group, and *Streptococcus mutans* group. The *anginosus* group (formerly *Streptococcus milleri* group) includes *S. anginosus*, *Streptococcus constellatus*, and *Streptococcus intermedius*. This group can have variable hemolysis, and approximately one third possess Lancefield groups A, C, F, or G antigens. Nutritionally variant “streptococci,” once believed to be viridans streptococci, now are classified in the genera *Abiotrophia* and *Granulicatella*. Group D streptococci include *S. galloyticus*, *Streptococcus infantarius*, and *Streptococcus pasteurianus*, now classified under the *S. galloyticus* group. Streptococci formerly classified as Lancefield groups R, S, and T are now known as *Streptococcus suis*.

The genus *Enterococcus* contains dozens of species, many of which have not been reported in humans, with *Enterococcus faecalis* and *Enterococcus faecium* accounting for most enterococcal infections in people. Outbreaks and health care-associated spread of intrinsically vancomycin-resistant enterococcal species including *Enterococcus gallinarum*, *Enterococcus casseliflavus*, or *Enterococcus flavescens* have occurred.

EPIDEMIOLOGY: The habitats that non-group A and B streptococci and enterococci occupy in humans include the skin (groups C and G), oropharynx (groups C and G and the *mutans* group), gastrointestinal tract (groups C and G streptococci, *S. galloyticus* group, and *Enterococcus* species), and vagina (groups C, D, and G streptococci and *Enterococcus* species). Typical human habitats of species of viridans streptococci are the oropharynx, epithelial surfaces of the oral cavity, teeth, skin, and gastrointestinal and genitourinary tracts. Intrapartum transmission is responsible for most cases of early-onset neonatal infection caused by non-group A and B streptococci and enterococci. Environmental contamination or transmission via hands of health care professionals

can lead to colonization of patients. Groups C and G streptococci can cause food-borne outbreaks of pharyngitis. Zoonotic infection, specifically from *Streptococcus equi* subspecies *zooepidemicus* and rarely *S equi* subspecies *equi*, can result from animal contact or consumption of unpasteurized dairy products or other contaminated food products and has been associated with the development of poststreptococcal glomerulonephritis. *S suis* infections are associated with contact with pigs or raw pork.

The **incubation period** and the period of communicability are unknown.

DIAGNOSTIC TESTS: Diagnosis is established by culture of usually sterile body sites or abscesses with appropriate biochemical testing and serologic analysis for definitive identification. Mass spectrometry is unreliable in differentiation of *S pneumoniae* from viridians streptococci. Genomic methods are being used increasingly, particularly for rapid identification of positive blood cultures. Antimicrobial susceptibility testing of isolates from usually sterile sites should be performed to guide treatment of infections caused by viridans streptococci or enterococci. The proportion of vancomycin-resistant enterococci (VRE), the vast majority of which are *E faecium*, among health care-associated enterococcal infections is about 30%. Selective agars are available for screening of VRE from stool specimens. Molecular assays are available for direct detection of *vanA* and *vanB* genes (which confer vancomycin resistance) from rectal and blood specimens to identify VRE.

TREATMENT: Penicillin G is the drug of choice for groups C and G streptococci. Other agents with good activity include ampicillin, third- and fourth-generation cephalosporins, vancomycin, and linezolid. The combination of gentamicin (when high level resistance is not present) with a beta-lactam antimicrobial agent (eg, penicillin or ampicillin) or vancomycin may enhance the antimicrobial activity needed for treatment of life-threatening infections (eg, endocarditis or meningitis).

Many viridans streptococci remain susceptible to penicillin (minimum inhibitory concentration [MIC] ≤ 0.12 $\mu\text{g/mL}$). Infections caused by strains susceptible to penicillin, including endocarditis, can be treated with penicillin or ceftriaxone. Strains with an MIC >0.12 $\mu\text{g/mL}$ and <0.5 $\mu\text{g/mL}$ are considered relatively resistant to penicillin by criteria in the American Heart Association guidelines for treatment of infective endocarditis in childhood.¹ In this situation, penicillin, ampicillin, or ceftriaxone for 4 weeks, combined for the first 2 weeks with gentamicin, is recommended. Strains with a penicillin MIC ≥ 0.5 $\mu\text{g/mL}$ are considered resistant. Nonpenicillin antimicrobial agents with good activity against viridans streptococci include cephalosporins (especially ceftriaxone), vancomycin, linezolid, and tigecycline, although pediatric experience with tigecycline is limited. Tigecycline also has a black box warning for an increase in all-cause mortality and should be reserved for situations where alternative agents are not suitable. *Abiotrophia* and *Granulicatella* organisms can exhibit relative or high-level resistance to penicillin. The combination of high-dose penicillin or vancomycin and an aminoglycoside can enhance treatment effectiveness. Some species of viridans streptococci (eg, *Streptococcus oralis*, *S mitis*, *S sanguinis*) have shown unexpected, rapid (eg, overnight) in vitro and/or in vivo development of high-level resistance to daptomycin (MIC ≥ 256 $\mu\text{g/mL}$), and therefore, daptomycin should be avoided for treatment of infections by these organisms.

¹ Baltimore RS, Gewitz M, Baddour LM, et al. Infective endocarditis in childhood: 2015 update. A scientific statement from the American Heart Association. *Circulation*. 2015;132(15):1487-1515

Enterococci exhibit intrinsic resistance to cephalosporins, aztreonam, and anti-staphylococcal penicillins. Most are intrinsically resistant to clindamycin and trimethoprim-sulfamethoxazole even if in vitro susceptibility indicates otherwise. The vast majority of *E. faecalis* strains are susceptible to ampicillin (which can be extrapolated to amoxicillin, piperacillin-tazobactam, and imipenem but not to penicillin). *E. faecium* strains may be multidrug resistant. Two types of vancomycin resistance are identified: intrinsic low-level resistance that occurs with *E. gallinarum* and *E. casseliflavus*/*E. flavescens* (these species are ampicillin susceptible), and acquired resistance, which has been seen in *E. faecium* and some *E. faecalis* strains but also has been recognized in *Enterococcus raffinosus*, *Enterococcus avium*, and *Enterococcus durans*.

Systemic enterococcal infections, such as endocarditis or meningitis, should be treated with penicillin or ampicillin (if the isolate is susceptible) combined with ceftriaxone or gentamicin (see endocarditis guidelines¹). Vancomycin plus an aminoglycoside (with appropriate monitoring of renal function) is suggested for patients unable to tolerate penicillins and who cannot be desensitized. Studies have established ampicillin plus ceftriaxone as equivalent to ampicillin plus gentamicin for *E. faecalis* endocarditis. Some experts consider ampicillin plus both ceftriaxone and gentamicin for treatment of enterococcal meningitis, although clinical data are lacking. Gentamicin should not be used if in vitro susceptibility testing demonstrates high-level resistance.

Combination therapy for treating central line-associated bloodstream infections is usually not needed. Options for treatment of other systemic infections caused by vancomycin-resistant *E. faecium* include linezolid or daptomycin. Linezolid is approved for use in children, including neonates. Isolates of VRE that are resistant to linezolid have been described, and resistance can develop during prolonged linezolid treatment. Most vancomycin-resistant isolates of *E. faecalis* and *E. faecium* are daptomycin-susceptible. Data suggest that clearance of daptomycin is more rapid in young children compared with adolescents and adults, and dosing may need to be adjusted accordingly. Daptomycin should not be used to treat meningitis or pneumonia, as penetration into cerebrospinal fluid is poor and daptomycin is inactivated by pulmonary surfactants. Microbiologic and clinical cure have been reported in children infected with vancomycin-resistant *E. faecium* who were treated with quinupristin-dalfopristin. This drug frequently causes phlebitis in peripheral intravenous lines, and pediatric dosing in children younger than 12 years is unclear. Tigecycline is approved for use in adults with complicated skin and skin structure infections or intra-abdominal infections caused by vancomycin-susceptible *E. faecalis*. Tigecycline has activity against both vancomycin-resistant *E. faecalis* and vancomycin-resistant *E. faecium*, but experience with this drug in children is limited. In children younger than 8 years, there may be reversible inhibition of bone growth and adverse effects on tooth development. Tigecycline has a black box warning for an increase in all-cause mortality and should be reserved for situations where alternative agents are not suitable.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended. For patients with infection or colonization attributable to VRE, contact precautions in addition to standard precautions are indicated. Patients harboring vancomycin resistant strains of *E. gallinarum* or *E.*

¹ Baltimore RS, Gewitz M, Baddour LM, et al. Infective endocarditis in childhood: 2015 update. A scientific statement from the American Heart Association. *Circulation*. 2015;132(15):1487-1515

casseliflavus/*E. flavescens* may be managed using only standard precautions, because these species harbor chromosomally encoded vancomycin resistance genes (*vanC*, *vanT*) that are not easily exchanged between bacterial populations. Common practice is to maintain precautions until the patient no longer harbors the organism or is discharged from the health care facility. Some experts recommend discontinuation of contact precautions if screening cultures are negative; there is, however, no accepted standard regarding the frequency (1, 2, or 3 cultures), timing (weekly, daily), or preferred site selection (eg, stool, axilla, etc).¹

CONTROL MEASURES: Use of vancomycin and treatment with broad-spectrum antimicrobial agents are risk factors for colonization and infection with VRE. Hospitals should develop institution-specific guidelines for the appropriate use of vancomycin.

Patients with a prosthetic valve or prosthetic material used for cardiac valve repair, previous infective endocarditis, or congenital heart disease associated with the highest risk of adverse outcome from endocarditis should receive antimicrobial prophylaxis to prevent endocarditis at the time of certain dental procedures (see Prevention of Bacterial Endocarditis, p 1127). For these patients, early instruction in proper diet; oral health, including use of dental sealants and adequate fluoride intake; and prevention or cessation of smoking will aid in prevention of dental caries and potentially will lower their risk of recurrent endocarditis.

***Streptococcus pneumoniae* (Pneumococcal) Infections²**

CLINICAL MANIFESTATIONS: *Streptococcus pneumoniae* is a common bacterial cause of acute otitis media, sinusitis, community-acquired pneumonia, and pediatric conjunctivitis; pleural empyema, mastoiditis, and periorbital cellulitis also occur. It is the most common cause of bacterial meningitis in infants and children ages 2 months to 11 years in the United States. *S pneumoniae* also may cause endocarditis, pericarditis, peritonitis, pyogenic arthritis, osteomyelitis, soft tissue infection, and neonatal septicemia. Overwhelming septicemia in patients with splenic dysfunction occurs, and hemolytic-uremic syndrome can accompany pneumococcal infection.

ETIOLOGY: *S pneumoniae* organisms (pneumococci) are lancet-shaped, gram-positive, catalase-negative diplococci. They are α -hemolytic (Table 3.66, p 807). More than 100 pneumococcal serotypes have been identified on the basis of unique polysaccharide capsules.

EPIDEMIOLOGY: Nasopharyngeal carriage rates in children range from 21% in industrialized settings to more than 90% in resource-limited settings. Transmission is from person to person by respiratory droplet contact. Viral upper respiratory tract infections, including influenza and respiratory syncytial virus, can predispose to pneumococcal infection and transmission. Pneumococcal infections are most prevalent during winter months. The period of communicability is unknown and may be as long as the

¹ Banach DB, Bearman G, Barnden M, et al. Duration of contact precautions for acute-care settings. *Infect Control Hosp Epidemiol*. 2018;39(2):127-144

² Centers for Disease Control and Prevention. Prevention of pneumococcal disease among infants and children—use of 13-valent pneumococcal conjugate vaccine and 23-valent pneumococcal polysaccharide vaccine. *MMWR Recomm Rep*. 2010;59(RR-11):1-18

organism is present in respiratory tract secretions but probably is less than 24 hours after effective antimicrobial therapy is begun.

The incidence and severity of infections are increased in people with congenital or acquired humoral immunodeficiency, human immunodeficiency virus (HIV) infection, absent or deficient splenic function (eg, sickle cell disease, congenital, or surgical asplenia), certain complement deficiencies, diabetes mellitus, chronic liver disease, chronic renal failure, nephrotic syndrome, or abnormal innate immune responses. Children with cochlear implants, particularly those who had placement of an older model that involved a cochlear electrode, have high rates of pneumococcal meningitis, as do children with congenital or acquired cerebrospinal fluid (CSF) leaks.¹ Children at presumed high or moderate risk of developing invasive pneumococcal disease are listed by underlying medical condition in Table 3.67. Infection rates are highest in infants, young children, elderly people, and in Black, Alaska Native, and some American Indian populations. Since introduction of the heptavalent pneumococcal conjugate vaccine (PCV7) in 2000 and the 13-valent pneumococcal conjugate vaccine (PCV13) in 2010, racial disparities in vaccine-type pneumococcal disease have diminished; however, rates of invasive pneumococcal disease (IPD) among some Alaskan Native and American Indian populations remain higher than the rate among children in the general US population. Recent data from Alaska and the southwestern United States indicate that the majority of IPD cases among American Indian/Alaska Native children are now caused by serotypes not contained in the PCV13 vaccine.

By 2019, 9 years after the introduction of PCV13, the incidence of PCV13-type invasive pneumococcal infections decreased by 98% compared with incidence before introduction of PCV7, and the incidence of all IPD decreased by 95% in children younger than 5 years. In adults 65 years and older, IPD caused by PCV13 serotypes decreased 86% compared with pre-PCV7 baseline, and all IPD decreased by 61%. Most of the reduction in cases in this latter group occurred before routine PCV13 use was recommended in 2014 for older adults, indicating the significant indirect (ie, herd effect) benefits of PCV13 immunization achieved by interruption of transmission of pneumococci from vaccinated children to adults. Although *S pneumoniae* strains that are nonsusceptible to penicillin G, ceftriaxone, and other antimicrobial agents have been identified throughout the United States and worldwide, a reduction in the proportion of isolates that are penicillin-nonsusceptible (intermediate or resistant) and ceftriaxone-resistant has been observed since introduction of PCV7 and PCV13.

The **incubation period** varies by type of infection but can be as short as 1 day.

DIAGNOSTIC TESTS: Recovery of *S pneumoniae* from a normally sterile site confirms the diagnosis. The finding of lancet-shaped gram-positive organisms and white blood cells in expectorated sputum (older children and adults) or pleural exudate suggests pneumococcal pneumonia. Recovery of pneumococci by culture of an upper respiratory tract swab specimen is not sufficient to assign an etiologic diagnosis of pneumococcal disease involving the middle ear, upper or lower respiratory tract, or sinus.

There are at least 2 multiplexed nucleic acid amplification tests (NAATs) cleared by the US Food and Drug Administration (FDA) to identify *S pneumoniae* and other

^dACIP Updates: Recommendations for use of 20-valent pneumococcal conjugate vaccine in children—United States, 2023. *MMWR Morb Mortal Wkly Rep.* 2023;72(39):1072

^eParticularly cyanotic congenital heart disease and cardiac failure.

^fIncluding moderate persistent or severe persistent asthma.

^gIncludes B- (humoral) or T-lymphocyte deficiency; complement deficiencies, particularly C₁, C₂, C₃, and C₄ deficiency; and phagocytic disorders (excluding chronic granulomatous disease).

bacterial and fungal pathogens from positive blood culture bottles. At least 1 real-time polymerase chain reaction (PCR) assay is cleared by the FDA for detection of *S pneumoniae* in CSF. The assay is a multiplexed PCR designed to detect a number of agents of bacterial, fungal, and viral meningitis or encephalitis. PCR testing should be accompanied by culture of CSF to obtain an isolate, which is needed for antimicrobial susceptibility testing.

Detection of C-polysaccharide (common to all pneumococci) in urine for diagnosis of pneumococcal pneumonia may have some utility in adults but is generally not useful in children, because asymptotically colonized children may have positive test results. Similarly, commercially available antigen detection tests performed on CSF or blood are not recommended for routine use because of low sensitivity.

Susceptibility Testing. All *S pneumoniae* isolates from normally sterile body fluids should be tested for antimicrobial susceptibility to determine the minimum inhibitory concentration (MIC) of penicillin, cefotaxime or ceftriaxone, and clindamycin. Susceptibility threshold breakpoints of *S pneumoniae* isolated from blood differ for CSF isolates (Table 3.68) as defined by the Clinical and Laboratory Standards Institute (CLSI). CSF isolates also should be tested for susceptibility to vancomycin, meropenem, and rifampin. Nonsusceptible strains can also be evaluated for susceptibility to erythromycin, trimethoprim-sulfamethoxazole, levofloxacin, and linezolid to treat various pneumococcal infections.

TREATMENT:

Bacterial Meningitis Possibly or Proven to Be Caused by *S pneumoniae*. For children with bacterial meningitis possibly or known to be caused by *S pneumoniae*, vancomycin should be administered in addition to third-generation cephalosporin because of the possibility of *S pneumoniae* organisms that are nonsusceptible to penicillin and third-generation cephalosporins. In neonates, when cefotaxime is not available then ceftazidime or cefepime can be used in addition to vancomycin. Vancomycin should be stopped if susceptibility to third-generation cephalosporins is documented (using central nervous system [CNS] breakpoints for thresholds of susceptibility, as defined in Table 3.68), if another

Table 3.68. Minimum Inhibitory Concentration Breakpoints ($\mu\text{g/mL}$) for *Streptococcus pneumoniae*, by Susceptibility Category, as per the Clinical and Laboratory Standards Institute

	Susceptibility category MIC ($\mu\text{g/mL}$)		
	Susceptible	Intermediate	Resistant
PENICILLIN			
Breakpoints (by clinical syndrome and administered route)			
Nonmeningitis, oral penicillin	≤ 0.06	0.12–1	≥ 2
Nonmeningitis, IV penicillin	≤ 2	4	≥ 8
Meningitis, IV penicillin	≤ 0.06	—	≥ 0.12
CEFOTAXIME OR CEFTRIAXONE			
Breakpoints (by clinical syndrome and administered route)			
Nonmeningitis	≤ 1	2	≥ 4
Meningitis	< 0.5	1	≥ 2

IV indicates intravenous; MIC, minimal inhibitory concentration; —, no intermediate category for meningitis.

From Clinical and Laboratory Standards Institute (CLSI). Performance Standards for Antimicrobial Testing; 29th Informational Supplement. Wayne, PA: Clinical and Laboratory Standards Institute; 2019. CLSI document M100-S29.

organism not requiring vancomycin is identified, or if the CSF culture is negative. Antibiotic dosing recommendations for meningitis are included in Tables 4.2, p 988 (neonatal), and 4.3, p 993 (nonneonatal), in Tables of Antibacterial Drug Dosages. If the *S pneumoniae* isolate is nonsusceptible to penicillin or third-generation cephalosporins, treatment options are provided in Table 3.69. Consultation with an infectious diseases specialist should be considered for all children with bacterial meningitis.

For children with serious proven hypersensitivity reactions to third- or fourth-generation cephalosporins, a pediatric infectious diseases specialist should be consulted for consideration of use of vancomycin plus either meropenem or rifampin.

A repeat lumbar puncture should be considered after 48 hours of therapy in the following circumstances:

- The organism is penicillin nonsusceptible by oxacillin disk or quantitative (MIC) testing, and results from cefotaxime and ceftriaxone quantitative susceptibility testing are not yet available or the isolate is cefotaxime and ceftriaxone nonsusceptible; or
- The patient’s condition has not improved or has worsened; or
- The child has received dexamethasone, which can interfere with the ability to interpret the clinical response, such as resolution of fever.

Dexamethasone. For infants and children 6 weeks and older, adjunctive therapy with dexamethasone may be considered after weighing the potential benefits and risks. Some experts recommend use of corticosteroids in pneumococcal meningitis, but this

Table 3.69. Antimicrobial Therapy for Infants and Children With Meningitis Caused by *Streptococcus pneumoniae* on the Basis of Susceptibility Test Results, as Defined in Table 3.68

Susceptibility Test Results	Antimicrobial Management ^a
<i>Susceptible</i> to penicillin	Discontinue vancomycin AND EITHER Continue cefotaxime or ceftriaxone alone ^b OR Begin penicillin (and discontinue cephalosporin)
<i>Nonsusceptible</i> to penicillin (<i>intermediate</i> or <i>resistant</i>) AND <i>Susceptible</i> to cefotaxime and ceftriaxone	Discontinue vancomycin AND Continue cefotaxime or ceftriaxone
<i>Nonsusceptible</i> to penicillin (<i>intermediate</i> or <i>resistant</i>) AND <i>Nonsusceptible</i> to cefotaxime and ceftriaxone (<i>intermediate</i> or <i>resistant</i>) AND <i>Susceptible</i> to rifampin	Continue vancomycin and high-dose cefotaxime or ceftriaxone AND Rifampin may be added in selected circumstances (see text)

^aInitial empiric therapy of nonallergic children older than 1 month of age with presumed bacterial meningitis should be vancomycin and cefotaxime or ceftriaxone. For dosages, see Tables 4.2, p 988 (neonatal), and 4.3, p 993 (nonneonatal), in Tables of Antibacterial Drug Dosages. Some experts recommend the maximum dosages.

^bSome physicians may choose this alternative for convenience but only in treatment of meningitis.

issue is controversial and data are not sufficient to make a routine recommendation for children. The Infectious Diseases Society of America recommends use of dexamethasone in adults with suspected or proven pneumococcal meningitis. If used, dexamethasone should be administered before or concurrently with the first dose of parenteral antimicrobial agents.

Nonmeningeal Invasive Pneumococcal Infections Requiring Hospitalization. For nonmeningeal invasive infections in previously healthy children who are not critically ill, antimicrobial agents that treat infections with *S pneumoniae* and other potential pathogens should be initiated at the usually recommended dosages (see Tables 4.2, p 988 [neonatal], and 4.3, p 993 [nonneonatal], in Tables of Antibacterial Drug Dosages).

For critically ill infants and children with invasive infections potentially attributable to *S pneumoniae*, vancomycin, in addition to empiric antimicrobial therapy (eg, cefotaxime or ceftriaxone or others), can be considered. Such patients include those with presumed septic shock, severe pneumonia with empyema, or significant hypoxia or myopericardial involvement. If vancomycin is administered, it should be discontinued as soon as antimicrobial susceptibility test results demonstrate effective alternative agents.

If the organism has in vitro nonsusceptibility to penicillin, cefotaxime, and ceftriaxone according to guidelines of the CLSI (see Table 3.68), therapy should be modified on the basis of clinical response, susceptibility to other antimicrobial agents, and results of follow-up cultures of blood and other infected body fluids. Consultation with an infectious diseases specialist should be considered.

For children with severe hypersensitivity to beta-lactam antimicrobial agents (ie, penicillins and cephalosporins), initial management should include vancomycin or clindamycin, in addition to antimicrobial agents for other potential pathogens, as indicated. Vancomycin should not be continued if the organism is susceptible to other appropriate non-beta-lactam antimicrobial agents. Consultation with an infectious diseases specialist should be considered.

Acute Otitis Media.¹ According to clinical practice guidelines of the American Academy of Pediatrics (AAP) and the American Academy of Family Physicians (AAFP) on acute suppurative otitis media (AOM), amoxicillin (80–90 mg/kg/day) is recommended for infants younger than 6 months, for those 6 through 23 months of age with bilateral disease, and for those older than 6 months with severe signs and symptoms (see *Haemophilus influenzae* Infections, p 400, and Appropriate and Judicious Use of Antimicrobial Agents, p 978). A watch-and-wait option can be considered for older children and those with nonsevere disease. Optimal duration of therapy is uncertain. For younger children and children with severe disease at any age, a 10-day course is recommended; for children 6 years and older with mild or moderate disease, a duration of 5 to 7 days is appropriate. Otolgia should be treated symptomatically.

Patients who fail to respond to initial management should be reassessed at 48 to 72 hours to confirm the diagnosis of AOM and exclude other causes of illness. If AOM is confirmed in the patient managed initially with observation, amoxicillin should be administered. If initial antibacterial therapy has failed, a change in antibacterial agent is indicated. Suitable alternative agents should be active

¹ Lieberthal AS, Carroll AE, Chonmaitree T, et al. Clinical practice guideline: diagnosis and management of acute otitis media. *Pediatrics*. 2013;131(3):e964-e999

against penicillin-nonsusceptible pneumococci as well as beta-lactamase-producing *Haemophilus influenzae* and *Moraxella catarrhalis*. Such agents include high-dose oral amoxicillin-clavulanate; oral cefdinir, cefpodoxime, or cefuroxime; or once-daily doses of intramuscular ceftriaxone for 3 consecutive days. Macrolide resistance in *S pneumoniae* is common, so clarithromycin and azithromycin are not considered appropriate alternatives for initial therapy even in patients with a type I (immediate, anaphylactic) reaction to a beta-lactam agent. In such cases, treatment with clindamycin (if susceptibility is known) or levofloxacin is preferred. For patients with a history of non-type I allergic reaction to penicillin, agents such as cefdinir, cefuroxime, or cefpodoxime can be used orally.

Myringotomy or tympanocentesis should be considered for children failing to respond to second-line therapy, for severe cases to obtain cultures to guide therapy, and for patients with invasive pneumococcal infection. For multidrug-resistant strains of *S pneumoniae*, use of levofloxacin or other agents should be considered in consultation with an infectious diseases specialist and based on the specific susceptibility profile.

Sinusitis. Antimicrobial agents effective for treatment of AOM also are likely to be effective for acute sinusitis and are recommended when a child meets clinical criteria for diagnosis.

Pneumonia.¹ Oral amoxicillin at a dose of 45 mg/kg/day in 3 equally divided doses or 90 mg/kg/day in 2 divided portions is likely to be effective in ambulatory children with pneumonia caused by susceptible and relatively resistant pneumococci, respectively. Intravenous ampicillin by intermittent dosing or penicillin by continuous infusion is recommended for therapy of hospitalized cases caused by penicillin-susceptible strains. Cefotaxime or ceftriaxone is recommended for treatment of inpatients infected with pneumococci suspected or proven to be penicillin-nonsusceptible strains, for serious infections including empyema, or in those not fully immunized with PCV13 or the more recently licensed 15-valent or 20-valent pneumococcal conjugate vaccines (PCV15 and PCV20, respectively). Vancomycin should be included in those with life-threatening infection. For patients with isolates nonsusceptible to penicillin (MICs of 4.0 µg/mL or higher; see Table 3.68) or significant allergy to beta-lactam antimicrobials, treatment with clindamycin (if susceptible) or levofloxacin should be considered, assuming that concurrent meningitis has been excluded.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended, including for patients with infections caused by drug-resistant *S pneumoniae*.

CONTROL MEASURES:

Active Immunization. Four pneumococcal vaccines are available for use in children in the United States: 3 pneumococcal conjugate vaccines (PCV13, PCV15, and PCV20), and 1 pneumococcal polysaccharide vaccine (the 23-valent PPSV23). PCV13, PCV15, and PCV20 are licensed for use in infants and children 6 weeks and older as well as in adults. PCV13 is composed of 13 purified capsular polysaccharide serotypes (1, 3, 4, 5, 6A, 6B, 7F, 9V, 14, 18C, 19A, 19F, and 23F). PCV15 contains all PCV13 serotypes plus serotypes 22F and 33F. PCV20 contains all PCV15 serotypes plus serotypes 8,

¹ Bradley JS, Byington CL, Shah SS, et al. The management of community-acquired pneumonia in infants and children older than 3 months of age: clinical practice guidelines by the Pediatric Infectious Diseases Society and the Infectious Diseases Society of America. *Clin Infect Dis*. 2011;53(7):e25–e76

10A, 11A, 12F, and 15B. PPSV23 is licensed for use in children 2 years and older and adults. PPSV23 is composed of 23 capsular polysaccharides, including all of those in PCV13, PCV15, and PCV20 except 6A. PPSV23 is available in single or multidose vials and single-dose prefilled syringes that do not contain latex. Each available vaccine is recommended in a dose of 0.5 mL to be administered intramuscularly. In contrast to immunization with PCV13, PCV15, and PCV20, immunization with PPSV23 does not induce immunologic memory or boosting with subsequent doses, has no effects on nasopharyngeal carriage, and therefore, does not interrupt transmission and indirectly protect unimmunized people.

Routine Immunization With Pneumococcal Conjugate Vaccine. PCV15 or PCV20 is recommended for all infants and children 2 through 59 months of age. There is no preference for one of these vaccines over the other. For infants, the vaccine should be administered at 2, 4, 6, and 12 through 15 months of age; catch-up immunization is recommended for all children 59 months of age or younger (Table 3.70). Infants should begin the PCV15 or PCV20 immunization series in conjunction with other recommended vaccines at the time of the first regularly scheduled health maintenance visit after 6 weeks of age. Infants of very low birth weight (1500 g or less) should be immunized when they attain a chronologic age of 6 to 8 weeks, regardless of their gestational age at birth. PCV15 or PCV20 can be administered concurrently with all other age-appropriate childhood immunizations (except PPSV23 and MenACWY-D [Menactra], see General Recommendations for Use of Pneumococcal Vaccines, below) using a separate syringe and a separate injection site.

Immunization of Children Under 6 Years of Age Who Are Unimmunized or Incompletely Immunized With PCV13, PCV15, or PCV20. For healthy children 2 through 59 months of age with an incomplete PCV vaccination status, use of either PCV15 or PCV20 according to the currently recommended dosing and schedules is recommended (see Table 3.70). For all children 2 through 71 months who are at high risk or presumed high risk of acquiring invasive pneumococcal infection, as defined in Table 3.67 (p 812), the recommended use of PCV15, PCV20, and PPSV23 is outlined in Table 3.71 (p 819).

Immunization of Children 6 Through 18 Years of Age With High-Risk Conditions Who Have Not Received Any Dose of PCV.¹⁻³

For children 6 through 18 years of age who previously have not received PCV13, PCV15, or PCV20 and who are at increased risk of IPD because of a high-risk condition (defined in Table 3.67, p 812), administration of a single PCV15 or PCV20 dose is recommended. When PCV15 is used, it should be followed by either a dose of PCV20 or a dose of PPSV23 at least 8 weeks later.

^eA single dose should be administered to all healthy children 24 through 59 months of age with any incomplete schedule.

Table 3.71. Recommendations for Pneumococcal Immunization With PCV15, PCV20, and/or PPSV23 Vaccine for Children at High Risk or Presumed High Risk of Pneumococcal Disease, as Defined in Table 3.67 (p 812)

Age	Previous Dose(s) of Any Pneumococcal Vaccine	Recommendations
23 mo or younger	None	PCV15 or PCV20, as in Table 3.70.
24 through 71 mo	4 doses of PCV13, PCV15, or PCV20	If none of the prior 4 doses were PCV20: 1 dose of PPSV23 or PCV20, ≥ 8 wk after last dose of PCV13 or PCV15.
		If ≥ 1 of the prior 4 doses was PCV20: no additional doses of any pneumococcal vaccine are indicated.
24 through 71 mo	Incomplete series of 3 previous doses of PCV13, PCV15, or PCV20 before 24 mo of age	1 dose of PCV15 or PCV20.
		If PCV15 is used for this dose and there are no prior doses of PCV20, 1 dose of PPSV23 ≥ 8 wk after the last dose of PCV15.
		If PCV20 is used for this or any prior dose, no additional doses of any pneumococcal vaccine are indicated.
24 through 71 mo	Incomplete series of <3 doses of PCV13, PCV15, or PCV20 before 24 mo of age	2 doses of PCV15 or PCV20, ≥ 8 wk after last dose of PCV13, PCV15, or PCV20 (if applicable).
		If PCV15 is used for this dose, 1 dose of PPSV23 vaccine, ≥ 8 wk after the last dose of PCV13 or PCV15.
		If PCV20 is used for this dose, no additional doses of any pneumococcal vaccine are indicated.
24 through 71 mo	1 dose of PPSV23	2 doses of PCV15 or PCV20, 8 wk apart, beginning at 8 wk after last dose of PPSV23.
6 years through 18 years with immunocompromising conditions ^{a,b,c,d}	No previous doses of PCV13, PCV15, PCV20, or PPSV23	1 dose of PCV15 followed by 1 dose of PPSV23 at least 8 weeks later and a second dose of PPSV23 5 years after the first ^e ; OR 1 dose of PCV20 with no additional doses of any pneumococcal vaccine indicated thereafter

Table 3.71. Recommendations for Pneumococcal Immunization With PCV15, PCV20, and/or PPSV23 Vaccine for Children at High Risk or Presumed High Risk of Pneumococcal Disease, as Defined in Table 3.67 (p 812), continued

Age	Previous Dose(s) of Any Pneumococcal Vaccine	Recommendations
	1 dose of PCV13, PCV15, or PCV20	If prior dose was with PCV13 or PCV15: 1 dose of PPSV23 and a second dose of PPSV23 5 years after the first. ^e If prior dose was with PCV20: no additional doses of any pneumococcal vaccine are indicated.
	≥1 dose of PPSV23 and no previous dose of PCV13, PCV15, or PCV20	1 dose of PCV15 or PCV20 (even if PCV7 previously administered) ≥8 weeks after the last PPSV23 dose; if a second PPSV23 dose is indicated, ^e it should be administered ≥5 years after the first PPSV23 dose

PCV13 indicates 13-valent pneumococcal conjugate vaccine; PCV15 indicates 15-valent pneumococcal conjugate vaccine; PCV20 indicates 20-valent pneumococcal conjugate vaccine; PPSV23, 23-valent pneumococcal polysaccharide vaccine.

^aIncludes anatomic or functional asplenia, human immunodeficiency virus (HIV) infection, cochlear implant, cerebrospinal fluid (CSF) leak, nephrotic syndrome, chronic renal failure, or other immunocompromising conditions.

^bAmerican Academy of Pediatrics, Committee on Infectious Diseases. Policy statement: Immunization for *Streptococcus pneumoniae* infections in high-risk children. *Pediatrics*. 2014;134(6):1230–1233

^cKobayashi M, Farrar JI, Gierke R, et al. Use of 15-valent pneumococcal conjugate vaccine among US children: updated recommendations of the Advisory Committee on Immunization Practices—United States, 2022. *MMWR Morb Mortal Wkly Rep*. 2022;71(4):1174–1181.

^dACIP Updates: Recommendations for use of 20-valent pneumococcal conjugate vaccine in children—United States, 2023. *MMWR Morb Mortal Wkly Rep*. 2023;72(39):1072.

^eA second dose of PPSV23 5 years after the first dose is recommended only for children who have functional or anatomic asplenia, HIV infection, or other immunocompromising conditions (Table 3.67, p 812). No more than 2 doses of PPSV23 are recommended.

A second dose of PPSV23 or a first dose of PCV20 (if no prior PCV20 has been administered) is recommended 5 years after the first dose of PPSV23 in children with sickle cell disease or functional or anatomic asplenia, HIV infection, or other immunocompromising conditions, but no more than a total of 2 PPSV23 doses should be administered before 65 years of age.

Immunization of Children 2 Through 18 Years of Age Who Are at Increased Risk of IPD With PPSV23 After PCV13, PCV15, or PCV20.^{1–3} Children 2 years or older with an underlying medical condition increasing the risk of IPD should receive a dose of PPSV23 at least

¹ American Academy of Pediatrics, Committee on Infectious Diseases. Immunization for *Streptococcus pneumoniae* infections in high-risk children. *Pediatrics*. 2014;134(6):1230–1233

³ ACIP Updates: Recommendations for use of 20-valent pneumococcal conjugate vaccine in children—United States, 2023. *MMWR Morb Mortal Wkly Rep*. 2023;72(39):1072

8 weeks after completing all recommended doses of PCV13 or PCV15. However, if they have received one or more doses of PCV20, no additional doses of any pneumococcal vaccine, including PPSV23, are indicated. In children who are candidates for solid organ transplantation and in cases when a splenectomy is planned for a patient older than 2 years, a dose of PPSV23 (if they previously had received only PCV13 or PCV15) or one dose of PCV20 should be administered at least 2 weeks before transplant or splenectomy. In candidates for solid organ transplantation not previously vaccinated with PCV13 or PCV15, a dose of PCV15 or PCV20 should be administered, even for those older than 6 years.

A second dose of PPSV23 or a first dose of PCV20 (if no prior PCV20 has been administered) is recommended 5 years after the first dose of PPSV23 in children with sickle cell disease or functional or anatomic asplenia, HIV infection, or other immunocompromising conditions, but no more than a total of 2 PPSV23 doses should be administered before 65 years of age.

General Recommendations for Use of Pneumococcal Vaccines.

- PPSV23 should not be given together with a conjugate pneumococcal vaccines (PCV15 or PCV20) but can be administered concurrently with other childhood vaccines, with 1 exception. For children for whom quadrivalent meningococcal conjugate vaccine is indicated, MenACWY-D (Menactra) should not be administered concomitantly OR within 4 weeks of administration of PCV15 or PCV20 immunization to avoid potential interference with the immune response to PCV15 or PCV20. Because of their high risk for IPD, children with functional or anatomic asplenia should not be immunized with MenACWY-D (Menactra) before 2 years of age so that they can complete their PCV15 or PCV20 series; only MenACWY-CRM (Menveo) should be used in this age group because it has been shown to not interfere with the immune response to PCV15 or PCV20 and because the only other alternative, MenACWY-TT (MenQuadfi), is only approved in children ≥ 2 years of age (see Table 3.40, p 594).
- When elective splenectomy is performed for any reason, immunization with PCV15 or PCV20 should be completed at least 2 weeks before splenectomy. Immunization also should precede initiation of immune-compromising therapy or placement of a cochlear implant by at least 2 weeks. PPSV23 should be administered 8 or more weeks after PCV15, but should not be administered if one or more doses of PCV20 has already been given (see Immunization and Other Considerations in Immunocompromised Children, p 93).
- Generally, pneumococcal vaccines should be deferred during pregnancy. However, pregnant people with underlying conditions that warrant pneumococcal immunization may be vaccinated when the benefit of the vaccination is considered to outweigh any potential risks.

Adverse Reactions to Pneumococcal Vaccines. Adverse reactions after administration of polysaccharide or conjugate vaccines generally are mild to moderate. The most commonly reported adverse reactions are local reactions of injection site, pain, redness, or swelling in addition to irritability, decreased appetite, or impaired sleep. Fever may occur within the first 1 to 2 days after injections, particularly after use of conjugate vaccine. Other systemic reactions include fatigue, headache, generalized muscle pain, decreased appetite, and chills.

Chemoprophylaxis. Daily antimicrobial prophylaxis is recommended for certain children with functional or anatomic asplenia, regardless of their immunization status, for prevention of pneumococcal disease on the basis of results of a large, multicenter study (see Asplenia and Functional Asplenia, p 108). Oral penicillin V (125 mg, twice a day, for children younger than 3 years; 250 mg, twice a day, for children 3 years and older) is recommended. The study, performed before routine use of any of the conjugate pneumococcal vaccines in the United States, demonstrated that oral penicillin V administered to infants and young children with sickle cell disease decreased the incidence of pneumococcal bacteremia by 84% compared with the placebo control group. Although overall incidence of IPD is decreased after penicillin prophylaxis, cases of penicillin-nonsusceptible IPD and nasopharyngeal carriage of penicillin-nonsusceptible strains in patients with sickle cell disease have increased since these studies were conducted. Parents should be informed that penicillin prophylaxis may not be effective in preventing all cases of IPD. In children with suspected or proven penicillin allergy, erythromycin is an alternative agent for prophylaxis.¹

The age at which prophylaxis is discontinued is an empiric decision. Most children with sickle cell disease who have received all recommended pneumococcal vaccines for age and who had received penicillin prophylaxis for prolonged periods, who are receiving regular medical attention, and who have not had a previous severe pneumococcal infection or a surgical splenectomy may discontinue prophylactic penicillin safely at 5 years of age. However, they must be counseled to seek medical attention promptly for all febrile events. The duration of prophylaxis for children with asplenia attributable to other causes is unknown. Some experts continue prophylaxis throughout childhood or longer.

Control of Transmission of Pneumococcal Infection and Invasive Disease Among Children

Attending Out-of-Home Child Care. Antimicrobial chemoprophylaxis is not recommended for contacts of children with IPD, regardless of their immunization status.

Public Health Reporting. Cases of IPD should be reported according to state standards. The majority of cases of invasive disease are caused by non-PCV13 serotypes. Therefore, the overwhelming majority of invasive pneumococcal disease cases occurring among immunized children do not represent vaccine failures. To differentiate PCV13 (or PCV15 or PCV20) failure in an immunized child from disease caused by a serotype not included in PCV13 (or PCV15 or PCV20), the isolate should be serotyped. If the invasive isolate is a serotype included in the vaccine, an evaluation of the patient's HIV status and immunologic function should be considered if the child had received an age-appropriate regimen of PCV13, PCV15, or PCV20 at least 2 weeks before the onset of the invasive infection.

Strongyloidiasis

(*Strongyloides stercoralis*)

CLINICAL MANIFESTATIONS: Most infections with *Strongyloides stercoralis* are asymptomatic. When symptoms occur, they are related most often to larval tissue migration and/or the presence of adult worms in the intestine. Infective (filariform) larvae are acquired from skin contact with contaminated soil, which may produce transient pruritic papules

¹ American Academy of Pediatrics, Committee on Genetics. Health supervision for children with sickle cell disease. *Pediatrics*. 2002;109(3):526-535 (Reaffirmed January 2011, February 2016)

at the site of penetration. Larvae then migrate to the lungs, where they may cause a transient pneumonitis or Löffler-like syndrome characterized by a dry cough. After ascending the tracheobronchial tree, larvae are swallowed and mature into adult forms within the gastrointestinal tract. Symptoms of intestinal infection may include non-specific abdominal pain (epigastric), vomiting, intermittent constipation, and diarrhea. Presentation rarely may resemble inflammatory bowel disease. Larval migration may produce migratory serpiginous pruritic erythematous skin lesions that advance rapidly (centimeters in hours). These tracks are referred to as “larva currens” and are pathognomonic for *Strongyloides*. Other dermatologic findings include urticaria and pruritus.

The most feared complication is *Strongyloides* hyperinfection syndrome and disseminated disease. Hyperinfection refers to increased larval migration within the gastrointestinal and pulmonary tracts; dissemination refers to migration of larva to distant organs such as the brain, liver, kidney, heart, and skin. Dissemination is associated with septicemia believed to occur when large numbers of larvae penetrate the intestinal wall, seeding the bloodstream with gram-negative bacteria. Hyperinfection/dissemination syndrome typically occurs in the immunocompromised host, most often those receiving immunosuppressive agents, particularly corticosteroids, for underlying disease (eg, malignancy or autoimmunity) but also in recipients of solid organ or hematopoietic cell transplants (through either reactivation of prior asymptomatic infection in the recipient or donor-derived infection). Hyperinfection/dissemination also is associated closely with human T-lymphotropic virus 1 (HTLV-1) coinfection, which is most common among persons from the Caribbean, East Asia (particularly southwest Japan), Latin America, and West Africa. *Strongyloides* hyperinfection/dissemination syndrome may be characterized by fever, abdominal pain, diffuse pulmonary infiltrates, and septicemia or meningitis caused by enteric gram-negative bacilli. Left untreated, mortality rates can approach 90%. For unknown reasons, it is extremely rare during childhood.

ETIOLOGY: *S. stercoralis*, a nematode (roundworm), is the major causative agent in humans, although other species, including zoonotic species, are reported rarely.

EPIDEMIOLOGY: Strongyloidiasis is endemic in the tropics and subtropics, including parts of the United States, wherever suitable moist soil and improper disposal of human waste coexist. Humans are the principal hosts, but dogs, cats, and other animals can serve as reservoirs. Transmission involves penetration of skin by filariform larvae from contact with soil contaminated by human feces. Infections also can be acquired via the fecal-oral route with ingestion of food contaminated with human feces containing larvae or from inadvertent coprophagy. Adult female worms release eggs in the small intestine, where they hatch as first-stage (rhabditiform) larvae that are excreted in feces. A small percentage of larvae molt to the infective (filariform) stage during intestinal transit and can penetrate the bowel mucosa or perianal skin, thus maintaining the life cycle within a single person (autoinfection). This capacity for autoinfection is unique among soil-transmitted infections and allows for infection to persist for decades (eg, in immigrants from or travelers to endemic regions many years before).

The **incubation period** in humans can range from weeks for acute strongyloidiasis to decades for chronic infection.

DIAGNOSTIC TESTS: Strongyloidiasis can be difficult to diagnose. Testing generally is performed on stool or serologically. Visualization of larvae (rhabditiform, or less often, filariform) with direct microscopy of stool (or from duodenal biopsy or fluid obtained

using the string test [Entero-Test] or a direct aspirate through a flexible endoscope) confirms the diagnosis. At least 3 consecutive stool specimens should be examined microscopically for characteristic larvae (not eggs) using a concentration method (eg, sedimentation techniques), but a negative test result does not exclude infection, because larvae excretion can be intermittent and of low intensity. Other techniques that provide greater sensitivity but are not available routinely in the United States include stool polymerase chain reaction (PCR) assay, stool agar culture, or other specialized tests on stool specimens. Filariform larvae may be identified in disseminated strongyloidiasis from other specimens such as sputum or bronchoalveolar lavage fluid, spinal fluid, pleural fluid, or peritoneal fluid or in skin biopsies.

Serologic tests, including enzyme-linked immunosorbent assays (ELISAs) that detect immunoglobulin (Ig) G to filariform larvae, are highly sensitive, but cross-reactivity may occur in patients with filariasis and other nematode infections. Serologic tests using recombinant antigens have similar high sensitivity but greater specificity for strongyloidiasis. Serologic testing has several limitations. Detection does not confirm active infection, because antibodies may remain positive for a period of time following infection resolution. False-negative results may occur, and therefore a negative test result does not eliminate the possibility of ongoing infection. Quantitative serologic monitoring may be useful in following treatment in immunocompetent patients, because antibody concentrations decline over time with successful treatment, although the timing of seroconversion following treatment, and how often it occurs, is unknown. The Centers for Disease Control and Prevention (CDC) performs reference serologic testing to confirm equivocal results (www.cdc.gov/parasites/strongyloides/health_professionals/index.html).

Eosinophilia (blood eosinophil count greater than 400–500/ μ L) is associated with acute and chronic infection, but may be absent in up to 50% of infected individuals. Eosinophilia often is absent in patients with hyperinfection/dissemination syndrome, which predicts a poor outcome.

TREATMENT: Ivermectin is the treatment of choice for all forms of strongyloidiasis and is approved by the US Food and Drug Administration for the treatment of intestinal strongyloidiasis. Ivermectin is contraindicated in people with confirmed or suspected coinfection with *Loa loa* and a high microfilarial load. An alternative agent is albendazole, although it is associated with lower cure rates (see Drugs for Parasitic Infections, p 1068). Prolonged or repeated treatment may be necessary in people with hyperinfection/disseminated strongyloidiasis, and relapse can occur.

Treatment for suspected or confirmed hyperinfection/dissemination syndrome is immediate ivermectin, continued until stool or sputum examinations are negative for 2 weeks. Rectal and subcutaneous routes have been used when oral or enteral tube administration was not possible. Suspected or confirmed hyperinfection/dissemination syndrome should be managed in consultation with an expert.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended. Hospital transmission has never been reported.

CONTROL MEASURES: Sanitary disposal of human waste is effective at interrupting transmission of *S. stercoralis*. Eligible refugees who arrive in the United States through the US Refugee Resettlement Program receive presumptive treatment with ivermectin before arrival, but other immigrants, including internationally adopted children, may

not. Any individual at risk epidemiologically for strongyloidiasis who will undergo a solid organ or hematopoietic cell transplant or immunosuppressant therapy, particularly with corticosteroids or tumor necrosis factor alpha inhibitors, either should be treated presumptively for strongyloidiasis or tested serologically and treated if the serologic test result is positive before initiation of immunosuppression. Providers should screen for *Strongyloides* in organ donors from areas with endemic infection and consider the diagnosis in select patients with hematologic malignancies, people on corticosteroids or other immune suppressants, people with HTLV-1 infection, people with persistent or unexplained eosinophilia, household contacts with shared risk factors, and people who traveled recently or remotely to areas with endemic disease.

Syphilis

CLINICAL MANIFESTATIONS:

Congenital Syphilis. Intrauterine infection with *Treponema pallidum* can result in stillbirth, hydrops fetalis, or preterm birth or may be asymptomatic at birth. Infected infants can have hepatosplenomegaly; snuffles (copious nasal secretions); lymphadenopathy; mucocutaneous lesions; pneumonia; osteochondritis, periostitis, and pseudoparalysis; edema; rash (maculopapular consisting of small dark red-copper spots that is most severe on the hands and feet); hemolytic anemia; or thrombocytopenia at birth or within the first 4 to 8 weeks of age. Untreated infants, including those asymptomatic at birth, may develop late manifestations, which usually appear after 2 years of age and involve the central nervous system (CNS), bones and joints, teeth, eyes, and skin. Some findings may not become apparent until many years after birth, such as interstitial keratitis, eighth cranial nerve deafness, Hutchinson teeth (peg-shaped, notched central incisors), anterior bowing of the shins, frontal bossing, mulberry molars, saddle nose, rhagades (perioral fissures), and Clutton joints (symmetric, painless swelling of the knees). Late manifestations can be prevented by treatment of early infection.

Acquired Syphilis. Acquired disease can be divided into 3 stages. The **primary stage** (or “**primary syphilis**”) can appear as painless or painful indurated ulcers (chancre) of the skin or mucous membranes at the site of inoculation. These lesions appear, on average, 3 weeks after exposure and heal spontaneously in a few weeks. Adjacent lymph nodes frequently are enlarged but are nontender. The **secondary stage** (or “**secondary syphilis**”), beginning 1 to 2 months later, is characterized by fever, sore throat, muscle aches, rash, mucocutaneous lesions, hepatitis, and generalized lymphadenopathy. The polymorphic maculopapular rash is generalized and typically includes the palms and soles. In moist areas of the perineum, hypertrophic papular lesions (condyloma lata) can be confused with condyloma acuminata secondary to human papillomavirus (HPV) infection. Malaise, splenomegaly, headache, alopecia, and arthralgia can be present. This stage resolves spontaneously without treatment in approximately 3 to 12 weeks. A variable asymptomatic latent period follows but may be interrupted during the first few years by recurrences of symptoms of secondary syphilis. **Latent syphilis** is the period after infection when patients are seroreactive but demonstrate no clinical manifestations of disease. Development of latent syphilis within the preceding year is referred to as **early latent syphilis**; if >1 year in duration, it is known as **late latent syphilis**. If the duration of infection is unknown, the patient should be considered to have late latent syphilis for the

purposes of management. The **tertiary stage** of syphilis occurs 15 to 30 years after the initial infection and can include gumma formation (soft, noncancerous, granulomatous growths that can destroy tissue) or cardiovascular involvement (including aortitis). Neurosyphilis, defined as infection of the central nervous system (CNS), can occur at any stage of infection, especially in people with advanced or poorly controlled human immunodeficiency virus (HIV) disease and in neonates with congenital syphilis; manifestations include meningitis, uveitis, seizures, optic atrophy, hearing loss, and (typically years after infection) dementia and posterior spinal cord degeneration (tabes dorsalis, including a characteristic high-stepping gait with the feet slapping the ground because of loss of proprioception).

ETIOLOGY: *T pallidum* subspecies *pallidum* (*T pallidum*) is a thin, motile spirochete that is extremely fastidious, surviving only briefly outside the host. It is very closely related to 3 other organisms causing nonvenereal human disease in distinct geographic regions of the world: *T pallidum* subspecies *pertenue*, which causes yaws; *T pallidum* subspecies *endemicum*, which causes endemic syphilis; and *Treponema carateum*, which causes pinta. The genus *Treponema* is classified in the family *Spirochaetaceae*.

EPIDEMIOLOGY: From 2016 to 2020, the primary and secondary syphilis rate increased 52% nationally, from 8.6 to 12.7 cases per 100 000 population. Rates increased among both male and female individuals and in most regions of the United States (Midwest, Northeast, South).¹ Rates of primary and secondary syphilis also increased in most racial and ethnic groups, with the greatest increases observed among non-Hispanic American Indian/Alaska Native persons as well as non-Hispanic multiracial persons.

In 2020, men who have sex with men (MSM) only and men who have sex with both men and women accounted for 43% of all primary and secondary syphilis cases among male patients when sex of the partner was known.

In 2020, a total of 2148 cases of congenital syphilis were reported, including 149 stillbirths and infant deaths. The 2020 national rate of 57 cases per 100 000 live births represents a 15% increase relative to 2019 (49.9 cases per 100 000 live births) and a 254% increase relative to 2016 (16.2 cases per 100 000 live births). This trend mirrors the increase in primary and secondary syphilis cases seen in women of reproductive age. From 2016 to 2020, rates of primary and secondary syphilis among women of reproductive age (15–44 years) increased 147%, from 1.9 to 4.7 per 100 000 female individuals.

Congenital syphilis may be contracted at any stage of the pregnant person's infection via transplacental transmission, at any time during pregnancy, or via contact with the birthing parent's lesions at the time of delivery. Among pregnant people with untreated early syphilis, up to 40% of their pregnancies will result in spontaneous abortion, stillbirth, or perinatal death. The rate of perinatal transmission is 60% to 100% in the setting of primary and secondary syphilis and decreases with later stages of infection of the birthing parent (approximately 40% with early latent infection and <8% with late latent infection). Among people who acquire syphilis during pregnancy, the risk of transmission to the infant increases directly with the gestational age at the time the pregnant person becomes infected. People with HIV, in particular, have a higher prevalence of untreated or inadequately treated syphilis during pregnancy; therefore, their newborn infants may be at higher risk of congenital syphilis.

¹ Unless otherwise noted, the terms male, female, men, and women refer to sex assigned at birth.

In addition, syphilis coinfection during pregnancy may also increase the rate of vertical transmission of HIV.

T pallidum is not transmitted through human milk, but transmission may occur if the breastfeeding person has an infectious lesion (chancere) on the breast.

Acquired syphilis almost always is contracted through direct sexual contact with ulcerative lesions of the skin or mucous membranes of infected people. Open, moist lesions of the primary or secondary stages are highly infectious. Syphilis acquired beyond the neonatal period should be considered diagnostic of sexual abuse in infants and young children once vertical transmission is excluded (see Sexual Assault and Abuse in Children and Adolescents/Young Adults, p 182).

The **incubation period** for acquired primary syphilis typically is 3 weeks but ranges from 10 to 90 days.

DIAGNOSTIC TESTS: Definitive diagnosis is made by molecular tests for detecting *T pallidum* or when spirochetes are identified by microscopic darkfield examination of lesion exudate, nasal discharge, or tissue, such as placenta, lymph node, umbilical cord, or autopsy specimens. Darkfield microscopy, however, no longer is routinely available in most clinics and laboratories because of its complexity. Although no *T pallidum* direct-detection molecular nucleic acid amplification test (NAAT) is available commercially, certain laboratories provide locally developed and validated polymerase chain reaction (PCR) tests.

Presumptive diagnosis requires the use of both nontreponemal and treponemal serologic tests. Nontreponemal tests for syphilis include the Venereal Disease Research Laboratory (VDRL) slide test and the rapid plasma reagin (RPR) test. These tests are inexpensive, can be performed across a range of laboratory levels of complexity with fairly rapid turnaround times for analysis, and provide semiquantitative results that can both help define disease activity and monitor response to therapy. Nontreponemal test results may be falsely negative (ie, nonreactive) in early primary syphilis, latent acquired syphilis of long duration, and late congenital syphilis. Occasionally, a nontreponemal test performed on serum containing high concentrations of antibody will be weakly reactive or falsely negative, a reaction termed the prozone phenomenon; diluting the serum being tested will then result in a positive test result. The prozone phenomenon may be observed more often in HIV-coinfected individuals. When nontreponemal tests are used serially to monitor treatment response, the same test (RPR or VDRL), ideally analyzed in the same laboratory, must be used throughout the follow-up period to ensure comparability of results.

Except with congenital infection, a reactive nontreponemal test result should be confirmed by a specific treponemal test to exclude a false-positive test result. False-positive nontreponemal results can be caused by certain viral infections (eg, Epstein-Barr virus infection, hepatitis, HIV, varicella, measles), lymphoma, tuberculosis, malaria, endocarditis, connective tissue disease, older age, abuse of injection drugs, or laboratory or technical error. A non-cord neonatal blood sample is preferred for testing. Cord blood samples are not recommended for testing a newborn infant's RPR or VDRL status, because blood from the birthing parent can contaminate the specimen and yield a false-positive result, and Wharton's jelly can yield a false-negative result.

Treponemal tests in use include the *T pallidum* particle agglutination (TP-PA) test (which is the preferred treponemal test), *T pallidum* enzyme immunoassay (TP-EIA), *T pallidum* chemiluminescence assay (TP-CIA), and fluorescent treponemal antibody

absorption (FTA-ABS) test. The Centers for Disease Control and Prevention (CDC) has assessed the performance characteristics of seven of the treponemal tests that are commercially available.¹ Generally, immunoassays have similar performance to manual treponemal assays, although certain immunoassays may be less specific. Most people who have reactive treponemal test results remain reactive for life, even after successful therapy. However, 15% to 25% of patients treated during primary syphilis revert to being serologically nonreactive on treponemal testing after 2 to 3 years. Treponemal test results may be variably positive in patients with other spirochetal diseases, such as yaws, pinta, leptospirosis, rat-bite fever, relapsing fever, and Lyme disease.

In most cases, if a patient has a positive RPR or VDRL result in low titer and has a negative treponemal test result, the nontreponemal test result will be a false positive. However, because false-negative test results can occur in early syphilis, retesting in 2 to 4 weeks and again later if clinically indicated should be considered in people at increased risk for syphilis, especially in pregnant people and those with HIV.

The CDC² and the US Preventive Services Task Force³ recommend syphilis serologic screening with a nontreponemal test; this screening is followed by confirmation using one of the several available treponemal tests (“conventional diagnostic” approach). Some clinical laboratories and blood banks, however, screen samples using treponemal tests first rather than beginning with a nontreponemal test. This is known as “reverse-sequence screening” and may result in false-positive results, especially in low-prevalence populations. When the reverse-sequence algorithm is used, people with a positive treponemal test result and a negative nontreponemal test result (eg, EIA positive, RPR negative) should have a second treponemal test targeting a different *T pallidum* antigen performed to confirm the results of the original test. If the second treponemal-specific test result is negative (eg, EIA-positive, RPR-negative, then TP-PA-negative) and the person is at low risk for syphilis, the original treponemal test result likely was a false positive. However, in individuals at high-risk for infection, retesting in 2 to 4 weeks and again later if clinically indicated should be considered.

Cerebrospinal Fluid Tests. Cerebrospinal fluid (CSF) abnormalities in adolescents and adults with neurosyphilis can include increased protein concentration, increased white blood cell (WBC) count, and/or a reactive CSF-VDRL test result. The CSF leukocyte count usually is elevated in neurosyphilis (>5 WBCs/mm³). Interpretation of CSF test results requires a nontraumatic lumbar puncture (ie, a CSF sample not contaminated with blood). The CSF-VDRL is highly specific but insensitive; therefore, a negative result does not exclude a diagnosis of neurosyphilis. A positive CSF FTA-ABS or TP-PA result can support the diagnosis of neurosyphilis but does not establish the diagnosis definitively.

Conversely, a reactive CSF-VDRL test in a neonate or infant from a nontraumatic lumbar puncture confirms the diagnosis of neurosyphilis. CSF cell count and protein can be difficult to interpret during the neonatal period; normal values differ by gestational age and are higher in preterm infants. Studies suggest that 95% of healthy

² Centers for Disease Control and Prevention. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(RR-4):1-185

³ US Preventive Services Task Force. Screening for syphilis infection in non-pregnant adults and adolescents. *JAMA*. 2016;315(21):2321-2327

neonates have values ≤ 16 to 19 white blood cells (WBCs)/mm³ and/or protein ≤ 115 to 118 mg/dL on CSF examination. During the second month of life, 95% of healthy infants have ≤ 9 to 11 WBCs/mm³ and/or protein of ≤ 89 to 91 mg/dL. Lower values (ie, 5 WBCs/mm³ and protein of 40 mg/dL) might be considered the upper limits of normal in older infants. Other causes of elevated CSF values should be considered when an infant is being evaluated for congenital syphilis.

Testing During Pregnancy. Prevention of congenital syphilis requires that pregnant people be screened serologically early in pregnancy. False-negative test results are possible in recent infection, and syphilis may be acquired later in pregnancy. In communities and populations in which the prevalence of syphilis is high and for people at high risk for infection, serologic testing at the first prenatal visit, with repeat serologic testing at 28 weeks' gestation and again at delivery, is recommended. A nontreponemal test (RPR or VDRL) is recommended for screening, followed by a treponemal test (eg, TP-PA) if the screening result is positive. In most cases, if the treponemal antibody test result is negative, the nontreponemal test result is falsely positive and no further evaluation is necessary. However, retesting in 2 to 4 weeks, and again later if clinically indicated, should be considered for pregnant people who are at high risk of syphilis, such as those living in communities with high rates of syphilis or those who have been at risk for syphilis acquisition during pregnancy (eg, sex with multiple partners, sex in conjunction with drug use or transactional sex, late or no prenatal care, incarceration of the pregnant person or partner, or unstable housing or homelessness).

If the reverse-sequence screening algorithm is used, pregnant people with reactive treponemal screening test results should have confirmatory testing with a quantitative nontreponemal test. If the nontreponemal test result is negative (eg, EIA positive, RPR negative), a second treponemal-specific test using a different *T pallidum* antigen should be obtained to determine whether the initial treponemal test result was a false positive (TP-PA preferred). If the second treponemal test result is negative (eg, EIA positive, RPR negative, then TP-PA negative) and the person is at low risk for syphilis, the original treponemal test result likely was a false positive. However, retesting in 2 to 4 weeks and again later if clinically indicated should be considered for pregnant people who are at high risk of syphilis.

Ultrasonographic evaluation of the fetus from the second trimester onward should be performed when syphilis is diagnosed at any time during pregnancy, even if appropriate treatment has been administered to the pregnant person. Pathologic examination of the placenta and/or umbilical cord at delivery also should be performed.

Evaluation of Infants for Congenital Infection During the Newborn Period to 1 Month of Age.

No newborn infant should be discharged from the hospital without confirmation of the birthing parent's serologic status for syphilis. This may prolong infant hospitalization, because a confirmatory maternal TP-PA for a birthing parent who is TP-CIA or TP-EIA positive and RPR or VDRL negative usually is performed off-site and takes several days to result. All infants born to seropositive persons require a careful examination and nontreponemal testing. A negative RPR or VDRL test result for the birthing parent at delivery does not rule out the possibility of the infant having congenital syphilis, although such a situation is rare. The diagnostic approach to infant evaluation for congenital syphilis is presented in Fig 3.18. In addition to the blood and CSF tests noted, infants in whom congenital syphilis is proven or highly probable should have long-bone radiographs as should those with possible congenital syphilis, for whom

FIG 3.18. ALGORITHM FOR DIAGNOSTIC APPROACH OF INFANTS BORN TO MOTHERS WITH REACTIVE SEROLOGIC TESTS FOR SYPHILIS

RPR indicates rapid plasma reagin; VDRL, Venereal Disease Research Laboratory.

^a*Treponema pallidum* particle agglutination (TP-PA) (which is the preferred treponemal test) or fluorescent treponemal antibody absorption (FTA-ABS).

^bTest for human immunodeficiency virus (HIV) antibody. Infants of HIV-infected mothers do not require different evaluation or treatment for syphilis.

^cA fourfold change in titer is the same as a change of 2 dilutions. For example, a titer of 1:64 is fourfold greater than a titer of 1:16, and a titer of 1:4 is fourfold lower than a titer of 1:16. When comparing titers, the same type of nontreponemal test should be used (eg, if the initial test was an RPR, the follow-up test should also be an RPR).

^dStable VDRL titers 1:2 or less or RPR 1:4 or less beyond 1 year after successful treatment are considered low serofast.

^eComplete blood cell (CBC) and platelet count; cerebrospinal fluid (CSF) examination for cell count, protein, and quantitative VDRL; other tests as clinically indicated (eg, chest radiographs, long-bone radiographs, eye examination, liver function tests, neuroimaging, and auditory brainstem response). For neonates, pathologic examination of the placenta or umbilical cord with specific fluorescent antitreponemal antibody staining, if possible.

long-bone radiographs can further support the diagnosis. Neonates known to be exposed to syphilis at delivery should not have delayed bathing.¹

Evaluation of Infants >1 Month of Age and Children. For the infant or child identified as having reactive serologic tests for syphilis, the birthing parent's serologic test results and records should be reviewed to assess whether the infant or child has congenital or acquired syphilis. Evaluation for congenital syphilis after 1 month of age includes: (1) CSF analysis for VDRL, cell count, and protein; (2) complete blood cell count with differential and platelet count; (3) if clinically indicated, long-bone radiographs, chest radiograph, liver function tests, ophthalmologic examination, neuroimaging, and auditory brain-stem response); and (4) testing for HIV infection.

TREATMENT²: Parenteral penicillin G is the preferred drug for treatment of syphilis at any stage. The type and duration of penicillin G therapy varies depending on the stage of disease and clinical manifestations. Parenteral penicillin G is the only documented effective therapy for patients who have neurosyphilis, congenital syphilis, or syphilis during pregnancy and also is recommended for people with HIV.

Penicillin Allergy. Infants and children with a history of penicillin allergy or who develop presumed penicillin allergy during treatment should be desensitized and then treated with penicillin whenever possible. Data to support the use of alternatives to penicillin are limited, but options for nonpregnant patients who are allergic to penicillin may include doxycycline, tetracycline, and ceftriaxone. Ceftriaxone also can be considered as an alternative therapy for neurosyphilis. These therapies should be used with close clinical and laboratory follow-up to ensure expected serologic response and cure. In pregnant people with penicillin allergy, desensitization and treatment with doses of intramuscular penicillin G benzathine, guided by the stage of syphilis diagnosed, is the only appropriate therapy. Erythromycin and azithromycin, which have been suggested as extended-course alternatives in nonpregnant adults with penicillin allergy, are not appropriate for treatment in pregnancy because they may suboptimally treat the pregnant person and will not cross the placenta adequately to treat the fetus. Similarly, doxycycline is not appropriate for use in the second and third trimesters of pregnancy.

Congenital Syphilis: Newborn Period to 1 Month of Age. The management of congenital syphilis is based on whether the infant has proven or probable congenital syphilis, has possible congenital syphilis, or is considered less likely or unlikely to have syphilis, as detailed in Fig 3.18 and Table 3.72. If more than 1 day of therapy is missed, the entire course should be restarted. Data supporting use of other antimicrobial agents (eg, ampicillin) for treatment of congenital syphilis are not available. When possible, a full 10-day course of penicillin is preferred, even if ampicillin initially was provided for possible sepsis. Use of agents other than penicillin requires close serologic follow-up to assess adequacy of therapy. Expert advice for evaluation and management of neonates, infants, or children with suspected or confirmed congenital syphilis is available within 1 to 5 business days from the National Network of STD Clinical Prevention Training Centers (NNPTC) STD Clinical Consultation Network, which is supported by the CDC Division of STD Prevention, at www.stdccn.org.

Table 3.72. Evaluation and Treatment of Infants Up To 1 Month of Age With Possible, Probable, or Confirmed Congenital Syphilis^a

Category	Findings	Recommended Evaluation	Treatment
Proven or highly probable congenital syphilis	Abnormal physical examination consistent with congenital syphilis	CSF analysis (CSF VDRL, cell count, and protein)	Aqueous crystalline penicillin G, 50 000 U/kg, IV, every 12 hours (1 wk or younger), then every 8 h for infants older than 1 wk, for a total of 10 days of therapy ^b (preferred)
	OR	CBC with differential and platelet count	
	A serum quantitative nontreponemal serologic titer fourfold (or greater) higher than the birthing parent's titer at delivery (eg, maternal titer = 1:2, neonatal titer $\geq$ 1:8; or maternal titer = 1:8, neonatal titer $\geq$ 1:32)	Long-bone radiography	OR
	OR	Other tests (as clinically indicated): Chest radiography Aminotransferases Neuroimaging Ophthalmologic examination Auditory brain stem response	Penicillin G procaine, 50 000 U/kg, IM, as single daily dose for 10 days
	A positive result of darkfield test or PCR assay of lesions or body fluid(s)	HIV testing	

Table 3.72. Evaluation and Treatment of Infants *Up To 1 Month of Age* With Possible, Probable, or Confirmed Congenital Syphilis,^a continued

Category	Findings	Recommended Evaluation	Treatment
Possible congenital syphilis	Normal infant examination AND A serum quantitative nontreponemal serologic titer less than fourfold the birthing parent's titer at delivery (eg, maternal titer = 1:8, neonatal titer ≤1:16) AND ONE OF THE FOLLOWING: Birthing parent was not treated, was inadequately treated, or had no documentation of receiving treatment; OR Birthing parent was treated with a regimen other than recommended in the guideline (ie, a nonpenicillin G regimen) OR Birthing parent received recommended regimen but treatment was initiated <30 days before delivery	CSF analysis (CSF VDRL, cell count, and protein) CBC with differential and platelet count Long-bone radiography	Aqueous crystalline penicillin G, 50 000 U/kg, IV, every 12 h (1 wk or younger), then every 8 h for infants older than 1 wk, for a total of 10 days of therapy ^b (preferred) OR Penicillin G procaine, 50 000 U/kg, IM, as single daily dose for 10 days OR Penicillin G benzathine, 50 000 U/kg, IM, single dose (recommended by some experts, but only if all components of the evaluation are obtained and are normal ^c and follow-up is certain)

Table 3.72. Evaluation and Treatment of Infants *Up To 1 Month of Age* With Possible, Probable, or Confirmed Congenital Syphilis,^a continued

Category	Findings	Recommended Evaluation	Treatment
Congenital syphilis less likely	Normal infant examination	Not recommended	Penicillin G benzathine, 50 000 U/kg, IM, single dose (preferred)
	AND		
	A serum quantitative nontreponemal serologic titer less than fourfold the birthing parent's titer at delivery (eg, maternal titer = 1:8, neonatal titer ≤1:16)		Alternatively, infants whose birthing parent's nontreponemal titers decreased at least fourfold after appropriate therapy for early syphilis or remained stable at low titer (eg, VDRL ≤1:2; RPR ≤1:4) may be followed every 2–3 mo without treatment until the nontreponemal test becomes nonreactive
	AND		
	Birthing parent was treated during pregnancy, treatment was appropriate for stage of infection, and treatment was initiated ≥30 days before delivery		Nontreponemal antibody titers should decrease by 3 mo of age and should be nonreactive by 6 mo of age; patients with increasing titers or with persistent stable titers 6 to 12 mo after initial treatment should be reevaluated, including a CSF examination, and treated with a 10-day course of parenteral penicillin G, even if they were treated previously
	AND		
	Birthing parent has no evidence of reinfection or relapse		

Table 3.72. Evaluation and Treatment of Infants Up To 1 Month of Age With Possible, Probable, or Confirmed Congenital Syphilis,^a continued

Category	Findings	Recommended Evaluation	Treatment
Congenital syphilis is unlikely	Normal infant examination	Not recommended	None, but infants with reactive nontreponemal tests should be followed serologically to ensure test result returns to negative
	AND		
	A serum quantitative nontreponemal serologic titer less than fourfold the birthing parent’s titer at delivery		
	AND		
	Birthing parent was treated adequately before pregnancy		
	AND		
	Birthing parent’s nontreponemal serologic titer remained low and stable (ie, serofast) before and during pregnancy and at delivery (eg, VDRL ≤1:2 or RPR ≤1:4)		Penicillin G benzathine, 50 000 U/kg, IM, single dose can be considered if follow-up is uncertain and infant has a reactive test (some experts)
			Neonates with a negative nontreponemal test result at birth and whose birthing parent was seroreactive at delivery should be retested at 3 mo to rule out incubating congenital syphilis

CBC indicates complete blood cell count; CSF, cerebrospinal fluid; IM, intramuscularly; IV, intravenously; PCR, polymerase chain reaction; RPR, rapid plasma reagin VDRL, Venereal Disease Research Laboratory.

Adapted and modified from Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines, 2021. *MMWR Recomm Rep.* 2021;70(RR-4):52-54.

^aFor treatment of infants ≥1 month of age with congenital syphilis, see text on p 832.

^bIf 24 hours or more of therapy is missed, the entire course must be restarted.

^cIf CSF is not obtained or uninterpretable (eg, bloody tap), a 10-day course is recommended.

Congenital Syphilis: Infants ≥ 1 Month of Age and Children. Infants older than 1 month who possibly have congenital syphilis and children older than 2 years who have late and previously untreated congenital syphilis should be treated with intravenous aqueous crystalline penicillin (200 000–300 000 U/kg/day, intravenously, administered as 50 000 U/kg, every 4–6 hours for 10 days). Some experts suggest giving such patients a single dose of penicillin G benzathine (50 000 U/kg, intramuscularly, not to exceed 2.4 million U) after the 10-day course of intravenous aqueous crystalline penicillin. If the patient has no clinical manifestations of disease, the CSF examination is normal, and the CSF-VDRL test result is negative, some experts would treat with 3 weekly doses of penicillin G benzathine (50 000 U/kg, intramuscularly, not to exceed 2.4 million U).

Congenital Syphilis: Penicillin Shortage. During periods when the availability of aqueous crystalline penicillin G is compromised, check local sources for aqueous crystalline penicillin G (potassium or sodium) and notify the CDC and US Food and Drug Administration of the limited supply. Information on current drug shortages in the United States can be found at www.ashp.org/shortages.

For infants with proven or highly probable congenital syphilis, if intravenous penicillin G is limited, then substitution of some or all daily doses with penicillin G procaine (50 000 U/kg/dose intramuscularly a day in a single daily dose for 10 days), if available, can be used; as of July 2023, however, penicillin G procaine production in the United States has been discontinued by the manufacturer. If aqueous crystalline penicillin G or penicillin G procaine is not available, ceftriaxone (50 to 75 mg/kg/day intravenously every 24 hours) can be considered with careful clinical and serologic follow-up and in consultation with a pediatric infectious diseases specialist, as evidence is insufficient to support the use of ceftriaxone for the treatment of congenital syphilis. In neonates ≤ 28 days of age, ceftriaxone is contraindicated if they have hyperbilirubinemia or if they require treatment with calcium-containing intravenous solutions because of the risk of precipitation of ceftriaxone-calcium.

For term infants with possible congenital syphilis or in whom congenital syphilis is less likely, penicillin G procaine (50 000 U/kg/dose intramuscularly in a single daily dose for 10 days) or penicillin G benzathine (50 000 U/kg intramuscularly as a single dose) should be used. If any part of the evaluation for congenital syphilis is abnormal or was not performed, CSF examination is not interpretable, or follow-up is uncertain, penicillin G procaine is recommended. A single dose of ceftriaxone is inadequate therapy.

For preterm infants with possible congenital syphilis or in whom congenital syphilis is less likely, who might not tolerate intramuscular injections because of decreased muscle mass, intravenous ceftriaxone can be considered with careful clinical and serologic follow-up and in consultation with a pediatric infectious diseases specialist; ceftriaxone dosing must be adjusted according to birth weight, and has the contraindications listed above for jaundice or if calcium-containing intravenous solutions are being administered concomitantly.

Syphilis in Pregnancy. Regardless of stage of pregnancy, pregnant people should be treated with penicillin according to the dosage schedules appropriate for the stage of syphilis as recommended for nonpregnant patients (see Table 3.73). Nonpenicillin treatment of syphilis during pregnancy cannot be considered reliable to cure infection in the pregnant person and will not cross the placenta adequately to ensure fetal treatment.

Acquired Primary, Secondary, Early Latent Syphilis; Late Latent Syphilis; Tertiary Syphilis; and Neurosyphilis. Treatment recommendations for children and adults are detailed in Table 3.73.

Table 3.73. Recommended Treatment for Acquired Primary, Secondary, Early Latent Syphilis; Late Latent Syphilis; Tertiary Syphilis; and Neurosyphilis^a

Status	Children	Adults
Primary, secondary, and early latent syphilis^b	Penicillin G benzathine, 50 000 U/kg, IM, up to the adult dose of 2.4 million U in a single dose	Penicillin G benzathine, 2.4 million U, IM, in a single dose
		OR
	<i>If allergic to penicillin and not pregnant,</i> Doxycycline, 4.4 mg/kg divided in 2 doses, max 200 mg per day, orally, twice a day for 14 days	<i>If allergic to penicillin,</i> Doxycycline, 100 mg, orally, twice a day for 14 days (avoid in the second and third trimesters of pregnancy)
	OR	OR
Late latent syphilis^d	Tetracycline, 25–50 mg/kg divided in 4 doses, max 2 g per day, orally, for 14 days (for age ≥8 years)	Tetracycline, 500 mg, orally, 4 times/day for 14 days (avoid in the second and third trimesters of pregnancy)
		OR
	Penicillin G benzathine, 50 000 U/kg, IM, up to the adult dose of 2.4 million U, administered as 3 single doses at 1-wk intervals (total 150 000 U/kg, up to the adult dose of 7.2 million U)	Ceftriaxone, 1 g daily either IM or IV for 10 days
	<i>If allergic to penicillin and not pregnant,</i> Doxycycline, 4.4 mg/kg divided in 2 doses, max 200 mg per day, orally, twice a day for 4 wk	Penicillin G benzathine, 7.2 million U total, administered as 3 doses of 2.4 million U, IM, each at 1-wk intervals; pregnant people who have delays in any dose of therapy beyond 9 days between doses should repeat the full course of therapy
		OR
		<i>If allergic to penicillin,</i> Doxycycline, 100 mg, orally, twice a day for 4 wk (avoid in the second and third trimesters of pregnancy)
		OR
		Tetracycline, 500 mg, orally, 4 times/day for 4 wk (avoid in the second and third trimesters of pregnancy)

Table 3.73. Recommended Treatment for Acquired Primary, Secondary, Early Latent Syphilis; Late Latent Syphilis; Tertiary Syphilis; and Neurosyphilis,^a continued

Status	Children	Adults
	OR	
	Tetracycline, 25–50 mg/kg divided in 4 doses, max 2 g per day, orally, for 4 wk (for age ≥8 years)	
Tertiary	...	Penicillin G benzathine, 7.2 million U total, administered as 3 doses of 2.4 million U, IM, at 1-wk intervals <i>If allergic to penicillin and not pregnant, consult an infectious diseases expert</i>
Neurosyphilis ^e	Aqueous crystalline penicillin G, 200 000–300 000 U/kg/day, IV, administered as 50 000 U/kg every 4–6 h or as a continuous infusion for 10–14 days, in doses not to exceed the adult dose	Aqueous crystalline penicillin G, 18–24 million U per day, administered as 3–4 million U, IV, every 4 h or as a continuous infusion for 10–14 days ^f OR Penicillin G procaine, ^e 2.4 million U, IM, once daily PLUS probenecid, 500 mg, orally, 4 times/day, both for 10–14 days ^f OR <i>If allergic to penicillin,</i> Ceftriaxone, 1–2 g daily either IM or IV for 10–14 days

IM indicates intramuscularly; IV, intravenously.
^aExcludes patients with either early or late recognition of congenital syphilis.
^bEarly latent syphilis is defined as being acquired within the preceding year.
^cPenicillin G benzathine and penicillin G procaine are approved for intramuscular administration only.
^dLate latent syphilis is defined as syphilis beyond 1 year's duration.
^ePatients who are allergic to penicillin should be desensitized.
^fPenicillin G benzathine, 2.4 million U, IM, once per week for up to 3 weeks after completion of these neurosyphilis treatment regimens can be considered.

Other Considerations.

- Outside of the neonatal period, all patients with syphilis should be tested for other sexually transmitted infections (STIs), including *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, HIV, hepatitis B, and hepatitis C. Patients who have syphilis should be retested for HIV infection after 3 months if the first HIV test result is negative. Immunization status for hepatitis B and HPV should be reviewed and vaccines should be administered if not up to date.
- All recent sexual contacts of people with acquired syphilis should be evaluated for other STIs as well as syphilis (see Control Measures, p 841).
- Children with acquired primary, secondary, or latent syphilis should be evaluated for possible sexual assault or abuse (see Sexual Assault and Abuse in Children and Adolescents/Young Adults, p 182).

Follow-up and Management.

Congenital Syphilis. All infants who have reactive serologic tests for syphilis or were born to a person who was seroreactive at delivery should receive careful follow-up evaluations during well-child care visits at 2, 4, 6, and 12 months of age. Serologic nontreponemal tests should be performed every 2 to 3 months until the test becomes nonreactive. Nontreponemal antibody titers typically decrease by 3 months of age and should be nonreactive by 6 months of age, whether the infant was infected and adequately treated or was not infected and initially seropositive because of transplacentally acquired maternal antibody. The serologic response after therapy may be slower for infants treated after the neonatal period. Patients with increasing titers or with persistent stable titers 6 to 12 months after initial treatment should be reevaluated, including a CSF examination. Retreatment with a 10-day course of parenteral penicillin G may be indicated, even if they were treated previously. Neonates with a negative nontreponemal test at birth whose birthing parent was seroreactive at delivery should be retested at 3 months to rule out incubating congenital syphilis.

Treponemal tests should not be used to evaluate treatment response, because results can remain positive despite effective therapy. Transplacentally acquired treponemal antibodies can persist in an infant until 15 months of age. A reactive treponemal test after 18 months of age is diagnostic of congenital syphilis and should be followed by evaluation and, if necessary, treatment for congenital syphilis. If the treponemal test is nonreactive at this time, no further evaluation or treatment is necessary.

Neonates whose initial CSF evaluations are abnormal do not need repeat lumbar puncture unless they exhibit persistent nontreponemal serologic test titers at age 6 to 12 months. After 2 years of follow-up, a reactive CSF VDRL test or abnormal CSF indices that cannot be attributed to another ongoing illness at the 6-month interval are indications for retreatment.

Acquired Syphilis. People with acquired primary or secondary syphilis should have clinical and serologic evaluations at 6 and 12 months after treatment. More frequent evaluation might be necessary if adherence to follow-up or reinfection is a concern. If signs or symptoms persist or recur, or a fourfold or greater increase in nontreponemal titers occurs, treatment failure or reinfection may be responsible. CSF analysis, HIV testing, and retreatment based on CSF findings are indicated. Failure of nontreponemal titers to decline fourfold within 6 to 12 months may also indicate treatment failure.

Following treatment, people with acquired latent syphilis should have serologic evaluation at 6, 12, and 24 months after treatment; people with HIV should

have serologic testing at 3, 6, 9, 12, and 24 months. Patients should experience a fourfold or greater decline in nontreponemal titers within 12 to 24 months. If titers increase at least fourfold or initial high titers fail to fall fourfold, or symptoms of syphilis develop, reevaluation, including a CSF examination, is warranted. Additional guidance can be found in the current CDC guidelines for the management of STIs.¹

Patients with neurosyphilis associated with acquired syphilis must have periodic serologic testing and clinical evaluation at 6-month intervals. Among immunocompetent persons and persons with HIV who are receiving effective antiretroviral treatment, normalization of the serum RPR titer predicts normalization of abnormal CSF parameters after neurosyphilis treatment, and repeated CSF examinations are not necessary. CSF abnormalities may persist for extended periods of time in people with combined HIV and neurosyphilis infections.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended for all patients, including infants with suspected or proven congenital syphilis. Because moist open lesions, secretions, and possibly blood are contagious in all patients with syphilis, gloves should be worn when caring for patients with congenital, primary, and secondary syphilis with skin and mucous membrane lesions until 24 hours of treatment has been completed.

CONTROL MEASURES:

- All recent sexual contacts of a person with acquired syphilis should be identified, examined, serologically tested, and treated as needed. Sexual contacts of people with primary, secondary, or early latent syphilis exposed within the preceding 90 days may be infected even if seronegative and should be treated for early-acquired syphilis. Sexual contacts exposed >90 days previously who have negative serologic tests do not require treatment; however, contacts should be treated presumptively if serologic test results are not available immediately and follow-up is uncertain. For identification of at-risk sexual partners, the periods before treatment are as follows: (1) 3 months plus duration of symptoms for primary syphilis; (2) 6 months plus duration of symptoms for secondary syphilis; and (3) 1 year for early latent syphilis.
- All people who have had close unprotected contact with a patient with early congenital syphilis before identification of the disease or during the first 24 hours of therapy should be examined clinically for the presence of lesions 2 to 3 weeks after contact. Serologic testing should be performed and repeated 3 months after contact or sooner if symptoms occur. If the degree of exposure is considered substantial, immediate treatment should be considered.
- Doxycycline, 200 mg, administered within 24 to 72 hours of condomless sex (doxy-PEP) has been shown in studies to reduce the incidence of syphilis, chlamydia, and gonorrhea among cisgender men who have sex with men (MSM) and transgender women with a recent history of these infections.

Public Health Reporting. Congenital syphilis is a nationally notifiable disease in the United States.

¹ Centers for Disease Control and Prevention. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(RR-4):1-187

Tapeworm Diseases

(Taeniasis and Cysticercosis)

CLINICAL MANIFESTATIONS:

Taeniasis. Infection with adult tapeworms often is asymptomatic. The most common sign is noting tapeworm segments passing from the anus or in feces. Other mild gastrointestinal tract symptoms, such as nausea or diarrhea, can occur.

Cysticercosis. Cysticercosis, caused by larval pork tapeworm (*Taenia solium*) infection, can have serious consequences. Manifestations depend on the location and number of pork tapeworm larval cysts (cysticerci) and on the host response. Cysticerci may be found anywhere in the body. The most common and serious clinical manifestations are caused by cysticerci in the central nervous system. Larval cysts of *T solium* in the brain (neurocysticercosis) can result in seizures, headache, obstructive hydrocephalus, and other neurologic signs and symptoms. Neurocysticercosis is the leading infectious cause of epilepsy in low- and middle-income countries. Most symptoms result from the host reaction to degenerating cysticerci. Cysts in the spinal column can cause gait disturbance, pain, or transverse myelitis. Subcutaneous cysticerci produce palpable nodules, and ocular involvement can cause visual impairment.

ETIOLOGY: Taeniasis is caused by intestinal infection by the adult tapeworm, *Taenia saginata* (beef tapeworm) or *T solium* (pork tapeworm). *Taenia asiatica* causes taeniasis in Asia. Human cysticercosis is caused only by the larvae of *T solium*.

EPIDEMIOLOGY: Tapeworm diseases have worldwide distribution. Prevalence is high in areas with poor sanitation and human fecal contamination in areas where cattle graze or swine are fed. Most cases of *T solium* infection in the United States are imported from Latin America, although the disease is prevalent in parts of Asia and sub-Saharan Africa as well. *T saginata* infection occurs at high rates in East Africa and the Middle East and also is prevalent in Latin America, much of Asia, and eastern Europe. *T asiatica* is common in China, Taiwan, and Southeast Asia. Taeniasis is acquired by eating undercooked beef (*T saginata*), pork (*T solium*), or pig viscera (*T asiatica*) that contain encysted larvae.

Cysticercosis in humans is acquired by ingesting eggs of the pork tapeworm (*T solium*). Transmission is fecal-oral from a person harboring the adult tapeworm — for example, eating food or drinking water contaminated with pork tapeworm eggs from an infected person. Studies in endemic areas show household clustering, suggesting increased risk of exposure for those residing with or near tapeworm carriers. Autoinfection, in which tapeworm carriers infect themselves, also occurs. Humans are the obligate definitive host and the only host to shed eggs. Pigs act as an intermediate host, developing cysts upon acquisition of eggs from human stool contaminating their feeding, and developing cysts in their muscles. Humans who eat undercooked pork swallow cysts in the meat, and larvae come out of these cysts to complete the infection cycle. Eating of undercooked infected pork does not directly cause cysticercosis, but can spread cysticercosis through release of eggs from an infected person and can lead to cysticercosis in the person who eats the undercooked pork through autoinfection. Eggs liberate oncospheres in the intestine that migrate through the blood and lymphatics to tissues throughout the body, including the central nervous system,

where the oncospheres develop into cysticerci. Although nearly all cases of cysticercosis in the United States are imported, cysticercosis can be acquired in the United States from tapeworm carriers who emigrated from an area with endemic infection and still have *T solium* intestinal-stage infection. *T saginata* and *T asiatica* do not cause cysticercosis.

The **incubation period** for taeniasis (the time from ingestion of the larvae until segments are passed in the feces) is 2 to 3 months. For cysticercosis, the **incubation period** between infection and onset of symptoms is typically several years.

DIAGNOSIS¹: Diagnosis of taeniasis (adult tapeworm infection) is based on demonstration of the proglottids or ova in feces or the perianal region, although these techniques are insensitive, so 3 tests on different days are recommended for evaluation. Antigen detection, nucleic acid tests, and immunoblot assays for tapeworm stage-specific antibody are more sensitive but are not commercially available. Species identification of the parasite is based on the different structures of gravid proglottids and scolex or on a nucleic acid amplification test (NAAT).

Diagnosis of neurocysticercosis typically depends on clinical presentation and imaging of the central nervous system. Serologic testing also can be helpful in certain cases. Computed tomography (CT) scanning or magnetic resonance imaging (MRI) of the brain or spinal cord are used to demonstrate lesions compatible with cysticerci. CT scans are helpful in identifying calcifications. MRI is better at identifying extra-parenchymal cysts (eg, in ventricles or the subarachnoid space) and the invaginated scolex within the parasite cysticercus. Antibody assays that detect specific antibodies to larval *T solium* in serum can be useful to confirm the diagnosis. Commercially available antibody tests that use crude antigen in an enzyme-linked immunosorbent assay (ELISA) format lack adequate sensitivity and specificity and are not reliable diagnostic techniques. In the United States, immunoblot assays (including the Enzyme-linked ImmunoTransfer Blot [EITB]) are available through the Centers for Disease Control and Prevention and a few commercial laboratories and are the antibody tests of choice. In general, immunoblot assays are more sensitive with serum specimens than with cerebrospinal fluid specimens. Even immunoblot tests can have limited sensitivity if only 1 cysticercus or only calcified cysticerci are present. Thus, results often are negative in children with solitary parenchymal lesions. A negative serologic test result does not exclude the diagnosis of neurocysticercosis when clinical suspicion is high. A serologic test result could be positive in patients who have *T solium* cysticerci in parts of the body other than the central nervous system. Antigen-detection assays are available commercially in Europe. NAATs have been used in diagnosis and follow-up of selected cases. Antigen-detection and NAATs are available from the National Institutes of Health for selected cases.

TREATMENT¹:

Taeniasis. Praziquantel is highly effective for eradicating infection with the adult tapeworm (see Drugs for Parasitic Infections, p 1068). Praziquantel is not approved for this indication, but dosing recommendations are available for children 4 years and older.

¹ White AC Jr, Coyle CM, Rajshekhar V, et al. Diagnosis and treatment of neurocysticercosis: 2017 clinical practice guidelines by the Infectious Diseases Society of America (IDSA) and the American Society of Tropical Medicine and Hygiene (ASTMH). *Clin Infect Dis*. 2018;66(8):1159-1163

Safety is not established in children younger than 4 years, but this drug has been used successfully to treat cases of *Dipylidium caninum* infection in children as young as 6 months. Praziquantel is detected in the milk of lactating people, and people should not breastfeed on the day of treatment or during the subsequent 72 hours. Niclosamide is an alternative agent for treatment of taeniasis but is not available commercially in the United States. Albendazole has been used successfully for taeniasis in a small number of individuals and is an alternative treatment if praziquantel and niclosamide are not available.

Cysticercosis. Neurocysticercosis treatment should be individualized based on the number, location, and viability of cysticerci as assessed by neuroimaging studies (MRI and CT scan) and clinical manifestations. Symptomatic therapy is critical and should include antiseizure medications for patients with seizures and surgery for patients with hydrocephalus. Two antiparasitic drugs—albendazole and praziquantel—are available (see Drugs for Parasitic Infections, p 1068). Praziquantel is not approved by the US Food and Drug Administration for this indication. Both drugs are cysticercidal and hasten radiologic resolution of cysts, but symptoms resulting from host inflammatory response may be exacerbated by treatment. In symptomatic patients with a single cyst within brain parenchyma, controlled studies demonstrate that clinical resolution and seizure recurrence rates are improved slightly when children are treated with albendazole along with corticosteroids. Two studies have demonstrated that in individuals with more than 2 lesions, the response rate was better when albendazole was coadministered with praziquantel and corticosteroids. When a single agent is used, albendazole is preferred over praziquantel, because it has fewer drug-drug interactions with anticonvulsants and steroids. Patients with calcified cysts do not benefit from antiparasitic treatment. An ophthalmic examination should be performed before antiparasitic treatment to rule out intraocular cysticerci (see below). Coadministration of corticosteroids during antiparasitic therapy decreases adverse effects during treatment and is recommended for all patients with viable intraparenchymal neurocysticercosis who are treated with antiparasitic drugs, starting before antiparasitic therapy is initiated. See footnote 61 of Drugs for Parasitic Infections, p 1112, for steroid dosing. Duration of corticosteroid therapy is longer in patients with subarachnoid disease, vasculitis, or encephalitis. Arachnoiditis, vasculitis, or diffuse cerebral edema (cysticercal encephalitis) are treated with corticosteroid therapy until cerebral edema is controlled. Corticosteroids can affect tissue concentrations of albendazole. Patients requiring steroids may need screening for strongyloidiasis, latent tuberculosis, and vitamin D deficiency.

Medical and surgical management of cysticercosis can be highly complex and often needs to be conducted in consultation with a neurologist or neurosurgeon and an infectious diseases or other specialist with experience treating neurocysticercosis. Seizures may recur for months or years. Anticonvulsant therapy is recommended until there is neuroradiologic evidence of resolution and seizures have not occurred for 6 months (for a single lesion) or 2 years (for multiple lesions). Calcification of cysts may require prolonged or indefinite use of anticonvulsants. Subarachnoid cysticercosis does not respond well to the regimens used for parenchymal disease and generally should be treated with prolonged courses of antiparasitic and anti-inflammatory medications, monitoring radiologic resolution and NAAT or antigen assay results. Methotrexate and/or tumor necrosis factor inhibitors have been used as steroid-sparing agents. Intraventricular cysticerci and hydrocephalus usually should be treated surgically. Surgical removal of

intraventricular cysticerci is the treatment of choice when possible and often can be accomplished by endoscopic surgery (lateral, third, and sometimes fourth ventricles) or open surgery (fourth ventricle). If cysticerci cannot be removed, hydrocephalus should be corrected with placement of intraventricular shunts. Adjunctive chemotherapy with antiparasitic agents and corticosteroids may decrease the rate of subsequent shunt failure. Ocular cysticercosis is treated by surgical excision of the cysticerci. Ocular cysticercosis generally is not treated with anthelmintic drugs, which can exacerbate inflammation. Spinal cysticercosis may be treated with medical and/or surgical therapy as there is not adequate evidence to guide the choice of therapy.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: Eating raw or undercooked beef or pork should be avoided. Whole cuts of meat should be cooked to at least 145°F (63°C) and then allowed to rest for 3 minutes before consuming, and ground meat and wild game meat should be cooked to at least 160°F (71°C). Freezing pork or beef below -5°C (23°F) for more than 4 days kills cysticerci. People known to harbor the adult tapeworm of *T solium* should be treated immediately. Careful attention to hand hygiene and appropriate disposal of fecal material are important preventive measures. People traveling to resource-limited countries with high endemic rates of cysticercosis should avoid eating uncooked vegetables and fruits that cannot be peeled. If someone in a household is found to have cysticercosis, household members should be screened for taeniasis (see Diagnosis), and people with compatible neurologic signs and symptoms should be evaluated for cysticercosis.

Other Tapeworm Infections

(Including Hydatid Disease)

Most intestinal tapeworm (cestode) infections are asymptomatic, but nausea, abdominal pain, and diarrhea have been observed in people who are heavily infected.

ETIOLOGIES, DIAGNOSIS, AND TREATMENT

Hymenolepis nana. This tapeworm, also called the dwarf tapeworm because it is the smallest of the adult human tapeworms (about 3 to 4 cm long), can complete its entire life cycle within humans. Transmission occurs by inadvertent ingestion of eggs present in feces of infected people or rarely by ingestion of infected arthropods (certain species of beetles and fleas) present in food. Autoinfection, in which eggs can hatch within the intestine and reinitiate the life cycle, leads to development of new worms and increases the worm burden. Most infections are asymptomatic. Young children may develop abdominal cramps, diarrhea, and anemia with heavy infection. Anal pruritus and difficulty sleeping mimic pinworm infections. Diagnosis is by identification of the characteristic eggs in stool. Praziquantel is the treatment of choice, with nitazoxanide as an alternative drug; niclosamide is another therapeutic option but is not available commercially in the United States (see Drugs for Parasitic Infections, p 1068). Praziquantel and nitazoxanide are not approved for this indication, but these drugs have been used safely and effectively in children as young as 6 months (praziquantel) and 1 year (nitazoxanide) for other indications. Stools should be reexamined 1 month after treatment to document cure. If infection persists, retreatment with praziquantel is indicated.

Dipylidium caninum. This is the most common tapeworm of dogs and cats and has a wide geographic distribution. Children develop infection with *D caninum* after inadvertently swallowing a dog or cat flea (the intermediate host). Most cases are asymptomatic and come to attention when motile proglottids are passed in stool. Some children have abdominal pain, diarrhea, and anal pruritus. Diagnosis is made by finding the characteristic eggs or motile proglottids in stool. Proglottids resemble rice kernels and may be mistaken for maggots (fly larvae) or pinworms. Infection is self-limiting in the human host and typically clears spontaneously by 6 weeks. Therapy with praziquantel is effective. Niclosamide is an alternative therapeutic option but is not available commercially in the United States (see Drugs for Parasitic Infections, p 1068). Praziquantel and niclosamide are not approved for this indication. These drugs have been used safely and effectively in children as young as 6 months (praziquantel) and 2 years (niclosamide) (www.cdc.gov/parasites/dipylidium/health_professionals/index.html).

Diphyllobothriid species (*Dibothriocephalus* and Related Species). These are the largest tapeworms that infect humans and are also known as fish tapeworm or broad tapeworm. Fish are intermediate hosts of the diphyllobothriid tapeworms, which were previously all known as *Diphyllobothrium* species. Consumption of infected raw or undercooked freshwater (including trout and pike), saltwater (at least 17 species including one shark), or anadromous (salmon) fish may lead to infection with these tapeworms. Three to 6 weeks after ingestion, the adult tapeworm matures and begins to lay eggs. The most common symptom is the passage of proglottids. Abdominal pain and diarrhea may occur. The worm rarely may cause mechanical obstruction of the bowel or gallbladder, diarrhea, or abdominal pain. Megaloblastic anemia secondary to vitamin B₁₂ deficiency has been noted only with the species *Dibothriocephalus latus* (formerly *Diphyllobothrium latum*) found in trout and pike in northern Europe and North America. Other common species include *Dibothriocephalus nihonkaiense*, found in salmon in Northeast Asia (Japan, Korea) and the North Pacific of North America, and *Adenocephalus pacificus*, found in marine fish off the Pacific coast of South America. Diagnosis is made by recognition of the characteristic proglottids or eggs passed in stool. Therapy with praziquantel is effective; niclosamide is an alternative but is not available commercially in the United States (see Drugs for Parasitic Infections, p 1068). Praziquantel and niclosamide are not approved for this indication. These drugs have been used safely and effectively in children as young as 6 months (praziquantel) and 2 years (niclosamide).

Echinococcus granulosus and Echinococcus multilocularis.¹ The larval forms of these tapeworms cause human echinococcosis. *Echinococcus granulosus* causes the disease cystic echinococcosis, also known as hydatid disease. The distribution of *E granulosus* is related to areas where sheep or cattle are raised and dogs, the definitive host, are used for herding. Areas of high prevalence include parts of South America, East Africa, Eastern Europe, the Middle East, the Mediterranean region, China, and Central Asia. The parasite also is endemic in Australia and New Zealand. In the United States, small foci of endemic transmission have been reported in Arizona, California, New Mexico, and Utah, and a strain of the parasite has adapted to wolves, moose, and caribou in Alaska, northern New England, and Canada. Dogs, coyotes, wolves, dingoes, and

¹ Brunetti E, Kern P, Vuitton DA; Writing Panel for the WHO-Informal Working Group on Echinococcosis. Expert consensus for the diagnosis and treatment of cystic and alveolar echinococcosis in humans. *Acta Trop*. 2010;114(1):1-16

jackals can become infected by swallowing protoscolices of the parasite within hydatid cysts in the organs of slaughtered sheep or other intermediate hosts. Dogs pass embryonated eggs in their feces, and humans become infected by ingesting the viable parasite eggs. Humans then develop cysts in various organs, such as the liver, lungs, kidneys, and spleen. Cysts caused by larvae of *E granulosus* usually grow slowly (1 cm in diameter per year in the liver) and eventually can contain several liters of fluid. If a cyst ruptures, anaphylaxis and multiple secondary cysts from seeding of protoscolices can result. Clinical diagnosis often is difficult. A history of contact with dogs in an area with endemic infection is helpful. Cystic lesions can be demonstrated by radiography, ultrasonography, or computed tomography of various organs. Serologic testing is helpful, but false-negative results occur. Treatment depends on ultrasonographic staging and may include antiparasitic therapy, PAIR (puncture, aspiration, injection of protoscolicidal agents, and reaspiration), surgical excision, or no treatment but with watchful waiting. Optimal therapy varies with the location, size, and stage of the parasite (www.cdc.gov/parasites/echinococcosis/health_professionals/index.html#tx). Small cysts in the liver may respond to antiparasitic drugs alone. For larger, uncomplicated liver cysts, treatment of choice is PAIR. Contraindications to PAIR include communication of the cyst with the biliary tract (eg, bile staining after initial aspiration), superficial cysts, and heavily septated cysts. Surgical therapy is indicated for complicated cases and requires meticulous care to prevent spillage, including preparations such as soaking of surgical drapes in hypertonic saline. In general, the cyst should be removed intact, because leakage of contents is associated with a higher rate of complications, including anaphylactic reactions to cyst contents. Treatment with albendazole (or mebendazole) alone or with praziquantel generally should be initiated days to weeks before surgery or PAIR and continued for several weeks to months thereafter (see Drugs for Parasitic Infections, p 1068). Degenerating cysts can be managed by watchful waiting with follow-up imaging studies. For lung lesions, small cysts often resolve with antiparasitic drugs alone. Larger cysts are best removed surgically. Many surgeons prefer to avoid preoperative antiparasitic drugs for lung cysts.

Echinococcus multilocularis, the causative agent for alveolar echinococcosis, also has definitive hosts (foxes, coyotes, other wild canines) and intermediate hosts (rodents). Alveolar echinococcosis is characterized by invasive growth of the larvae in the liver (which may mimic neoplasm) with occasional metastatic spread. Alveolar echinococcosis is limited to the Northern Hemisphere and usually is diagnosed in people 50 years or older. The disease has been reported frequently from western China and also is endemic in central Europe. More recently, a focus was identified in western Canada. Diagnosis can be confirmed by imaging and serologic testing. The preferred treatment is surgical removal of the entire larval mass followed by treatment with albendazole. In nonresectable cases, continuous treatment with albendazole has been associated with clinical improvement (see Drugs for Parasitic Infections, p 1068). Two other species, *Echinococcus vogeli* and *Echinococcus oligarthrus*, rarely infect humans; they cause polycystic echinococcosis.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: Preventive measures for *H nana* include educating the public about personal hygiene and sanitary disposal of feces.

Infection with *D caninum* is prevented by keeping dogs and cats free of fleas and worms. Children should wash their hands after playing with dogs and cats and after playing in areas soiled with pet feces.

To protect against diphyllbothriid infections, fish should be cooked thoroughly to an internal temperature of 63°C (145°F) or should be frozen per the following recommendations:

- At -4°F (-20°C) or below for 7 days (total time), or
- At -31°F (-35°C) or below until solid, and storing at -31°F (-35°C) or below for 15 hours, or
- At -31°F (-35°C) or below until solid and storing at -4°F (-20°C) or below for 24 hours.

Control measures for prevention of *E granulosus* and *E multilocularis* include educating the public about hand hygiene and avoiding exposure to dog and wild canid feces. Prevention and control of infection in dogs (preventing dogs from feeding on rodents or carcasses of sheep, treating dogs for parasitic infections) decreases the risk of subsequent human infection.

Tetanus (Lockjaw)

CLINICAL MANIFESTATIONS: Tetanus is caused by neurotoxin produced by the anaerobic bacterium *Clostridium tetani* in a contaminated wound and can manifest in 3 overlapping clinical forms: generalized, local, and cephalic.

Generalized tetanus (lockjaw) is a neurologic disease manifesting as trismus and severe muscular spasms, including risus sardonicus, which is a facial expression characterized by raised eyebrows and grinning distortion of the face resulting from spasm of facial muscles. Onset is gradual, occurring over 1 to 7 days, and symptoms progress to severe painful generalized muscle spasms, which often are aggravated by any external stimulus. Autonomic dysfunction, manifesting as diaphoresis, tachycardia, labile blood pressure, and arrhythmias, often is present. Other potential complications include fractures associated with muscle spasms, laryngospasm, pulmonary embolism, and aspiration pneumonia. Severe spasms persist for 1 week or more and subside over several weeks in people who recover. Neonatal tetanus is a form of generalized tetanus occurring in newborn infants lacking protective passive immunity because their birthing parent was not immune. Early symptoms include inability to suck or breastfeed and excessive crying that then progress to findings typical of generalized tetanus.

Local tetanus manifests as local muscle spasms in areas contiguous to a wound.

Cephalic tetanus is the rarest form of tetanus and usually causes flaccid cranial nerve palsies, although trismus can occur. It is associated with infected wounds on the head and neck including, rarely, suppurative otitis media. Local and cephalic tetanus can precede generalized tetanus.

ETIOLOGY: *C tetani* is a spore-forming, obligate anaerobic, gram-positive bacillus. This organism is a wound contaminant that causes neither tissue destruction nor an inflammatory response. The vegetative form of *C tetani* produces a potent plasmid-encoded exotoxin (tetanospasmin). The heavy chain of tetanospasmin binds to the presynaptic motor neuron and facilitates entry of the light chain, a zinc-dependent protease, into the cytosol. As a result, gamma-aminobutyric acid- and glycine-containing vesicles are not released, and inhibitory action on motor and autonomic neurons is lost.

EPIDEMIOLOGY: Tetanus occurs worldwide and is more common in warmer climates and during warmer months, in part because of higher frequency of contaminated wounds associated with those locations and seasons. The organism, a normal inhabitant of soil and animal and human intestines, is ubiquitous in the environment, especially where contamination by excreta is common. Organisms multiply in wounds, recognized or unrecognized, and elaborate toxins in the presence of anaerobic conditions. Contaminated wounds, especially wounds with devitalized tissue and deep-puncture trauma, are at greatest risk. Neonatal tetanus is common in many resource-limited countries where pregnant people are not immunized appropriately against tetanus and nonsterile practices for umbilical cord care are followed. Globally, activities are ongoing to eliminate tetanus in pregnant people and neonates by improving vaccination coverage among pregnant people and promoting safe delivery practices. In December 2020, only 12 countries had not yet achieved tetanus elimination in pregnant people and neonates; globally, the estimated burden of neonatal tetanus has declined by more than 90% since the 1980s.¹

Widespread active immunization against tetanus has modified the epidemiology of disease in the United States, where it is now rare. Tetanus is not transmissible from person to person.

In the United States, nearly all cases of tetanus occur in individuals who have never received a tetanus vaccine or who have not received their 10-year booster vaccine. At particular risk are people with immune-compromising conditions, people with diabetes mellitus, or people who use intravenous drugs.

The **incubation period** ranges from 3 to 21 days, with most cases occurring within 8 days. In general, the farther the injury site from the central nervous system, the longer the incubation period. Shorter incubation periods have been associated with more heavily contaminated wounds, more severe disease, and a worse prognosis. In neonatal tetanus, the **incubation period** from birth to onset of symptoms is usually 4 to 14 days, averaging 7 days. Cephalic tetanus may have an **incubation period** as short as 1 to 2 days.

DIAGNOSTIC TESTS: The diagnosis of tetanus is made clinically by excluding other causes of tetanic spasms, such as hypocalcemic tetany, phenothiazine reaction, strychnine poisoning, and conversion disorder. Attempts to culture *C tetani* are associated with poor yield, and a negative culture does not rule out disease. A protective serum anti-toxin concentration should not be used to exclude the diagnosis of tetanus, because tetanus disease has been known to occur rarely despite adequate antibody concentrations.

TREATMENT: Human tetanus immune globulin (TIG) binds circulating unbound toxin and prevents further progression of disease, but it does not reverse the effects of already bound toxin. A single dose of human TIG is recommended for treatment. However, the optimal therapeutic dose has not been established. Most experts recommend 500 IU, which appears to be as effective as higher doses ranging from 3000 to 6000 IU and causes less discomfort. Available preparations must be administered intramuscularly. Infiltration of part of the dose locally around the wound is recommended, although the efficacy of this approach has not been proven. Results of studies on the benefit from intrathecal administration of TIG are conflicting. The TIG preparation

¹ GBD 2019 Diseases and Injuries Collaborators. Global burden of 369 diseases and injuries in 204 countries and territories, 1990-2019: a systematic analysis for the Global Burden of Disease Study 2019. *Lancet*. 2020;396(10258):1204-1222

in use in the United States is not licensed or formulated for intrathecal or intravenous use. If TIG is not available (as is the case in some countries), immune globulin intravenous (IGIV) can be used at a dose of 200 to 400 mg/kg. IGIV is not approved by the US Food and Drug Administration for this use, and antitetanus antibody concentrations can vary from lot to lot. In some countries, equine tetanus antitoxin may be considered if TIG is not available and the patient is tested for sensitivity and desensitized as necessary. Additional management is as follows:

- All wounds should be cleaned and débrided properly, especially if extensive necrosis is present. In neonatal tetanus, wide excision of the umbilical stump is not indicated.
- Supportive care and pharmacotherapy to control tetanic spasms and autonomic instability are of major importance.
- Oral (or intravenous) metronidazole is effective in decreasing the number of vegetative forms of *C tetani* and is the antimicrobial agent of choice. Parenteral penicillin G is an alternative treatment. Therapy for 7 to 10 days is recommended.
- Active immunization against tetanus always should be undertaken during convalescence from tetanus. Because of the extreme potency of tiny amounts of toxin, tetanus disease may not result in immunity.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES:

Care of Exposed People (see Fig 3.19). Risk of tetanus disease depends on the type of wound and immune status of the patient. Depending on the clinical scenario, there are 3 potential interventions to prevent tetanus: wound care, active immunization, and passive immunization. Antimicrobial prophylaxis has not been shown to prevent tetanus and is not recommended.

- Wound care: Although any open wound is a potential source of tetanus, wounds contaminated with dirt, feces, soil, or saliva (eg, animal bites) are at increased risk. Punctures and wounds containing devitalized tissue, including necrotic or gangrenous wounds, frostbite, crush and avulsion injuries, and burns, are particularly conducive to *C tetani* infection. Wounds with devitalized tissue should be débrided and have dirt removed. It is not necessary or appropriate to débride puncture wounds extensively.
- Active immunization: Immunization status should be assessed for all wounds, and age-appropriate vaccine should be administered (see Immunization) if not contraindicated on the basis of clinical scenario (Fig 3.19). For infants younger than 6 months, prior infant doses and maternal tetanus toxoid immunization history at time of delivery should be considered in determining need for infant immunization (and need for TIG, if clinically indicated).
- Passive immunization: Patients with tetanus-prone wounds who have not completed a primary series of tetanus vaccine should be considered nonimmune and should receive passive immunization with TIG (in addition to active immunization with tetanus toxoid vaccine, as clinically appropriate). In patients with human immunodeficiency virus (HIV) or other severe immunodeficiency, TIG should be administered for tetanus-prone wounds regardless of the history of tetanus toxoid immunization. When TIG is required for wound prophylaxis, it is administered intramuscularly in a dose of 250 U (regardless of age or weight). If tetanus toxoid vaccine and TIG are administered concurrently, separate syringes and sites should be used. Administration of tetanus toxoid vaccine simultaneously with or at an interval after receipt of TIG

FIG 3.19. SUMMARY GUIDE TO TETANUS PROPHYLAXIS IN ROUTINE WOUND MANAGEMENT

¹A primary series consists of a minimum of 3 doses of tetanus- and diphtheria-containing vaccine (DTaP/DTP/Tdap/DT/Td).

²Age-appropriate vaccine:

- DTaP for infants and children 6 weeks up to 7 years of age.
- Tetanus-diphtheria (Td) toxoid for persons 7 through 9 years of age and 65 years of age and older.
- Tdap for persons 11 through 64 years of age if using Adacel* or 10 years of age and older if using Boostrix*, unless the person has received a prior dose of Tdap.*

³No vaccine or TIG is recommended for infants younger than 6 weeks of age with clean, minor wounds. (And no vaccine is licensed for infants younger than 6 weeks of age.)

⁴Tdap* is preferred for persons 11 through 64 years of age if using Adacel* or 10 years of age and older if using Boostrix* who have never received Tdap. Td is preferred to tetanus toxoid (TT) for persons 7 through 9 years, 65 years and older, or who have received a Tdap previously. If TT is administered, and adsorbed TT product is preferred to fluid TT. (All DTaP/DTP/Tdap/Td products contain adsorbed tetanus toxoid.)

⁵Give TIG 250 U IM for all ages. It can and should be given simultaneously with the tetanus-containing vaccine.

⁶For infants younger than 6 weeks of age, TIG (without vaccine) is recommended for "dirty" wounds (wounds other than clean, minor).

⁷Persons who are HIV positive should receive TIG regardless of tetanus immunization history.

*Brand names are used for the purpose of clarifying product characteristics and are not an endorsement of either product. Tdap vaccines:

Boostrix (GSK) is licensed for persons 10 years of age and older.

Adacel (sanofi) is licensed for persons 11 through 64 years of age.

Courtesy of the Minnesota Department of Health (www.health.state.mn.us/diseases/tetanus/hcp/tetwdmgmt.html), with modifications.

does not impair development of protective antibody substantially. Efforts should be made to initiate active immunization and arrange for its completion.

Immunization. Antibody to tetanus toxoid is detectable 4 to 7 days after a dose of tetanus vaccine, and its concentration peaks at 2 to 4 weeks. Protective antibody is not reliably achieved following a first dose of vaccine to prevent tetanus disease. After completing a vaccination series, circulating antitoxin usually lasts at least 10 years and for a longer time after a booster dose.

Active immunization against tetanus always should be undertaken during convalescence from tetanus, because this exotoxin-mediated disease usually does not confer immunity.

Active immunization with tetanus toxoid vaccine is recommended for all people. For all appropriate indications, tetanus immunization is administered with diphtheria toxoid-containing vaccines or with diphtheria toxoid- and acellular pertussis-containing vaccines. Vaccine is administered intramuscularly and may be administered concurrently with other vaccines (see Simultaneous Administration of Multiple Vaccines, p 63). Conjugate vaccines containing tetanus toxoid (eg, *Haemophilus influenzae* type b) are not substitutes for tetanus toxoid immunization. Recommendations for use of tetanus toxoid-containing vaccines (<https://publications.aap.org/redbook/pages/Immunization-Schedules>) are as follows:

- Immunization for children from 6 weeks through 6 years (up to the seventh birthday) of age:
 - ♦ Recommended schedule: should consist of 5 doses of tetanus- and diphtheria toxoid-containing vaccine. All doses are administered as DTaP (or DTaP-containing vaccines) at 2, 4, and 6 months of age, then a dose at 15 through 18 months of age, and another dose at 4 through 6 years of age (recommended before kindergarten or elementary school entry). DTaP can be administered concurrently with other vaccines (see Simultaneous Administration of Multiple Vaccines, p 63). If a dose of Tdap is administered inadvertently instead of DTaP as any one of the primary 3 dose series, then it should not be counted as valid. DTaP can be administered at any interval after the Tdap dose and remaining DTaP doses can be administered as per the recommended schedule. If Tdap is inadvertently administered as the 4th or 5th dose in the series, the Tdap dose is counted as valid toward the 5-dose DTaP series.
 - ♦ Catch up vaccination: the 5-dose DTaP series can be administered with a minimum of 4 weeks between each of the first 3 doses and 6 months between dose 3 and 4 as well as dose 4 and 5. If the fourth dose is administered at 4 years or older, the fifth dose is not needed.
 - ♦ Pertussis vaccination contraindicated: Contraindications to DTaP and Tdap occur only very rarely, and in questioning about them providers should probe whether a true contraindication actually exists. DTaP and Tdap contraindications are limited to severe allergic reactions (eg, anaphylaxis) and encephalopathy (eg, coma, decreased level of consciousness, or prolonged seizures) not attributable to another identifiable cause within 7 days after administration of a previous dose of diphtheria and tetanus toxoids and pertussis vaccine (see Pertussis [Whooping Cough], p 656). Note that as of 2023, DT is no longer available in the United States (www.cdc.gov/vaccines/vpd/dtap-tdap-td/hcp/recommendations.html and www.cdc.gov/vaccines/vpd/dtap-tdap-td/hcp/td-offlabel.html; see Diphtheria p 357, and Pertussis p 656). For young children with a contraindication to pertussis-containing vaccines, vaccine providers may administer Td for all recommended remaining doses in place of DTaP. Td contains a lower dose (approximately 1/12th the amount) of diphtheria toxoid compared with DT. The impact of this lower dose on the protection provided against diphtheria in young children is uncertain. Available evidence suggests young children who receive Td in place of DTaP may have suboptimal protection against diphtheria.
 - ♦ Series was started with DT, but pertussis vaccination is desired and is not contraindicated: doses of DTaP should be administered to complete the recommended pertussis immunization schedule (see Pertussis, p 656); however, the total number

of doses of diphtheria and tetanus toxoid vaccines (as DT, DTaP, or DTwP) should not exceed 6 before the seventh birthday.

- Immunization for children ≥ 7 years (see <https://publications.aap.org/redbook/pages/Immunization-Schedules> and Pertussis [Whooping Cough], p 656)¹:
 - ♦ Adolescents 11 years and older should receive a single dose of Tdap instead of Td for booster immunization against tetanus, diphtheria, and pertussis. The preferred age for Tdap immunizations is 11 through 12 years of age.
 - ♦ Adolescents who received Td but not Tdap should receive a single dose of Tdap to provide protection against pertussis regardless of time since receipt of Td.
 - ♦ Simultaneous administration of Tdap and all other recommended vaccines is recommended when feasible.
 - ♦ Inadvertent administration of DTaP instead of Tdap in people 7 years and older is counted as a valid dose of Tdap.
 - ♦ Children 7 through 10 years of age who have not completed their immunization schedule with DTaP before 7 years of age or who have an unknown vaccine history should receive at least 1 dose of Tdap. If further dose(s) of tetanus and diphtheria toxoids are needed in a catch-up schedule, either Td or Tdap can be used. The preferred schedule is Tdap followed by Td or Tdap at 2 months and 6 to 12 months (if needed).
 - ♦ Children 7 through 9 years of age who receive Tdap or DTaP for any reason should receive the adolescent Tdap booster at 11 through 12 years of age.
 - ♦ A Tdap or DTaP dose received by a 10 year-old for any reason can count as the adolescent Tdap booster dose.
- If more than 5 years have elapsed since the last dose, a booster dose of a tetanus-containing vaccine should be considered for people at risk of occupational exposure in locations where tetanus boosters may not be available readily. Tdap is preferred over Td if the person has not received Tdap previously.
- Tdap is approved for use by the US Food and Drug Administration (FDA) for use in the third trimester of pregnancy to prevent pertussis in infants younger than 2 months of age. Pregnant people should receive Tdap during each pregnancy, preferably between 27 and 36 weeks' gestation, but the vaccine may be administered at any time during the pregnancy. Pregnant people who have not completed their primary tetanus series should receive 3 vaccinations containing tetanus and reduced diphtheria toxoids, if time permits. The recommended schedule is 0, 4 weeks, and 6 months or later. The risk of neonatal tetanus is minimal if a previously unimmunized person receives at least 2 properly spaced doses of tetanus toxoid-containing vaccines. If there is insufficient time, 2 doses of Td or Tdap should be administered at least 4 weeks apart, and the second dose should be administered at least 2 weeks before delivery. Tdap should be used for at least one of the tetanus-containing doses, preferably early in the interval between 27 and 36 weeks' gestation (see Pertussis [Whooping Cough], p 656).

Adverse Events, Precautions, and Contraindications. Severe anaphylactic reactions, Guillain-Barré syndrome (GBS), and brachial neuritis attributable to tetanus toxoid have been reported but are rare. No increased risk of GBS has been observed with use of DTaP in children. For a child with a history of GBS, the decision to administer

¹ Havers FP, Moro PL, Hunter P, Hariri S, Bernstein H. Use of tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccines: updated recommendations of the Advisory Committee on Immunization Practices—United States, 2019. *MMWR Morb Mortal Wkly Rep.* 2020;69(3):77-83

additional doses of DTaP should be made on the basis of consideration of the benefit of further immunization versus the risk of recurrence of GBS.

An immediate anaphylactic reaction to tetanus- and diphtheria toxoid-containing vaccines (ie, DTaP, Tdap, DT, Td, or conjugate vaccine containing diphtheria or tetanus toxoid) is a contraindication to further doses unless the component responsible is determined and the patient can be desensitized to that component. Because of the importance of tetanus vaccination, people who experience anaphylactic reactions should be referred to an allergist to determine whether they have a specific allergy to tetanus toxoid and can be desensitized to tetanus toxoid.

Injection site pain and erythema are common. Fever may occur, and rarely, whole limb swelling occurs (with or without pain and erythema). Repeat vaccination, as age appropriate, appears to be safe in children who had whole limb swelling.

Arthus-type hypersensitivity reaction has been reported in adults who received excessive doses of Td over a short period and usually is associated with high concentrations of tetanus antitoxin. Arthus reactions are rare in children and did not occur in clinical trials of Tdap vaccines. People who experienced an Arthus-type hypersensitivity reaction after a previous dose of a tetanus toxoid-containing preparation should not receive dose(s) of tetanus toxoid-containing preparation more frequently than every 10 years, even if they have a wound that is neither clean nor minor.

Other Control Measures. Sterilization of hospital supplies will prevent the rare instances of tetanus that may occur in a hospital from contaminated sutures, instruments, or plaster casts.

For prevention of neonatal tetanus, preventive measures (in addition to immunization of pregnant people) include community immunization programs for people capable of becoming pregnant and appropriate training of obstetric providers (including midwives) in recommendations for immunization and sterile technique.

Tinea Capitis

(Ringworm of the Scalp)

CLINICAL MANIFESTATIONS: Dermatophytic fungal infections of the scalp usually present with an area of localized alopecia and scaling but may include subtle findings of mild hair loss with faint scaling or a large hairless, boggy erythematous area (kerion). Other manifestations include a common “black dot” pattern reflecting stubs of broken-off hairs at the scalp surface; a less common “grey patch” seborrheic dermatitis-like pattern with or without hair loss and prominent, well-demarcated areas of scaling and erythema; or a vesiculopustular pattern resembling bacterial folliculitis. Regional lymphadenopathy may be present.

The differential diagnosis for tinea capitis depends on the clinical presentation. In the classic scaling presentation, clinicians should consider atopic dermatitis, seborrheic dermatitis, and psoriasis. Alopecia should raise the possibility of trichotillomania and alopecia areata, although these disorders usually are not associated with scaling. When vesiculopustular in nature, lice infestation and bacterial infection should be considered. A boggy fluctuant mass likely represents a kerion, but primary (or secondary) bacterial infection can be considered. Although scalp scarring can result from tinea, particularly when a kerion suppurates, presence of scalp scarring should raise the possibility of an autoimmune disorder, such as discoid lupus.

An associated skin eruption, known as a dermatophytic or “id” reaction, can occur as a hypersensitivity reaction to the infecting fungus and can manifest as diffuse, pruritic, papular, vesicular, and/or eczematous lesions occurring at sites distant from the fungal infection including the trunk and extremities. Id reactions often begin after starting therapy but do not represent a drug allergy and should not prompt discontinuation of treatment.

Tinea capitis can occur in association with tinea corporis. Examination of the body (face, trunk, and limbs) should be performed, particularly in wrestlers and others engaged in contact sports.¹ Close contacts including parents, siblings, and other close contacts should be examined for clinical findings consistent with tinea capitis.

ETIOLOGY: Tinea capitis develops when dermatophyte fungal elements invade the scalp hair follicle and shaft. The specific pathogen varies by geographic region and mode of transmission. The primary causes are fungi of the genus *Trichophyton*, including *Trichophyton tonsurans* and *Trichophyton violaceum*, as well as *Microsporum*, including *Microsporum canis* and *Microsporum audouinii*.

EPIDEMIOLOGY: Tinea capitis primarily occurs in prepubertal children but may occur in children of all ages and in adults. In the United States, *T tonsurans* is responsible for up to 95% of tinea capitis and is most common in school-aged children. Infection with *T tonsurans* is contracted from direct contact with an infected individual, animal, or contaminated object such as hat or brush. *T violaceum* is the dominant organism in eastern Europe and south Asia and is seen more frequently in immigrant populations in the United States.

M canis is associated with less than 5% of infections in the United States. *M canis* infection almost always results from contact with infected pets, particularly kittens or puppies. *M canis* outbreaks in schools and child care facilities have followed visits from infected animals. Unlike infections caused by *Trichophyton* species, infections caused by *M canis* are often associated with inflammatory lesions early in the course.

The dermatophyte organism remains viable for prolonged periods on fomites (eg, brushes, combs, hats, towels), and the rate of asymptomatic carriage and infected individuals among family members of index cases is high. Asymptomatic carriers almost certainly serve as a reservoir of infection within families, schools, and communities.

Immunocompromised people and those with trisomy 21 have an increased susceptibility to dermatophyte infections.

The **incubation period** is unknown but is believed to be 1 to 3 weeks. Dermatophyte infections have been reported as early as 3 days of age.

DIAGNOSTIC TESTS: The presence of alopecia, pruritus, scale, and posterior cervical lymphadenopathy makes the diagnosis of tinea capitis almost certain. Treatment can be initiated based on clinical findings, but fungal culture should be obtained to confirm the diagnosis. Diagnosis can also be confirmed at the time of initial evaluation by dermatoscopic examination of the affected area and by microscopic evaluation of a potassium hydroxide wet mount of cutaneous scrapings. Dermatoscopic evaluation of areas of alopecia with a lighted magnifier may show comma, corkscrew, or elbow-shaped hairs. Potassium hydroxide wet mount microscopy may be used to

¹ Davies HD, Jackson MA, Rice SG; American Academy of Pediatrics, Committee on Infectious Diseases, Council on Sports Medicine and Fitness. Infectious diseases associated with organized sports and outbreak control. *Pediatrics*. 2017;140(4):e20172477

examine hairs and scale obtained by gentle scraping of an area of the scalp with a blunt scalpel or scalpel blade, hairbrush, toothbrush, or cotton swab or by plucking with tweezers. Visualization of spores filling the interior of the hair shaft indicates an endothrix infection caused by *T tonsurans*, while coating of the outside of the hair shaft with spores indicates an ectothrix infection, such as from *M canis*. In both forms, septate hyphae may be visualized in scrapings from the scalp surface. Clinicians should obtain a fungal culture to establish a diagnosis, in conjunction with microscopy. To obtain a fungal culture, a cotton-tipped applicator can be used to swab an affected area. The sample is transported to a mycology laboratory for processing; 2 to 4 weeks of incubation on Sabouraud dextrose agar are required for results. Nucleic acid amplification tests (NAATs) are very useful and increasingly available. Under Wood lamp, tinea lesions are not fluorescent unless the etiologic agent is of the *Microsporum* genus, in which blue-green fluorescence is noted, because it is an ectothrix infection.

TREATMENT: Tinea capitis always requires systemic medication, because the fungal infection is found within the hair follicles, where topical agents do not reach. Optimal treatment of tinea capitis includes consideration of drug tolerability, availability, and cost. Current treatment options are summarized in Table 3.74.

Griseofulvin is approved by the US Food and Drug Administration (FDA) for children 2 years and older, is available in either liquid or tablet form, can be administered on a daily basis, and should be taken with fatty foods. Experts generally use higher doses of griseofulvin than have been approved by the FDA or that were used in clinical trials. Laboratory testing of serum hepatic enzymes is not required if duration of griseofulvin therapy is less than 8 weeks (but treatment of longer than 8 weeks is often required for resolution of infection). High-dose griseofulvin is considered standard of care for *M canis* infection.

Terbinafine granules are approved by the FDA for tinea capitis in children 4 years and older but are no longer available in the United States. Terbinafine clearance is higher in children than adults; pharmacokinetic data derived from studies of the granule formulation are the best information available regarding terbinafine clearance in children, and some experts extrapolate this “higher dosing” when utilizing tablets. Advantages of terbinafine for treatment of *T tonsurans* infection include the possibility of shorter treatment duration (Table 3.74) and equal or superior effectiveness compared with griseofulvin.

Two triazole agents can be considered in therapy. Fluconazole is the only oral antifungal agent approved by the FDA for children younger than 2 years, albeit not for tinea capitis. It had lower cure rates than other oral agents in a large randomized controlled trial. Accumulating evidence supports that itraconazole (currently not FDA approved for use in children or for tinea capitis) can be effective and safe for this disease. Liver function testing need not be assessed at baseline unless the child has preexisting liver disease or is on concomitant hepatotoxic medications.

Topical treatment, such as shampoos containing selenium sulfide, ketoconazole, or ciclopirox, may be useful as an adjunct to systemic therapy to decrease carriage of viable conidia for all forms of tinea capitis. Shampoo can be applied 2 to 3 times per week and left in place for 5 to 10 minutes. Treatments should continue for at least 2 weeks, and some experts recommend continuing topical treatments until clinical and mycologic cure occurs.

Table 3.74. Recommended Systemic Therapy for Tinea Capitis

Drug	Dosage	Duration	FDA Approved for Tinea Capitis
Griseofulvin microsize (liquid, 125 mg/5 mL)	15–25 mg/kg/day (max 1 g/day)	6–8 wk; continue until clinically clear	Yes (children ≥2 y)
Griseofulvin ultramicrosize (tablets of varying size)	10–15 mg/kg/day (max 750 mg/day)		
Terbinafine tablets (250 mg) ^a	4–6 mg/kg/day (max: 250 mg); or 10–20 kg: 62.5 mg 20–40 kg: 125 mg >40 kg: 250 mg	<i>T tonsurans</i> : 4–6 wk <i>M canis</i> : 8–12 wk	No
Terbinafine granules (125 mg and 187.5 mg) ^b	<25 kg: 125 mg 25–35 kg: 187.5 mg >35 kg: 250 mg	<i>T tonsurans</i> : 4–6 wk <i>M canis</i> : 8–12 wk	Yes (children ≥4 y)
Fluconazole ^c (liquid, 10 mg/mL; suspension, 40 mg/mL; tablet, 50 mg, 100 mg 150 mg, and 200 mg)	6 mg/kg/day (max 400 mg/day)	3–6 wk, depending on severity	No
Itraconazole ^c solution (10 mg/mL)	3 mg/kg/day (max 600 mg/day)	2–4 wk or longer, depending on severity	No
Itraconazole capsule (65 mg, 100 mg)	5 mg/kg/day (max 600 mg/day)		

^aSome experts use “higher” dosing listed for terbinafine granules instead.

^bTerbinafine granules have been discontinued in the United States.

^cSee Antifungal Drugs for Systemic Fungal Infections, p 1017, and Recommended Doses of Parenteral and Oral Antifungal Drugs, p 1026, for adverse reactions and therapeutic drug monitoring recommendations.

Affected patients receiving therapy should be reassessed in 1 month for clinical response. Fungal cultures may be obtained to evaluate for a mycologic response. Poor response may prompt retreatment with a different agent if compliance with the initial drug is confirmed.

Kerion is managed by systemic antifungal treatment as outlined previously. Removal of crusts with wet compresses is thought to decrease the risk of secondary bacterial infection. Combined antifungal and corticosteroid therapy (either oral or intralesional) has not been shown to be superior to antifungal therapy alone. Nonetheless, if the condition is unresponsive to traditional therapy, many experts will add systemic prednisone, 1 mg/kg/day for 2 weeks, to decrease likelihood of scarring. Treatment with antibacterial agents is unnecessary unless secondary bacterial infection occurs.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions apply.

CONTROL MEASURES: If discovered while at school, the affected student need not be sent home early. Once therapy is initiated, children should not be excluded from school. Family members and close contacts should be questioned regarding symptoms, and anyone with symptoms should be evaluated. Some experts recommend topical antifungal shampoo therapy for asymptomatic family members, but evidence is lacking regarding efficacy of this intervention. Sharing of items such as hats and combs/brushes should be avoided in households with an affected person. If pets are suspected as a source of *M canis* infection, evaluation and appropriate treatment of the affected animal should be implemented.

Tinea Corporis (Ringworm of the Body)

CLINICAL MANIFESTATIONS: Superficial fungal infections (superficial mycoses) are called tinea corporis when involving the skin of the trunk and extremities, and tinea faciei when involving the face. Lesions often are ring-shaped or circular (hence, the lay term “ringworm”) and are sharply margined. Involved skin is slightly erythematous and scaly, with color variations from red to brown. The classic eruption displays a scaly, vesicular, or pustular border (often serpiginous) with central clearing. Small confluent plaques or papules as well as multiple lesions can occur, particularly in wrestlers (tinea gladiatorum).¹ Although tinea faciei may have the above clinical features, the findings may be more variable in this location.

The differential diagnosis for tinea corporis includes pityriasis rosea (particularly the herald patch), candidiasis, psoriasis, other dermatitides (seborrheic, atopic, irritant or allergic, generally caused by therapeutic agents applied to the area), pityriasis versicolor (tinea versicolor), nummular eczema, granuloma annulare, erythema annulare centrifugum, impetigo and erythrasma (an eruption of reddish brown patches resulting from superficial bacterial skin infection caused by *Corynebacterium minutissimum*).

The typical appearance of the lesions is altered in patients who have been treated erroneously with topical corticosteroids. Known as tinea incognito, this altered appearance includes diminished erythema and absence of typical scaling borders. Such patients also can develop Majocchi granuloma, a fungal invasion of the hair shaft and surrounding dermis, which causes a granulomatous dermal reaction that can extend into the surrounding subcutaneous fat. Majocchi granuloma also can occur without prior use of corticosteroids.

An associated dermatophytic or “id” reaction can be present as a hypersensitivity reaction to the infecting fungus, manifesting as diffuse, pruritic, papular, vesicular, or eczematous lesions, which can occur at sites distant from the fungal infection. Sometimes id reactions first appear following institution of therapy, but they do not represent a drug allergy.

Skin lesions can occur as grouped papules or pustules without erythema or scaling in patients with diminished T-lymphocyte function (eg, human immunodeficiency virus infection). Tinea corporis presenting with rapidly progressive lesions that include vesicles, pus-filled bullae, nonindurated, nontender erythema-mimicking cellulitis is

¹ Davies HD, Jackson MA, Rice SG; American Academy of Pediatrics, Committee on Infectious Diseases, Council on Sports Medicine and Fitness. Infectious diseases associated with organized sports and outbreak control. *Pediatrics*. 2017;140(4):e20172477

called inflammatory tinea. Tinea corporis can occur in association with tinea capitis. The scalp should be examined, particularly in wrestlers and others engaged in contact sports.

ETIOLOGY: Tinea corporis develops when dermatophytic fungi (dermatophytes) invade the outer skin layers at the affected body region. Primary etiologic agents are *Trichophyton* species, especially *Trichophyton tonsurans*, *Trichophyton rubrum*, and *Trichophyton mentagrophytes*; *Microsporum* species, especially *Microsporum canis*; and *Epidermophyton floccosum*.

EPIDEMIOLOGY: Causative fungi occur worldwide and are transmissible by direct contact with infected humans, animals, soil, or fomites (eg, brushes, combs, hats, towels), where organisms can remain viable for prolonged periods. Drug-resistant strains of *Trichophyton* have been reported globally and are considered endemic in India and Iran. *Trichophyton indotineae* is antifungal-resistant, including to terbinafine, and has caused epidemics in South Asia. It is highly transmissible and characterized by widespread, inflamed, pruritic plaques on the body (tinea corporis), the crural fold, pubic region, and adjacent thigh (tinea cruris), or the face (tinea faciei). *T indotineae* isolates have recently been reported in the United States.¹

Immunocompromised people have an increased susceptibility to dermatophyte infections.

The **incubation period** is believed to be 1 to 3 weeks but can be shorter, as reported cases have occurred at 3 days of age.

DIAGNOSTIC TESTS: Tinea corporis is diagnosed by clinical manifestations and can be confirmed by microscopic examination of a potassium hydroxide wet mount of skin scrapings or fungal culture. Skin scrapings, ideally at the scaly edges of lesions for best recovery of organisms, are obtained by gentle scraping of a cleansed, moistened area with a scalpel blade or blunt scalpel, glass microscope slide or brush such as a toothbrush. If fungal culture is desired, a cotton-tipped applicator can be premoistened with sterile saline or water and used to swab an affected area gently. The sample is transported to a mycology laboratory for processing; 2 to 4 weeks of incubation on Sabouraud dextrose agar are required for results. Nucleic acid amplification tests (NAATs) are available but generally are not necessary. Under Wood lamp, tinea is not fluorescent unless the etiologic agent is of the genus *Microsporum*, in which case a blue-green fluorescence can be seen because it is an ectothrix infection. For recurrent tinea infections, especially those associated with international travel, consideration should be given to obtaining culture for species identification and antifungal susceptibility testing.

TREATMENT: A myriad of topical antifungal options are available for treatment and should be applied on the lesions and 1 to 2 cm beyond the borders. Some topical agents are approved by the US Food and Drug Administration (FDA) only for certain lesion locations and age groups and with applications specified as once or twice daily (Table 3.75). Any of the following products (applied twice daily) are reasonable first-line therapies if appropriate for age: miconazole, clotrimazole, tolnaftate, or ciclopirox. Any of the following products also can be used (applied once daily) if appropriate for age: ketoconazole, terbinafine, econazole, naftifine, luliconazole, or butenafine.

¹ Caplan AS, Chaturvedi S, Zhu Y, et al. Notes from the field: first reported U.S. cases of tinea caused by *Trichophyton indotineae*—New York City, December 2021–March 2023. *MMWR Morb Mortal Wkly Rep*. 2023;72(19):536–537

Table 3.75. Products for Topical Treatment of Tinea Corporis, Cruris, and Pedis

Topical Product	Age for Use	Daily Application
Miconazole (cream, 2%)	Age ≥2 y	Twice
Clotrimazole (cream or solution, 1%)	All ages	Twice
Tolnaftate (cream or solution, 1%)	Age ≥2 y	Twice
Ciclopirox (cream or lotion, 0.77%)	Age ≥10 y	Twice
Ciclopirox (gel, 0.77%)	Age ≥16 y for tinea corporis or pedis	Twice
Ketoconazole (cream, gel, and foam 2%) ^a	Seborrheic dermatitis, age ≥12 y	Once
Terbinafine (cream, 1%)	Age ≥12 y	Once for tinea corporis and cruris Twice for tinea pedis
Econazole (cream, foam 1%)	Foam for tinea pedis, age ≥12 y	Once
Naftifine (cream and gel, 1% and 2%)	2% products for tinea cruris/pedis: Age ≥12 y Tinea corporis: Age ≥2 y	Once or twice
Luliconazole (cream, 1%)	Age ≥2 y for tinea corporis Age ≥12 y for tinea cruris and pedis	Once
Butenafine (cream, 1%)	Age ≥12 y	Once for tinea corporis and tinea cruris Twice for tinea pedis
Oxiconazole (cream, lotion 1%)	All ages	Once or twice
Sulconazole (cream or solution, 1%)	Adults only	Once or twice
Sertaconazole (cream, 2%)	Age ≥12 y, for tinea pedis only	Twice

^aSafety and effectiveness in children have not been established for ketoconazole 2% cream.

Oxiconazole and sulconazole can be used (once or twice daily) if appropriate for age (also see Topical Drugs for Superficial Fungal Infections, p 1037).
Although clinical resolution may be evident within 2 weeks of therapy, continuing therapy for another 2 to 4 weeks generally is recommended. If significant clinical improvement is not observed after 2 weeks of treatment, an alternate diagnosis and/or

systemic therapy should be considered. Topical preparations of antifungal medication combined with a corticosteroid should not be used because of inferior effectiveness, the possibility of leading to Majocchi granuloma, and increase in the rate of relapse, higher cost, and potential for adverse corticosteroid effects.

If lesions are extensive or unresponsive to topical therapy or involving a hair-bearing area such as the beard, griseofulvin (for children ≥ 2 years) or terbinafine (for children ≥ 4 years) may be administered orally for 4 to 6 weeks (see Tinea Capitis, p 854). Terbinafine granules are no longer available in the United States. Griseofulvin may be preferred over terbinafine in cases known to be caused by *Microsporum* species. Oral itraconazole and fluconazole do not have FDA indications for treatment of many tinea conditions. There are reports of successful treatment of terbinafine-resistant *Trichophyton* infections with itraconazole. If a Majocchi granuloma is present, oral antifungal therapy is recommended, because topical therapy is unlikely to penetrate adequately to eradicate infection.

Dermatophyte infections in other locations, if present, should be treated concurrently.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions apply. Recent outbreaks of tinea infection in both acute and chronic care facilities among patients and caregivers illustrate the need for education regarding clinical manifestations of tinea and infection control procedures in the care of infected individuals.

CONTROL MEASURES¹: Infections should be treated promptly. Direct contact with known or suspected sources of infection should be avoided. Periodic inspections of contacts for early lesions and prompt therapy are recommended. Pet rodents, including guinea pigs, may carry dermatophytes in their claws. Scratches by these animals should be washed immediately. Athletic mats and equipment should be cleaned frequently, and actively infected athletes in sports with person-to-person contact must be excluded from competitions. Athletes with tinea corporis may resume participation in contact sports a minimum of 72 hours after initiation of topical therapy and when the affected area can be covered. Prophylaxis of wrestling team members is controversial. Fluconazole, 100 mg per day for 3 days, given prophylactically before initiation of competitive interscholastic high school wrestling and given again 6 weeks into the season, has been reported to reduce the incidence of *T corporis* significantly, from 67.4% to 3.5%. The risk-benefit analysis of giving fluconazole prophylactically in this manner has not been determined, however, and its use should be in consultation with an infectious diseases expert. Infected pets also should receive antifungal treatment.

Tinea Cruris

(Jock Itch)

CLINICAL MANIFESTATIONS: Tinea cruris is a common superficial fungal disorder of the groin, pubic/perianal area, suprapubic abdomen, and upper thighs. It is more common in male adults and adolescents and uncommon in prepubertal children.² The

¹ Davies HD, Jackson MA, Rice SG; American Academy of Pediatrics, Committee on Infectious Diseases, Council on Sports Medicine and Fitness. Infectious diseases associated with organized sports and outbreak control. *Pediatrics*. 2017;140(4):e20172477

² The term male refers to sex assigned at birth.

lesions often are ring-shaped or circular (hence, the lay term “ringworm”), are sharply margined, and can be intensely pruritic (jock itch). The involved skin is slightly erythematous and scaly, with color variations from red to brown. Lesions can display a scaly, vesicular, or pustular border (often serpiginous) with central clearing. Maceration may also develop. Scaling is less prominent in the presence of maceration. The disorder usually spares the scrotum unless candidiasis also is present. The margins can be subtle in chronic infections, and lichenification may be present.

The differential diagnosis for tinea cruris includes intertrigo, candidiasis, psoriasis (particularly inverse psoriasis), other dermatitides (seborrheic, atopic, irritant or allergic contact, generally caused by therapeutic agents applied to the area), pityriasis versicolor (tinea versicolor), nummular eczema, erythema annulare centrifugum, and erythrasma (an eruption of reddish brown patches resulting from superficial bacterial skin infection caused by *Corynebacterium minutissimum*).

An altered appearance known as tinea incognito can occur in patients who have been treated erroneously with topical corticosteroids, which includes diminished erythema and absence of typical scaling borders. Such patients also can develop Majocchi granuloma when fungi invade the hair shaft and surrounding dermis, causing a granulomatous dermal reaction that can extend into the surrounding subcutaneous fat. Majocchi granuloma also can occur without prior use of topical corticosteroid.

An associated skin eruption, known as a dermatophytic or “id” reaction, can occur as a hypersensitivity reaction to the infecting fungus and manifests as diffuse, pruritic, papular, vesicular, or eczematous lesions at sites distant from the fungal infection. An id reaction can first occur following institution of therapy but does not represent a drug allergy.

Concomitant tinea pedis, tinea unguium, and tinea corporis have been reported in patients with tinea cruris.

ETIOLOGY: Tinea cruris develops when dermatophyte fungi invade the outer skin layers of the affected body region. The fungi *Epidermophyton floccosum*, *Trichophyton rubrum*, and *Trichophyton mentagrophytes* are the most common causes. *Trichophyton tonsurans*, *Trichophyton verrucosum*, and *Trichophyton interdigitale* also have been identified as causes.

EPIDEMIOLOGY: Tinea cruris occurs predominantly in male adolescents and adults and is acquired principally through indirect contact with desquamated epithelium or hair. Direct person-to-person transmission also occurs. Moisture, close-fitting garments, noncotton underwear, friction, and obesity are predisposing factors. Recurrence is common.

Immunocompromised patients have increased susceptibility to dermatophyte infections. In patients with diminished T-lymphocyte function (eg, human immunodeficiency virus infection), skin lesions can appear as grouped papules or pustules unaccompanied by scaling or erythema.

The **incubation period** is unknown but is thought to be approximately 1 to 3 weeks.

DIAGNOSTIC TESTS: Confirmatory diagnostic modalities for tinea cruris are similar to that for tinea corporis (see Tinea Corporis, p 858).

TREATMENT: Treatment is similar to that for tinea corporis (see Tinea Corporis, Table 3.75, p 860). Treatment of concurrent onychomycosis (tinea unguium) and tinea pedis may reduce recurrence. Recurrence is common, particularly if predisposing

factors such as moisture and friction are not minimized. Loose-fitting clothing and use of antifungal powders, such as tolnaftate and miconazole, should aid in recovery and prevent recurrence.

Oral terbinafine, itraconazole, and fluconazole are options but do not have a US Food and Drug Administration indication for tinea cruris. Griseofulvin, administered orally for 4 to 6 weeks, may be effective if lesions are unresponsive to topical therapy (see Tinea Capitis, p 854). Oral antifungal therapy is recommended if a Majocchi granuloma (deep folliculitis) is present, because topical therapy is unlikely to penetrate adequately to eradicate infection. Dermatophyte infections in other locations, if present, should be treated concurrently, and may be an indication for oral therapy.

Topical steroids are not recommended, even in formulations coupled with antifungal agents, as these may exacerbate the infection.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions apply.

CONTROL MEASURES: Infections should be treated promptly. Involved areas should be kept dry to prevent recurrences, and antifungal powders and wearing loose fitting undergarments may be useful. Patients should be advised to dry the groin area before drying their feet to avoid inoculating dermatophytes of tinea pedis into the groin area. When infection is present, towel sharing should be avoided.

Tinea Pedis and Tinea Unguium (Onychomycosis)

(Athlete's Foot, Ringworm of the Feet)

CLINICAL MANIFESTATIONS: Tinea pedis can have a variety of clinical manifestations in children. Lesions can involve all areas of the foot but usually are patchy in distribution, with a predisposition to cause fissures, macerated areas, and scaling between toes. A pruritic, fine scaly, or vesiculopustular eruption is most common and can be associated with a confluent, hyperkeratotic, dry scaling of the soles. Recurrence of tinea pedis is common, and it can be a chronic infection. Toenails can be infected (onychomycosis or tinea unguium) and become distorted, discolored, and thickened with accumulation of subungual debris. A superficial white form of toenail fungal infection can occur in children. Toenails may be the source for recurrent tinea pedis.

Tinea pedis must be differentiated from dyshidrotic eczema, atopic dermatitis, psoriasis, contact dermatitis, juvenile plantar dermatosis, palmoplantar keratoderma, and erythrasma (reddish brown patches that can affect the feet and axillae resulting from superficial bacterial skin infection caused by *Corynebacterium minutissimum*).

An associated skin eruption, known as a dermatophytid or "id" reaction, can occur as a hypersensitivity reaction to the infecting fungus and manifests as diffuse, pruritic, papular, vesicular, or eczematous lesions at sites distant from the fungal infection. An id reaction can occur first following institution of therapy but does not represent a drug allergy. Id reaction lesions may appear as grouped papules or pustules unaccompanied by erythema or scaling in patients with diminished T-lymphocyte function (eg, human immunodeficiency virus infection).

The differential diagnosis of tinea unguium includes trauma (particularly if only 1 nail is involved), psoriasis, congenital malalignment of the great toenails (if only great toenails are involved), twenty nail dystrophy (trachyonychia), and subungual exostosis if only 1 nail is involved.

Concomitant tinea in other body sites has been reported in patients with tinea pedis and tinea unguium.

ETIOLOGY: Tinea pedis and unguium develop when dermatophytic fungi invade the skin layers and nails of the affected body region. The fungi *Trichophyton rubrum*, *Trichophyton mentagrophytes*, and *Epidermophyton floccosum* are the most common causes of tinea pedis.

EPIDEMIOLOGY: Tinea pedis is a common infection worldwide in adolescents and adults but is less common in young children. Fungi are acquired by contact with infected skin scales or organisms present in damp areas, such as swimming pools, locker rooms, and showers. Tinea pedis may spread among family members in the household; this may represent enhanced genetic susceptibility as well as increased exposure to the organism. The incidence of onychomycosis, which is more common in toenails, increases with age, with worldwide prevalence in children estimated to be from 0.1% to 0.87%. The increased use of occlusive footwear earlier in childhood and exposure to high-risk areas (eg, swimming pools, gyms) earlier in life may be associated with an increase of tinea pedis in children. Childhood onychomycosis is associated with a history of tinea pedis, a history of family member infection, increased number of siblings, and male sex.¹

Immunocompromised people and those with trisomy 21 have increased susceptibility to dermatophyte infections.

The **incubation period** is unknown.

DIAGNOSTIC TESTS: Confirmatory diagnostic tests for tinea pedis are similar to those for tinea corporis (see Tinea Corporis, p 858). Fungal infection of the nail (tinea unguium or onychomycosis) can be verified by direct microscopic examination with potassium hydroxide, fungal culture of desquamated subungual material, or fungal stain of nail clippings fixed in formalin. Nucleic acid amplification tests (NAATs) are a useful and increasingly used tool.

TREATMENT: A myriad of topical options are available for treatment of tinea pedis (see Tinea Corporis, Table 3.75, p 860; also see Topical Drugs for Superficial Fungal Infections, p 1037). Therapy duration of 2 weeks usually is sufficient for milder cases of tinea pedis in children. Acute vesicular lesions can be treated with intermittent use of open wet compresses (eg, with Burow solution, diluted 1:80). Tinea pedis that is severe, chronic, or refractory to topical treatment can be treated with oral therapy similar to that for tinea capitis (see Tinea Capitis, Table 3.74, p 857).

Recurrence of tinea pedis is prevented by proper foot hygiene, which includes keeping the feet dry and cool, cleaning gently, drying between the toes, use of absorbent antifungal foot powder, exposing affected areas to air frequently, and avoidance of occlusive footwear, nylon socks, and other fabrics that interfere with dissipation of moisture. Wearing protective footwear in public facilities such as pools and gyms may prevent transmission.

Topical antifungal lacquers and solutions that are effective for distal toenail infections that do not involve the nail matrix now are available. Despite lower cure rates, topical agents are preferred because of substantially lower adverse effects, lack of drug-drug interactions, and avoidance of need for laboratory test monitoring for toxicity.

¹ The term male refers to sex assigned at birth.

Topical ciclopirox 8% lacquer, with a US Food and Drug Administration (FDA) indication for tinea unguium for patients 12 years and older, can be applied to affected toenail(s) once daily for up to 48 weeks, or twice daily for shorter durations, in combination with a comprehensive nail management program. Efinaconazole 10% solution and tavaborole 5% solution are indicated for onychomycosis for patients 6 years and older, applied once daily for up to 48 weeks; both have higher cure rates in adults than ciclopirox. Topical therapies appear to show a higher cure rate in children than in adults, possibly because of thinner nail plates and faster nail growth rate in children. Most of these agents are expensive and not usually covered by insurance.

Studies in adults have demonstrated the best cure rates for onychomycosis (tinea unguium) are with oral terbinafine or itraconazole. Although oral therapies are more likely to lead to cure, they also require laboratory monitoring and can induce drug–drug interactions. Guidelines for dosing of terbinafine for children are based on studies for treatment of tinea capitis and are weight based (see Table 3.74, p 857). The duration of therapy is the same as for adults (6 weeks for fingernail infection, 12 weeks for toenail infection). Pediatric dosing of oral itraconazole is not established for superficial mycoses, although a suggested dosing may follow that for tinea capitis (see Table 3.74, p 857, Antifungal Drugs for Systemic Fungal Infections, p 1017, and Recommended Doses of Parenteral and Oral Antifungal Drugs, p 1026, for dosing, adverse reactions, and therapeutic drug monitoring recommendations). Griseofulvin, although approved by the FDA for treatment of tinea unguium, is rarely used for this indication.

Factors that influence choice of therapy include severity of infection, results of fungal culture or potassium hydroxide preparation (if performed), prior treatments, concomitant drug therapy for other illnesses, patient preference, and cost. Topical and systemic therapy may be used concurrently to increase therapeutic response. Cure rates following oral or combined therapy approach 80% in children. Mechanical and chemical débridement of the nail, using 40% urea ointment daily under occlusion for 10 days to soften the nail, should be performed in refractory cases or when severe thickening of the nail is likely to decrease absorption and response to therapy.

Dermatophyte infections in other locations, if present, should be treated concurrently.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions apply.

CONTROL MEASURES: Treatment of patients with active infections should decrease transmission. Using public areas conducive to transmission (eg, swimming pools) is discouraged in those with untreated, active infection. Chemical foot baths can facilitate spread of infection. Because recurrence after treatment is common, proper foot hygiene is important (as described in Treatment). Patients should be advised to dry the groin area before drying the feet to avoid inoculating dermatophytes from tinea pedis into the groin area. Prevention of tinea unguium includes keeping nails short and not sharing nail clippers.

Toxocariasis

CLINICAL MANIFESTATIONS: Clinical disease is caused by migration of parasitic nematode larvae through tissues. Signs and symptoms differ depending on the affected organ and host inflammatory response. Toxocariasis can be of following types: covert

toxocariasis, visceral larva migrans, neurotoxocariasis, or ocular larva migrans. Most infected children are asymptomatic. Covert disease presents with nonspecific symptoms and may be accompanied by eosinophilia. Symptoms of visceral toxocariasis include fever, cough, wheezing, abdominal pain, anorexia, and malaise, with myocarditis and rash less common. Hepatomegaly or pneumonia may be present, along with eosinophilia. Neurotoxocariasis may manifest with an eosinophilic meningoencephalitis, space-occupying lesions, myelitis, or cerebral vasculitis, and may present with change in mental status or seizures. Laboratory abnormalities include leukocytosis, eosinophilia, and hypergammaglobulinemia. Ocular invasion (resulting in uveitis, endophthalmitis, or retinal granulomas) most often manifests as unilateral vision loss (with subsequent strabismus), frequently without other systemic signs or eosinophilia.

ETIOLOGY: Toxocariasis is caused by *Toxocara* species, which are nematode (round-worm) parasites of dogs and cats, specifically *Toxocara canis* and *Toxocara cati*, respectively; most cases are caused by *T canis*.

EPIDEMIOLOGY: Toxocariasis is most common in the tropics. In the United States, 5% of the population 6 years and older have serologic evidence of *Toxocara* infection. Visceral toxocariasis typically occurs in children 2 to 7 years of age but can occur in older children and adults. Ocular toxocariasis usually occurs in older children and adolescents. Infection is more likely among people who own dogs and people living in poverty and is more prevalent in hot and humid regions (in the United States, the southern states) where eggs can remain viable in soil for years. Humans are infected by ingestion of soil containing infective eggs of the parasite. Eggs may be found wherever dogs and cats defecate, often in sandboxes and playgrounds. Eggs become infective after 2 to 4 weeks in the environment and may persist long-term in the soil. Direct contact with dogs or cats does not typically lead to infection, because eggs are not infectious immediately when shed in the feces.

The **incubation period** cannot be determined accurately.

DIAGNOSTIC TESTS: Laboratory findings include marked leukocytosis with eosinophilia and occasionally anemia and hypergammaglobulinemia (elevated serum concentrations of immunoglobulin [Ig] G and IgE). Patients with visceral disease frequently have increased titers of isohemagglutinin to the A and B blood group antigens. Diagnosis is made most commonly by enzyme-linked immunosorbent assay (ELISA) for *Toxocara* antibodies in serum or vitreous fluid. A positive antibody test result does not distinguish between past and current infection, and the test is less sensitive for diagnosis of ocular toxocariasis. For visceral disease, imaging of the liver using ultrasonography, computed tomography, or magnetic resonance imaging may reveal diffuse nodular lesions measuring less than 2 cm in diameter. Microscopic identification of larvae in a liver biopsy specimen is diagnostic, but this test is not sensitive or specific and therefore rarely indicated.

TREATMENT: Albendazole is recommended for treatment of visceral and ocular toxocariasis (see Drugs for Parasitic Infections, p 1068). The drug has been approved by the US Food and Drug Administration but not for this indication. Mebendazole is an alternative. In severe cases with myocarditis or involvement of the central nervous system, corticosteroid therapy administered concurrently with albendazole is warranted. Control of inflammation of the eye with oral or topical corticosteroids may be required; surgical therapy may be helpful in complicated ophthalmic cases.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended. There is no person-to-person spread.

CONTROL MEASURES: Proper disposal of cat and dog feces is essential. Regular veterinary care and periodic deworming of dogs and cats, and especially puppies and kittens, decreases environmental contamination with *Toxocara* eggs and has public health benefit. Covering sandboxes when not in use is helpful. No specific management following exposure is recommended.

***Toxoplasma gondii* Infections¹**

(Toxoplasmosis)

CLINICAL MANIFESTATIONS: Up to 50% of patients with acute *Toxoplasma* infection are asymptomatic. When present, common signs and symptoms of acute *Toxoplasma* infection can include influenza-like symptoms, lymphadenopathy with atypical lymphocytosis, fever, myalgia, arthralgia, sweats, chills, fatigue, headache, chorioretinitis, hepatic dysfunction, pneumonitis, meningoencephalitis, myocarditis, myositis, acute disseminated encephalomyelitis (ADEM), and myelitis. Reactivation of chronic *Toxoplasma* infection in immunocompromised patients may result in fever, pneumonia, septic shock, brain abscesses, diffuse encephalitis without brain-space occupying lesions, seizures, chorioretinitis, myocarditis, myelitis, and polymyositis.

Congenital Infection. People are not screened routinely for toxoplasmosis during pregnancy in the United States. Clinically apparent signs and symptoms of congenital toxoplasmosis are found on routine physical examination in a minority of infected infants at birth, but more specific testing (of cerebrospinal fluid [CSF], dilated eye examination, or central nervous system imaging) can reveal evidence of infection. Visual or hearing impairment, learning disabilities, or severe developmental delay will become apparent later in life in a large proportion of congenitally infected infants. Chorioretinitis occurs in approximately 70% of congenitally infected infants whose birthing parents were not treated during pregnancy and in up to 25% of those whose birthing parents were treated.

Clinical illness is more likely to be severe when infection occurs in the first trimester and is not treated during pregnancy. The classic triad of chorioretinitis, cerebral calcifications, and hydrocephalus is highly suggestive of congenital toxoplasmosis. Additional signs at birth include microcephaly, seizures, hearing loss, strabismus, petechial rash, jaundice, generalized lymphadenopathy, hepatomegaly, splenomegaly, pneumonia, thrombocytopenia, and anemia. Meningoencephalitis may be associated with CSF abnormalities including high protein concentrations, hypoglycorrachia, and eosinophilia. Some severely affected fetuses/infants with disseminated congenital toxoplasmosis die in utero or within a few days of birth. Cerebral calcifications can be demonstrated by plain radiography, ultrasonography, computed tomography (CT), or magnetic resonance imaging (MRI) of the head. CT is the radiologic technique most sensitive for intracranial calcifications and can reveal them when ultrasonographic studies are normal.

¹ Maldonado YA, Read JS; American Academy of Pediatrics, Committee on Infectious Diseases. Diagnosis, treatment, and prevention of congenital toxoplasmosis in the United States. *Pediatrics*. 2017;139(2):e20163860

Postnatally Acquired Primary Infection. Postnatally acquired *Toxoplasma gondii* infections in immunocompetent patients usually are asymptomatic. When symptoms develop, they may be nonspecific and can include malaise, fever, headache, sore throat, arthralgia, and myalgia. Lymphadenopathy, frequently cervical, is the most common sign. Patients occasionally have a mononucleosis-like illness associated with a maculopapular rash, hepatosplenomegaly, hepatic dysfunction, and atypical lymphocytosis. The clinical course usually is benign and self-limited.

In a subset of patients, primary infection may be severe and/or persistent, including fever, myocarditis, pericarditis, myositis, hepatitis, pneumonia, encephalitis with and without brain abscesses, and skin lesions (maculopapular rash). These severe syndromes are especially common in patients who acquired primary *T. gondii* infections with high parasite loads and/or in areas where atypical, more virulent strains are present (eg, Mexico, French Guiana, Brazil, and Colombia).

Chorioretinitis. Toxoplasmic chorioretinitis can occur: (a) with congenital infection; (b) from a postnatally acquired acute infection; and (c) from reactivation of a congenital or postnatally acquired infection. Acute onset of blurred vision, eye pain, decreased visual acuity, floaters, scotoma, photophobia, epiphora, nystagmus, or strabismus are noted. Ocular findings in toxoplasmic eye disease include white focal retinitis with overlying vitreous inflammation (“headlight in the fog”), nearby prior pigmented retinochoroidal scar, retinal vasculitis, vitreous inflammation, cataracts, iridocyclitis and stellate keratic precipitates (accompanying chorioretinitis), and elevated intraocular pressure. Complications can include retinal detachment, cystoid macular edema, optic atrophy, chronic iridocyclitis, cataract formation, secondary glaucoma, or band keratopathy.

Reactivation of Chronic Infection in Immunocompromised Patients. Reactivation of latent infection may occur in immunosuppressed patients. Reactivation can result in encephalitis, brain abscesses, seizures, pneumonia, myocarditis, hepatitis, skin lesions, posterior uveitis or panuveitis with chorioretinitis, fever of unknown origin, and disseminated disease and death. Toxoplasmic encephalitis (TE) can present as a single or multiple brain lesions on MRI or as a “diffuse form” with a rapidly progressive clinical course leading to death despite apparently normal brain imaging. MRI is superior to CT for the diagnosis of TE. In patients with acquired immunodeficiency syndrome (AIDS), TE is the most common cause of space-occupying brain lesions and typically presents with acute to subacute neurologic or psychiatric symptoms and multiple ring-enhancing brain lesions. In these patients, a clear improvement in the neurologic examination within 7 to 10 days of beginning empiric anti-*Toxoplasma* therapy is considered diagnostic of TE. Lack of radiographic response 2 weeks after initiation of anti-*Toxoplasma* therapy is an indication to consider alternative diagnoses. Patients without AIDS who have multiple brain lesions should not be treated empirically for only toxoplasmosis, and other etiologies should be considered for diagnostic and empiric treatment purposes.

Seropositive hematopoietic cell transplant and solid organ transplant recipients are at risk of reactivation of latent infection in the absence of appropriate prophylaxis. Transmission occurs in $\geq 50\%$ of seronegative recipients who receive hearts from seropositive donors unless appropriate prophylaxis is prescribed. Toxoplasmosis in this setting presents as pneumonia, unexplained fever or seizures, myocarditis, hepatitis, hepatosplenomegaly, lymphadenopathy, skin lesions, or brain abscesses and diffuse

encephalitis. Transplant donors and recipients should be screened pretransplant for *Toxoplasma* infection.

ETIOLOGY: *T gondii* is a protozoan and obligate intracellular parasite. The infectious forms include tachyzoites, tissue cysts containing bradyzoites, and oocysts containing sporozoites. The tachyzoite and the corresponding host immune reaction are responsible for observed symptoms. The tissue cyst is responsible for latent infection and usually is present in brain, eye, cardiac tissue, and skeletal muscle.

EPIDEMIOLOGY: Seroprevalence of *T gondii* infection varies by geographic locale and socioeconomic strata of the population. The overall *T gondii* seropositivity rate in the United States (according to the National Health and Nutrition Examination Survey 2011–2014) in people older than 6 years was 11.1% and among women 15 to 44 years of age was 7.5%.

Individuals become infected through foodborne, zoonotic, or person-to-person modes of transmission (eg, vertical transmission). Congenital transmission occurs in most cases as a result of acute primary infection acquired during pregnancy or within 3 months before conception. In utero infection rarely can occur as a result of reactivated parasitemia in a latently infected immunocompromised person in the absence of prophylaxis. Rarely, congenital toxoplasmosis is acquired from an immunocompetent pregnant person reinfected with a different *T gondii* strain. Incidence of acute primary *T gondii* infection during pregnancy in the United States is estimated to be 0.2 to 1.1/1000 pregnant people on the basis of data from Massachusetts and New Hampshire, which are the only 2 states in the United States with universal toxoplasmosis newborn screening. Transmission through organ donation or blood transfusions is rare.

The **incubation period** of postnatally acquired infection is approximately 7 days, with a range of 4 to 21 days. Parasites can be detected in the blood for up to 2 weeks after acute infection; prolonged parasitemia also has been reported.

DIAGNOSTIC TESTS: Serologic tests are the primary means of diagnosis. *Toxoplasma* immunoglobulin (Ig) G and IgM can be performed by commercial laboratories in most situations; exceptions are testing of pregnant people with suspected acute *Toxoplasma* infections during gestation and neonates with suspected congenital toxoplasmosis, for whom testing should be performed at a reference laboratory (see below). *Toxoplasma* IgM results from commercial laboratories can be falsely positive; confirmation should be obtained from reference laboratories with special expertise such as the Palo Alto Medical Foundation Toxoplasma Serology Laboratory (PAMF-TSL; Palo Alto, CA; www.sutterhealth.org/RemingtonLab; telephone: 650-853-4828; email: RemingtonLab@sutterhealth.org). Confirmatory testing at the reference laboratory may include IgM, IgA, IgE, IgG avidity, and the differential agglutination (of acetone [AC]-fixed versus that of formalin [HS]-fixed tachyzoites) test (AC/HS test).

IgG-specific antibodies achieve a peak concentration 3 to 5 months after infection and remain positive indefinitely. IgM-specific antibodies can be detected 1 to 2 weeks after infection (IgG-specific antibodies usually are negative during this period), achieve peak concentrations in 1 month, and usually become undetectable within 6 to 9 months, but may also persist for years without apparent clinical significance. The lack of *T gondii*-specific IgM antibodies in a person with low-positive titers of IgG antibodies (eg, a dye test at PAMF-TSL $\leq 1:512$) indicates infection of at least 6 months'

duration. In contrast, detectable *T gondii*-specific IgM antibodies can indicate recent infection, chronic (latent) infection, or a false-positive reaction. If timing of infection is clinically important (eg, in a pregnant person), sera with positive *T gondii* IgM test results can be sent to PAMF-TSL to establish acute versus chronic infection using an additional panel of tests such as IgG avidity, AC/HS, and IgA- and IgE-specific antibody tests.

Polymerase chain reaction (PCR) detection has been applied to body fluid or tissue, and *T gondii*-specific immunoperoxidase staining can be performed with any tissue, depending on the clinical scenario. A positive PCR test result in tissue must be interpreted with caution, because it may amplify tachyzoite or bradyzoite DNA and cannot distinguish between tachyzoites with acute infection or reactivation or bradyzoites with chronic latent infection. CSF PCR for *T gondii* has high specificity (96%–100%), but sensitivity is only 50%. CSF PCR results can also be negative because of anti-*Toxoplasma* therapy.

Congenital Toxoplasmosis. During pregnancy, PCR assay of amniotic fluid is the method of choice to confirm fetal infection. Fetal ultrasonography can assess for anatomical abnormalities. Examination of the placenta by histologic testing and PCR assay may provide additional information but is not sufficiently sensitive or specific for diagnostic purposes. At birth or postnatally, serologic tests for IgG, IgM, and IgA should be performed. Neonates who are born to persons with primary infection during pregnancy, or in whom there is high suspicion for congenital toxoplasmosis, should have a lumbar puncture for CSF analysis and toxoplasma PCR. Urine and whole blood should be sent for *T gondii* PCR assay. Positive neonatal serum *Toxoplasma* IgM (after 5 days of life) and/or IgA (after 10 days of life), along with a positive IgG, is considered diagnostic of congenital toxoplasmosis. IgM immunosorbent agglutination assay (ISAGA) test results can be falsely positive after transfusion of blood products but usually become negative 14 days after transfusion. Occasionally, false-positive results for IgG, IgM, and IgA can be observed as a result of platelet transfusions or immune globulin intravenous infusions. Diagnosis of congenital toxoplasmosis also can be made definitively in an infant who remains *Toxoplasma* IgG positive at 12 months of life.

Newborn infants being evaluated for toxoplasmosis also should have a complete blood cell count (CBC) with differential, liver function tests, and cerebrospinal fluid cell count, differential, protein, and glucose performed (in addition to *T gondii* PCR, above). Ophthalmologic and audiologic assessments should be conducted, and head ultrasonography (readily available but does not detect calcifications well), brain MRI (allows avoidance of radiation but may require sedation), or brain CT (the best modality for detecting calcifications) should be performed. Abdominal ultrasonography can be considered to evaluate for hepatosplenomegaly or intrahepatic calcifications.

Asymptomatic newborn infants with low suspicion for congenital toxoplasmosis but who were initially IgG positive but IgM and IgA negative should have follow-up serologic testing with IgG only at 4- to 6-week intervals until complete disappearance of transplacentally acquired IgG antibodies, usually within 6 to 12 months. In the absence of postnatal treatment, disappearance of IgG antibodies in the infant safely excludes the diagnosis of congenital toxoplasmosis.

Expert advice for evaluation and management of neonates/infants with suspected or confirmed congenital toxoplasmosis is available at: (a) the PAMF-TSL (www.sutterhealth.org/RemingtonLab; telephone 650-853-4828; email

RemingtonLab@sutterhealth.org) and (b) the Toxoplasmosis Center, University of Chicago, Chicago, IL (**www.uchicagomedicine.org/conditions-services/ophthalmology/toxoplasmosis-center**; telephone 773-834-4131; email **rmcleod@bsd.uchicago.edu**).

TREATMENT: Most cases of acquired acute *T gondii* infections in immunocompetent hosts do not require specific therapy unless: (a) infection occurs during pregnancy; (b) there is ocular involvement; or (c) symptoms are severe or persistent. Treatment of acute *T gondii* infections in immunocompromised patients is always recommended.

Neonates and infants with confirmed/strongly suspected congenital toxoplasmosis should receive oral therapy with pyrimethamine, sulfadiazine, and folinic acid (P/S/FA), usually for 12 months, as outlined in Table 3.76. While receiving pyrimethamine, neonates/infants should be monitored for development of neutropenia weekly for 4 weeks; if the absolute neutrophil count (ANC) is stable, then a CBC should be obtained every 2 weeks for 2 to 3 months and then every 3 to 4 weeks for the remainder of treatment. If the ANC decreases to <750 cells/mm³, the frequency of folinic acid administration should be increased to daily dosing and pyrimethamine therapy should be held temporarily.

Ophthalmologic evaluations should be continued at least every 3 to 6 months during the first 3 years of life for children with confirmed/probable congenital toxoplasmosis, even if the initial evaluation at or near birth was normal. Long-term neurodevelopmental evaluation also is required.

Infected neonates/infants with asymptomatic congenital toxoplasmosis with normal fetal ultrasonography and normal findings in all postnatal evaluations, including head ultrasonography or head CT/MRI, abdominal ultrasonography, eye examination, hearing test, CBC, and liver function tests, should be managed with the regimen used for symptomatic infants (P/S/FA). Treatment duration may be shorter than 12 months (but should be at least 3 months) and should be discussed with a congenital toxoplasmosis expert. Ophthalmologic and neurodevelopmental follow-up should be performed as detailed above.

Older children with active toxoplasmic chorioretinitis represent a medical emergency, and treatment should be initiated as soon as possible, as outlined in Table 3.77. Close monitoring by a retinal specialist with expertise in management of toxoplasmic eye disease and a toxoplasmosis infectious diseases expert is recommended. Treatment for eye disease usually is given for 1 to 2 weeks beyond complete resolution of all clinical signs and symptoms and usually is approximately 4 to 6 weeks total. Treatment courses up to 3 months total are required occasionally.

Immunocompetent and immunocompromised children with severe primary (acute) toxoplasmosis and **immunocompromised children with reactivation of latent (chronic) Toxoplasma infection** should receive oral therapy with P/S/FA, as outlined in Table 3.78. In patients for whom P/S/FA is not immediately available, who are allergic or unable to take P or S, or who have significant issues with absorption of oral medications, see alternative regimens listed in Table 3.78.

While children are receiving pyrimethamine, weekly monitoring with CBC and differential is recommended. If neutropenia is detected, the dose of folinic acid (leucovorin) should be increased.

Table 3.76. Treatment of Neonates/Infants With Confirmed or Strongly Suspected Congenital Toxoplasmosis

Regimen	Dosing and Duration
Pyrimethamine PLUS Sulfadiazine PLUS Folinic acid ^a	Doses: Pyrimethamine ^b : 1 mg/kg every 12 hours orally for 2 days, followed by 1 mg/kg once daily for 2–6 months (6 months should be considered for symptomatic cases), followed by 1 mg/kg once per day every Monday, Wednesday, Friday to complete a total course of 12 months PLUS Sulfadiazine: 50 mg/kg every 12 hours orally for 12 months PLUS Folinic acid (leucovorin): 10 mg/dose 3 times per week orally (during and up to 1 week after completing pyrimethamine) Duration: Treatment usually is recommended for 1 year ^c Prednisone (if CSF protein ≥1 g/dL or severe chorioretinitis in vision threatening area): 0.5 mg/kg (maximum 20 mg/dose) every 12 hours orally until CSF protein <1 g/dL or resolution of severe chorioretinitis (if prednisone is used, it should be started 48–72 hours after the initiation of anti- <i>Toxoplasma</i> therapy)

CSF indicates cerebrospinal fluid.

^aFolic acid should not be used as a substitute for folinic acid (leucovorin).

^bIn some centers in Europe, the regimen of pyrimethamine/sulfadoxine (Fansidar) every 10 days, plus folinic acid, is used for subclinical/mild forms of congenital toxoplasmosis and/or for poor compliance and/or frequent hematologic adverse effects. This regimen is used after the first 2 months of daily therapy with pyrimethamine/sulfadiazine (plus folinic acid 2 to 3 times per week). No other alternative medications have been studied adequately for treatment of congenital toxoplasmosis.

^cFor infants with delayed diagnosis of congenital toxoplasmosis (several months after birth), optimal duration of treatment should be discussed with a toxoplasmosis expert.

Primary and Secondary Prophylaxis. Current treatment recommendations and recommendations for primary and secondary toxoplasmosis prophylaxis in children and adolescents with human immunodeficiency virus (HIV) infection are available at <https://clinicalinfo.hiv.gov/en/guidelines/pediatric-opportunistic-infection/toxoplasmosis>.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

Table 3.77. Treatment of Older Children With Active Toxoplasmic Chorioretinitis

- Active toxoplasmic chorioretinitis, particularly in patients with severe eye disease in vision-threatening areas, is a medical emergency and treatment should begin as soon as possible.
- Duration: Treatment is usually given for 1 to 2 weeks beyond resolution of clinical manifestations, and usually is approximately 4–6 weeks total; prolonged treatment courses up to 3 months sometimes may be needed.
- Consultation with a retinal specialist (with experience in management of patients with toxoplasmic chorioretinitis) AND with a toxoplasmosis infectious diseases expert should be requested to assist with optimal medication dosing, duration of therapy, and necessary monitoring.

Doses:

Pyrimethamine^{a,b,c}:

Loading dose: 1 mg/kg once every 12 hours orally (maximum 50 mg/day) for 2 days, followed by maintenance dose: 1 mg/kg once per day orally (maximum 25 mg/day)

PLUS

Sulfadiazine:

Loading dose: 75 mg/kg (first dose), followed (12 hours later) by maintenance dose: 50 mg/kg every 12 hours orally (maximum 4 g/day)

PLUS

Folinic acid (leucovorin)^d:

10–20 mg/dose daily orally (during and 1 week after therapy with pyrimethamine)

Prednisone (for severe eye disease in vision-threatening areas [eg, fovea/macula]): 0.5 mg/kg every 12 hours orally (maximum 40 mg/day). If steroids are used, they should be started after 48–72 hours of anti-*Toxoplasma* therapy, with rapid taper. Use steroids at the lowest possible dose and for the shortest possible duration.

Suppressive therapy for recurrent toxoplasmic chorioretinitis:

Although there are no pediatric clinical trials for primary or secondary prophylaxis (suppressive therapy), 2 adult randomized trials in Brazil for secondary prophylaxis showed that after recurrent active toxoplasmic chorioretinitis, initiation of chronic suppressive anti-*Toxoplasma* therapy (1 double strength TMP/SMX every 2–3 days, for 12–20 months) significantly decreased the incidence of recurrences.^e

^aIf pyrimethamine tablets cannot be obtained immediately, compounded pyrimethamine can be obtained by calling Impri-mis Rx at: 844-446-6979. Treatment should change back to pyrimethamine tablets as soon as they are acquired.

^bTrimethoprim-sulfamethoxazole (TMP/SMX) can also be used when the first-line therapy (pyrimethamine/sulfadiazine) is not readily available, but ONLY until the first-line therapy with pyrimethamine/sulfadiazine/folinic acid becomes available. In those cases, the highest doses should be used (15–20 mg/kg TMP, 75–100 mg/kg SMX per day, divided every 6–8 h).

^cWhile on pyrimethamine therapy, a complete blood cell count should be performed weekly. Screening for glucose-6-phosphate dehydrogenase (G6PD) deficiency before starting sulfadiazine or TMP/SMX should be performed for patients from regions with high prevalence of severe G6PD deficiency.

^dFolic acid should not be used as a substitute for folinic acid (leucovorin).

^eSilveira C, Belfort R Jr, Muccioli C, et al. The effect of long-term intermittent trimethoprim-sulfamethoxazole treatment on recurrences of toxoplasmic retinochoroiditis. *Am J Ophthalmol*. 2002;134(1):41-46; and Fernandez Felix JP, Cavalcanti Lira RP, Santos Zaccchia R, et al. Trimethoprim-sulfamethoxazole versus placebo to reduce the risk of recurrences of toxoplasma gondii retinochoroiditis: randomized controlled clinical trial. *Am J Ophthalmol*. 2014;157(4):762-766.e1.

Table 3.78. Treatment Regimens for Children and Adolescents With Severe Primary (Acute) Toxoplasmosis^a and Immunocompromised Children and Adolescents With Severe Toxoplasmosis Attributable to Reactivation^b

Regimen	Dose
<u>PREFERRED REGIMEN</u>	
Pyrimethamine ^{c,d} (PO)	Loading dose: 1 mg/kg every 12 hours (maximum 100 mg/day) for 2 days; followed by 1 mg/kg once per day (up to 50 mg/day [if <60 kg] or up to 75 mg/day [if ≥60 kg] in older patients with severe disease)
PLUS	
Folinic acid ^e (PO)	10–20 mg/dose once per day (up to 50 mg/day) (during and 1 week after therapy with pyrimethamine)
PLUS	
Sulfadiazine (PO)	100–200 mg/kg/day divided every 6 hours (maximum 4–6 g/day for severe disease)
<u>PREFERRED ALTERNATIVE REGIMEN</u>	
Trimethoprim-sulfamethoxazole ^d (IV or PO)	
<u>ALTERNATIVE REGIMENS (WITH LIMITED DATA)</u>	
Pyrimethamine + Folinic acid + Clindamycin	
Pyrimethamine + Folinic acid + Atovaquone	
Pyrimethamine + Folinic acid + Clarithromycin	
Pyrimethamine + Folinic acid + Azithromycin	
Atovaquone + Sulfadiazine	

IV intravenous; PO, oral.

^aIncludes immunocompetent or immunocompromised children with severe acute *Toxoplasma gondii* infection, particularly in the setting of myocarditis, myositis, hepatitis, pneumonia, brain lesions, and lymphadenopathy accompanied by severe or persisting symptoms (**for drug dosing for ocular toxoplasmosis, see Table 3.77**). For toxoplasmic encephalitis in HIV patients, treatment should be continued for 6 weeks, assuming clinical improvement, followed by suppressive therapy. Longer courses of treatment may be required for extensive disease or poor response after 6 weeks (<https://clinicalinfo.hiv.gov/en/guidelines/pediatric-opportunistic-infection/toxoplasmosis>).

^bExpert advice is available at the PAMF-TSL (www.sutterhealth.org/RemingtonLab; telephone 650-853-4828; email RemingtonLab@sutterhealth.org) and the Toxoplasmosis Center, University of Chicago, Chicago, IL (www.uchicagomedicine.org/conditions-services/ophthalmology/toxoplasmosis-center; telephone 773-834-4131; email rmcleod@bsd.uchicago.edu).

^cIf pyrimethamine tablets cannot be obtained immediately, compounded pyrimethamine can be obtained by calling Impri-mis Rx at: 844-446-6979. Treatment should change back to pyrimethamine tablets as soon as they are acquired. Refer to www.daraprimdirect.com regarding access to pyrimethamine in the United States.

^dTrimethoprim-sulfamethoxazole (TMP/SMX) can also be used when the first-line therapy (pyrimethamine/sulfadiazine) is not readily available, and ONLY until the first-line therapy with pyrimethamine/sulfadiazine/folinic acid becomes avail-able. In those cases, the highest doses of TMP/SMX should be used (10–15 mg/kg/day of the TMP component, divided every 8–12 hours).

^eFolinic acid = leucovorin; folic acid must not be used as a substitute for folinic acid.

CONTROL MEASURES: Testing household or close family members of individuals diagnosed with acute *Toxoplasma* infection should be considered in settings in which there are individuals at high risk (eg, pregnant people, immunocompromised individuals, and young children in whom visual impairment associated with acute infection may be missed). HIV-infected, immunocompromised, and pregnant individuals should be counseled about avoidance of sources of *Toxoplasma* infection (see below). Pregnant people and immunocompromised patients whose serostatus for *T. gondii* is negative or unknown should avoid activities that may expose them to cat feces by avoiding changing litter boxes, gardening, and landscaping or wearing gloves while doing so and washing hands immediately thereafter. If it must be done, changing of cat litter daily decreases risk of infection, because oocysts are not infective during the first 1 to 2 days after passage. Domestic cats can be protected from infection by feeding them commercially prepared cat food and preventing them from eating undercooked meat and hunting wild rodents and birds.

Oral ingestion of viable *T. gondii* can be prevented by the following:

- Avoiding consumption of raw or undercooked meat and cooking meat—particularly pork, lamb, and venison—to an internal temperature of 65.5°C to 76.6°C (150°F–170°F), whole cuts of meat (excluding poultry) to at least 145°F (63°C), ground meat (excluding poultry) to at least 160°F (71°C), and all poultry to at least 165°F (74°C) before consumption;
- Avoiding consumption of smoked meat and meat cured in brine;
- Freezing meat to –20°C for 48 hours before consumption;
- Washing fruits and vegetables;
- Washing hands and cleaning kitchen surfaces after handling fruits, vegetables, and raw meat;
- Washing hands after gardening or other contact with soil;
- Preventing contamination of food with raw or undercooked meat or soil;
- Avoiding ingestion of raw shellfish such as oysters, clams, and mussels;
- Avoiding ingestion of raw goat milk; and
- Avoiding ingestion of untreated water, particularly in resource-limited countries.

Additional resources for health care personnel can be found at www.cdc.gov/parasites/toxoplasmosis/health_professionals/index.html.

Trichinellosis

(*Trichinella spiralis* and Other Species)

CLINICAL MANIFESTATIONS: The clinical spectrum of *Trichinella* infection ranges from inapparent infection to fulminant and fatal illness; most infections are asymptomatic. Severity of disease is proportional to the infective dose and varies with the causative species of *Trichinella*. During the first week after ingesting infected meat, a person may experience abdominal discomfort, nausea, vomiting, and/or diarrhea as excysted larvae penetrate the intestinal mucosa. Two to 8 weeks later, as progeny larvae migrate into tissues, fever, myalgia, periorbital edema, urticarial rash, and conjunctival and subungual hemorrhages may develop. Other findings may correlate with organ system involvement, for example arrhythmia and myocarditis (cardiac), meningitis and encephalitis (central nervous system), myositis (musculoskeletal), and proteinuria or hematuria (renal). Larvae may remain viable in tissues for years; calcification of some

larvae in skeletal muscle usually occurs within 6 to 24 months and may be detected using various imaging modalities.

ETIOLOGY: Infection is caused by nematodes (roundworms) of the genus *Trichinella*. *Trichinella spiralis* is the most common of the 7 species that cause human infection.

EPIDEMIOLOGY: Animal infections occur worldwide in carnivores and omnivores, especially scavengers. Humans acquire the infection following ingestion of raw or insufficiently cooked meat containing larvae of *Trichinella* species. Commercial and home-raised pork remain a source of human infections, but meats other than pork, such as venison, horse meat, and particularly meats from wild carnivorous or omnivorous game (especially bear, boar, seal, and walrus) now are the most common sources of infection. US cases have occurred after ingestion of homemade jerky and sausage. The disease is not transmitted from person to person.

The **incubation period** usually is less than 1 month.

DIAGNOSTIC TESTS: Eosinophilia of up to 70% in the setting of compatible symptoms and dietary history suggests the diagnosis. Increases in concentrations of muscle enzymes, such as creatinine phosphokinase and lactic dehydrogenase, may occur but are not always present. Larvae can be detected in suspect meat, but this is not often feasible. Encapsulated larvae in a skeletal muscle biopsy specimen (particularly deltoid and gastrocnemius) are visible under light microscopy beginning 2 weeks after infection by examining hematoxylin-eosin-stained slides or sediment from digested muscle tissue. Serologic testing is available through the Centers for Disease Control and Prevention, some state reference laboratories, and commercial laboratories. Serum antibodies are detectable at 3 or more weeks postinfection and may remain for years. Testing of paired acute and convalescent serum specimens showing an increase in titer is diagnostic, but a single positive test result in the appropriate clinical setting makes the diagnosis likely.

TREATMENT: Albendazole and mebendazole are each recommended for treatment of acute trichinellosis (see Drugs for Parasitic Infections, p 1068), although anthelmintics typically do not kill larvae that have already encysted within muscles. Administration of corticosteroids with or without anthelmintics is recommended when systemic symptoms are severe. Corticosteroids can be lifesaving when the central nervous system or heart is involved.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended. There is no person-to-person spread.

CONTROL MEASURES: Transmission to pigs can be prevented by not feeding them garbage, by preventing cannibalism among animals, and by effective rat control. The public should be educated about the importance of cooking pork and wild game meat thoroughly. Curing, drying, smoking, and microwaving do not kill *Trichinella* worms reliably. Specific recommendations include the following:

- For whole cuts of meat (excluding poultry and wild game): cook to at least 145°F (63°C) as measured with a food thermometer placed in the thickest part of the meat, then allow the meat to rest for 3 minutes before carving or consuming.
- For ground meat (including wild game, excluding poultry): cook to at least 160°F (71°C); ground meats do not require a rest time. Clean meat grinders thoroughly after each use.

- For all wild game (whole cuts and ground): cook to at least 160°F (71°C). Freezing pork less than 6 inches thick at 5°F (−15°C) for 20 days kills *T spiralis*. *Trichinella* organisms in wild animals, such as bears and raccoons, are resistant to freezing. For people who have ingested undercooked meat known to be contaminated with *Trichinella* organisms, preemptive therapy with albendazole or mebendazole may be considered if initiated within 6 days of exposure.

Public Health Reporting. Trichinellosis is a notifiable disease (see Appendix III: Nationally Notifiable Infectious Diseases in the United States, p 1141).

***Trichomonas vaginalis* Infections**

(Trichomoniasis)

CLINICAL MANIFESTATIONS: A *Trichomonas vaginalis* (TV) infection, which has been described as the most common nonviral sexually transmitted infection (STI) affecting approximately 3.7 million people in the United States, is asymptomatic in 70% to 85% of infected individuals. Untreated infections may persist for months to years. Clinical manifestations in symptomatic pubertal or postpubertal females may include a diffuse vaginal discharge, odor, and vulvovaginal pruritus and irritation.¹ Dysuria and, less often, lower abdominal pain can occur. Vaginal discharge may be any color but classically is yellow-green, frothy, and malodorous. The vulva and vaginal mucosa can be erythematous and edematous. The cervix can be inflamed and sometimes is covered with numerous punctate cervical hemorrhages and swollen papillae, referred to as “strawberry” cervix. This finding occurs in fewer than 5% of infected female patients, is most often seen on colposcopy, and is highly suggestive of trichomoniasis. Clinical manifestations in symptomatic male individuals include urethritis and, rarely, epididymitis or prostatitis. Reinfection is common, and resistance to treatment is uncommon but increasing. Rectal and oral infections are uncommon.

TV infections in pregnant people have been associated with increased risks of premature rupture of the membranes and preterm delivery, although direct causation has not been clearly established. Perinatal infection may occur in up to 5% of neonates born to infected individuals. TV in female newborn infants may cause vaginal discharge during the first weeks of life but usually is self-limited. Respiratory infections in newborn infants may occur as well.

ETIOLOGY: *T vaginalis* is a flagellated protozoan approximately the size of a leukocyte. It requires adherence to host cells for survival.

EPIDEMIOLOGY: Among sexually active female participants in the 2013–2016 cycles of the National Health and Nutrition Examination Survey, the estimated prevalence was 0.7% among 14- through 19-year-olds and 2.7% and 20- through 29-year-olds. Unlike chlamydia and gonorrhea, TV prevalence rates were low among female participants 14 through 19 years of age and high among female participants 20 through 29 years and did not differ significantly among women 30 through 39 years of age or 40 through 49 years of age. Overall prevalence was almost 4-fold higher among female than male individuals and almost 11-fold higher among non-Hispanic Black female individuals than non-Hispanic white female individuals. Prevalence was higher among people with lower family income, those with less education, and

¹ The terms female, male, women, and men refer to sex assigned at birth.

those who were unmarried. Among female participant, younger age at coitarche and higher number of sex partners were associated with higher TV prevalence. Female individuals with bacterial vaginosis (BV) are at higher risk for TV. Male partners of female individuals with TV are likely to have infection, although the prevalence of trichomoniasis in men who have sex with men is low. Transmission results almost exclusively from sexual contact. The presence of TV in a child or preadolescent beyond the perinatal period is considered indicative of sexual abuse (see STI Evaluation After Sexual Assault of a Prepubertal Child, p 184, and Table 2.5, p 183). TV infection can increase both the acquisition and transmission of human immunodeficiency virus (HIV).

The **incubation period** averages 1 week but ranges from 5 to 28 days.

DIAGNOSTIC TESTS¹: Wet mount microscopy of vaginal discharge traditionally has been used as the preferred diagnostic test for TV among female individuals, but its sensitivity is low (44%–68%) compared with culture. TV culture in Diamond media or other trichomonas-specific culture systems is a specific method of diagnosis in female patients with a sensitivity of 44% to 75% and specificity of nearly 100%. In female patients, vaginal secretions are the preferred specimen type for culture, because urine culture is less sensitive. In male patients, culture specimens require a urethral swab, urine sediment, and/or semen specimen.

In contrast, nucleic acid amplification tests (NAATs) are highly sensitive, detecting more TV infections than wet-mount microscopy among women. Sensitivities and specificities generally are in the 95% to 100% range. TV NAATs can be used on various specimens including vaginal swab (self- or provider-collected), endocervical swab, urine, and liquid Pap smear specimens from female patients and urine specimens from male patients. Some TV NAAT platforms also test for chlamydia or gonorrhea. Other TV NAATs test for pathogens causing vaginitis, such as BV-associated bacteria and *Candida* species. The GeneXpert TV (Cepheid) is a moderately complex rapid test that can be performed in less than 1 hour as a point-of-care (POC) test with a sensitivity and specificity of 99.5% to 100% and 99.4% to 99.9%, respectively.

There are also antigen-detection tests that use immunochromatographic capillary flow dipstick technology that have high sensitivity and specificity.

TREATMENT¹: The recommended treatment for TV infection in female patients is metronidazole, 500 mg, orally, twice daily for 7 days. In male patients, the recommended treatment is metronidazole 2 g, orally in a single dose. An alternative regimen in both female and male individuals is tinidazole 2 g, orally, in a single dose. Tinidazole is generally more expensive, reaches higher concentrations in serum and the genitourinary tract, has a longer half-life than metronidazole (12.5 hours versus 7.3 hours), and has fewer gastrointestinal adverse effects. Metronidazole gel does not reach therapeutic concentrations in the urethra and perivaginal glands. Because it is less efficacious than oral metronidazole, it is not recommended. Secnidazole is also approved by the US Food and Drug Administration for treatment of TV in people 12 years and older.

¹ Centers for Disease Control and Prevention. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(RR-4):1-187. Available at: www.cdc.gov/std/treatment-guidelines/trichomoniasis.htm

A recurrent infection can result from reinfection from an untreated sex partner, treatment failure because of antimicrobial resistance, or lack of adherence to therapy. In cases of persistent or recurrent trichomoniasis, retesting with culture is preferred. If NAAT is used, it should not be conducted before 3 weeks after treatment completion because of possible detection of residual nucleic acid from the prior infection that is not clinically relevant.

If treatment failure occurs in a female patient after completing a 7-day course of metronidazole and the patient has been reexposed to an untreated partner, a repeat course of the same regimen is recommended. If there has been no reexposure, the female patient should be treated with 2 g of metronidazole or tinidazole, once daily, for 7 days. If a male patient is still infected with TV after a single dose of 2 g of metronidazole and has been reexposed to an untreated partner, the patient should be given another single dose of 2 g of metronidazole. If there has been no reexposure, the male patient should be given a course of metronidazole, 500 mg, twice daily for 7 days. Nitroimidazole-resistant TV is concerning, because few alternatives to standard therapy exist. For people who are experiencing persistent infection not attributable to reexposure, clinicians should request a kit from the Centers for Disease Control and Prevention (CDC) to perform drug susceptibility testing (www.cdc.gov/laboratory/specimen-submission/detail.html?CDC_TestCode=CDC-10239). Treatment can then be determined based on the test results. The CDC can perform susceptibility testing for people with clinical treatment failure and can provide guidance regarding treatment in cases of nitroimidazole resistance. Treatments for infections caused by antimicrobial-resistant TV strains can include metronidazole or tinidazole 2 g daily for 7 days. If a person has treatment failure after the 7-day regimen of high-dose oral metronidazole or tinidazole, high-dose oral tinidazole, 2 g daily, plus intravaginal tinidazole, 500 mg, 2 times/day for 14 days, has been successful among female patients. If this regimen fails, high-dose oral tinidazole (1 g, 3 times/day) plus intravaginal paromomycin (4 g of 6.25% intravaginal paromomycin cream nightly) for 14 days should be considered.

Pregnancy and Lactation. TV infection in pregnant people has been associated with adverse pregnancy outcomes, particularly premature rupture of membranes, preterm delivery, and delivery of an infant with low birth weight. In symptomatic infected pregnant people, regardless of pregnancy stage, consideration should be given to treatment with metronidazole. Although metronidazole crosses the placenta, data indicate that it poses a low risk to the developing fetus. No evidence of teratogenicity or mutagenic effects among infants has been found in multiple cross-sectional and cohort studies among pregnant people examining single-dose (2 g) and multidose metronidazole regimens. Metronidazole is secreted in human milk. With oral therapy of the lactating parent, breastfed infants receive metronidazole in doses that are lower than those used to treat infections in infants, although the active metabolite adds to the total infant exposure. Multiple reported case series identified no evidence of metronidazole-associated adverse effects for breastfed infants. Data from studies involving human subjects are limited regarding use of tinidazole in pregnancy; however, animal data suggest this drug poses moderate risk. Thus, tinidazole should be avoided in pregnant people, and breastfeeding should be deferred for 72 hours following a single 2-g dose of tinidazole.

Neonatal. For newborn infants, infection with TV acquired perinatally is self-limited, and treatment generally is not recommended.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: Measures to prevent STIs, particularly the consistent and correct use of condoms, are indicated. Patients should be instructed to avoid sexual activity until they and their sexual partners are treated and there is resolution of symptoms. Testing for other STIs including HIV, syphilis, gonorrhea, and chlamydia should be performed.

Follow-up. Because of the high rate of trichomoniasis reinfection among female individuals, retesting for TV is recommended for all sexually active female patients within 3 months following initial treatment, regardless of whether they are symptomatic or believe their sex partners were treated. If retesting at 3 months is not possible, clinicians should retest at the next presentation for medical care within 12 months following initial treatment. Data are insufficient to support retesting male patients.

Routine Screening Tests.¹ Although routine TV screening of asymptomatic adolescents is not recommended, screening can be considered for people receiving care in high-prevalence settings (eg, STI clinics and correctional facilities) and for asymptomatic women at high risk of infection. Risk factors that may put female individuals at higher risk of TV include new or multiple partners, exchanging sex for payment, illicit drug use, or an STI history. The CDC recommends screening for TV in all female individuals with HIV infection at least annually and at their first prenatal visit.

Management of Sexual Partners. All people with a known exposure to TV infection should be treated routinely, regardless of a diagnostic test result. Expedited partner therapy might have a role in partner management for trichomoniasis and may be used in states where this approach is permissible.

Trichuriasis (Whipworm Infection)

CLINICAL MANIFESTATIONS: Disease caused by the whipworm *Trichuris trichiura* generally is proportional to the intensity of the infection. Most infected children are asymptomatic, but those with heavy infestations may develop colitis that mimics inflammatory bowel disease, with signs and symptoms that include chronic abdominal pain and diarrhea, physical growth restriction, and clubbing. A more serious condition is *Trichuris* dysentery syndrome, which is characterized by severe abdominal pain, tenesmus, bloody diarrhea, and occasionally rectal prolapse. Children may have anemia and peripheral eosinophilia.

ETIOLOGY: *T trichiura*, the human whipworm, is the causative agent of trichuriasis. Adult worms are 30 to 50 mm long with a large, thread-like anterior end that embeds in the mucosa of the large intestine. Adult worms typically reside in the cecum and ascending colon; with heavy infection, worms may extend further into the colon and rectum.

¹ American Academy of Pediatrics, Committee on Adolescence; Society for Adolescent Health and Medicine. Screening for nonviral sexually transmitted infections in adolescents and young adults. *Pediatrics*. 2014;134(1):e302-e311

EPIDEMIOLOGY: *T trichiura* is the second most prevalent soil-transmitted helminth in the world, with approximately 600 to 800 million people infected worldwide, most in tropical regions that lack proper sanitation infrastructure. It is frequently coendemic with *Ascaris* and hookworm species. Humans are the natural reservoir. Eggs excreted in moist soil require a range of 10 days to 4 weeks of incubation, depending on temperature, before they are infectious. Children become infected by accidental ingestion of infective eggs in food or on hands contaminated with soil. The disease is not communicable directly from person to person.

The time between infection and appearance of eggs in the stool (**incubation period**) is approximately 12 weeks; worms may live 1 to 3 years or more.

DIAGNOSTIC TESTS: Quantitative techniques like the Kato-Katz, McMaster, and FLOTAC methods are used typically in research settings to quantify fecal egg excretion as a measure of infection intensity. Direct microscopic visualization of eggs using stool concentrating techniques is recommended in routine clinical settings, and for screening at-risk populations such as immigrants, refugees, and international adoptees. Adult worms may be seen on proctoscopy or colonoscopy.

TREATMENT: Mebendazole and albendazole are considered first-line therapies in the treatment of trichuriasis, although cure rates for both are low. Combination therapy with albendazole plus ivermectin is also a reasonable treatment approach. The recommended duration of therapy is 3 days, although a longer course (5–7 days) of albendazole may be warranted for heavy infections (see Drugs for Parasitic Infections, p 1068).

Stool specimens should be reexamined approximately 2 weeks after therapy to document cure. Those in whom therapy fails should be retreated, with consideration of combination therapy (albendazole plus ivermectin). Iron supplements should be prescribed to patients with severe or symptomatic anemia.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended; there is no direct person-to-person transmission.

CONTROL MEASURES: Proper disposal of contaminated feces is the most effective means of control for whipworm and other soil-transmitted helminths. Depending on prevalence, annual or biannual administration of anthelmintics in communities with endemic *Trichuris* burden is currently recommended by the World Health Organization for control of soil-transmitted helminth infections, including *T trichiura*.

African Trypanosomiasis (Sleeping Sickness)

CLINICAL MANIFESTATIONS: The clinical course of human African trypanosomiasis has 2 stages: the hemolymphatic stage, in which the parasite multiplies in subcutaneous tissues, lymph, and blood; and the neurologic stage, after the parasite crosses the blood-brain barrier and infects the central nervous system (CNS). The rapidity of disease progression and clinical manifestations vary with the infecting subspecies. With *Trypanosoma brucei gambiense* infection (found in western and central Africa), initial symptoms may be mild and include intermittent fever, headaches, muscle and joint aches, and malaise. Pruritus, rash, hepatosplenomegaly, weight loss, and lymphadenopathy (mainly posterior cervical [Winterbottom sign] but also possible in axillary,

inguinal, and epitrochlear areas) can occur. CNS involvement typically develops after 1 to 2 years with development of confusion, behavioral changes, cachexia, headache, sensory disturbances, poor coordination and movement disorders, seizures, tremors, speech disorders (eg, dysarthria, logorrhea), hallucinations, delusions, and daytime somnolence followed by night-time insomnia. Trypanosome infiltration of endocrine organs (mainly thyroid and adrenal glands) and the heart may lead to disruptions of hormonal secretions and mild perimyocarditis.

Symptoms of *Trypanosoma brucei rhodesiense* infection (found in eastern and southern Africa) are similar to those of *T brucei gambiense* infection. An inoculation chancre may develop at the site of the tsetse fly bite. Initial manifestations include high fever, headaches, pruritis, lymphadenopathy (more often submandibular, axillary, and inguinal), rash, and muscle and joint aches. Thyroid dysfunction, adrenal insufficiency, and hypogonadism are found more frequently in *T brucei rhodesiense* infection and myopericarditis may be earlier and more severe. Edema is reported more frequently in *T brucei rhodesiense* infection, and liver involvement with hepatomegaly is usually moderate, sometimes with ascites.

Clinical meningoencephalitis can develop after onset of the untreated systemic illness caused by both *Trypanosoma* subspecies. As the disease progresses, severe but less frequent complications can include renal failure requiring dialysis, multiorgan failure, disseminated intravascular coagulopathy, and coma. Both forms of African trypanosomiasis have high fatality rates; without treatment, infected patients usually die within 6 months after clinical onset of disease caused by *T brucei rhodesiense* and within 2 to 3 years from disease caused by *T brucei gambiense*.

ETIOLOGY: Human African trypanosomiasis (sleeping sickness) is caused by *Trypanosoma brucei* subspecies, which are protozoan parasites transmitted by blood-feeding tsetse flies. The west and central African (Gambian) form is caused by *T brucei gambiense*, and the east and southern African (Rhodesian) form is caused by *T brucei rhodesiense*. Both are extracellular protozoan hemoflagellates that live in blood and tissue of the human host.

EPIDEMIOLOGY: The number of cases of human African trypanosomiasis is decreasing, with 663 cases reported to the World Health Organization (WHO) in 2020, a 98% reduction since 2000. Most reported cases worldwide (>95%) are caused by *T brucei gambiense*. There are occasional reported cases of African trypanosomiasis in the United States, typically in returning travelers who became infected with *T brucei rhodesiense* in East Africa. Transmission of *T brucei* subspecies is confined to an area in Africa between the latitudes of 14° north and 29° south, corresponding to the distribution of the tsetse fly vector (*Glossina* species), although many tsetse-infested areas are free of disease risk. Humans are the main reservoir of *T brucei gambiense* in West and Central Africa, although the parasite sometimes can be found in domestic animals, such as dogs and pigs. In East Africa, wild animals, such as antelope, bush buck, and hartebeest, constitute the major reservoirs for sporadic infections with *T brucei rhodesiense*, although cattle serve as reservoir hosts in local outbreaks. *T brucei* subspecies also can be transmitted congenitally. Accidental infections in laboratories have occurred as a result of pricks with contaminated needles.

The **incubation period** for acute disease symptoms from *T brucei rhodesiense* infection ranges from 3 to 21 days, and for most cases is 5 to 14 days. For *T brucei gambiense* infection, the **incubation period** for acute disease symptoms usually is longer

but is not well defined; it is generally <1 month for travelers from countries without endemic disease.

DIAGNOSTIC TESTS: Diagnosis is made by identification of trypanosomes in specimens of blood, cerebrospinal fluid (CSF), or fluid aspirated from a chancre or lymph node, or by inoculation of susceptible laboratory animals (mice) with heparinized blood in the case of *T brucei rhodesiense* infection. Examination of CSF is critical to management, and all patients diagnosed in the United States should undergo lumbar puncture; concentration methods (such as the double centrifugation or modified single centrifugation techniques) typically should be used. Concentration and Giemsa staining of the buffy coat layer of peripheral blood are easier for *T brucei rhodesiense*, because the density of organisms in circulating blood is higher than for *T brucei gambiense*. Wet preparations of the buffy coat and of concentrated CSF sediment should be examined within a few minutes for motile trypanosomes. *T brucei gambiense* is more likely to be found in lymph node aspirates than in blood. The most widely used criteria for stage determination to assess CNS involvement include identification of trypanosomes in CSF or a CSF white blood cell count of 6 cells/ μ L or higher; elevated CSF neopterin and an increase in intrathecal immunoglobulin M also may suggest second-stage disease. Serologic testing for antibodies to *T brucei gambiense* is available outside the United States and typically is used only for screening purposes to help identify suspect cases; there is no comparable serologic screening test for *T brucei rhodesiense*.

TREATMENT: The choice of drug(s) used for treatment depends on the type and stage of African trypanosomiasis (www.cdc.gov/parasites/sleepingsickness/index.html). When no evidence of CNS involvement is present, the drugs of choice for the acute hemolymphatic stage of infection are pentamidine for *T brucei gambiense* infection and suramin for *T brucei rhodesiense* infection (pentamidine is also effective, although less well documented). For treatment of *T brucei gambiense* infection with CNS involvement, the drug of choice is eflornithine in combination with nifurtimox, or eflornithine alone if nifurtimox is not available or contraindicated; for *T brucei rhodesiense* infection with CNS involvement, the drug of choice is melarsoprol (eflornithine is not effective for CNS treatment of *T brucei rhodesiense* infection). Melarsoprol encephalopathy may be reduced in severity by pretreatment with corticosteroids. Eflornithine is not approved by the US Food and Drug Administration (FDA) but is available through the Centers for Disease Control and Prevention (CDC) under an individual provider investigational new drug application from the FDA. Oral fexinidazole, a nitroimidazole adapted for use in rural health facilities in Africa to be administered under directly observed therapy in selected patients, was approved recently (including by the FDA, in 2021) for children ≥ 6 years of age and ≥ 20 kg for the treatment of both first-stage (hemolymphatic) and second-stage (meningoencephalitic) gambiense trypanosomiasis. Because of decreased efficacy observed in patients with severe second-stage human African trypanosomiasis (CSF white blood cell count >100 cells/ μ L) attributable to *T brucei gambiense* disease, fexinidazole tablets should be used only if there are no other available treatment options. Suramin, eflornithine, and melarsoprol can be obtained from the CDC (phone: 404-718-4745). As of 2023, fexinidazole is not available commercially or through the CDC in the United States. Consultation with a specialist familiar with the disease and its treatment is recommended. Patients who have had CNS involvement should undergo repeated follow-up CSF examinations every 6 months for 2 years because of the risk of relapse. The optimal approach to treatment of relapse is

uncertain. The WHO has developed interim updated guidelines for the treatment of human African trypanosomiasis caused by *T brucei gambiense* (apps.who.int/iris/bitstream/handle/10665/326178/9789241550567-eng.pdf?ua=1). These guidelines allow for certain patients (older children and adults without clinically apparent severe disease) to forego a lumbar puncture when oral fexinidazole is an option and certain conditions are met by the patient.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: Travelers to areas with endemic infection should avoid known foci of sleeping sickness and tsetse fly infestation and should minimize fly bites by wearing long-sleeved shirts and pants of medium-weight material in neutral colors. Avoid light-weight cloth that tsetse flies can bite through and bright or dark colors that attract the flies (especially blue and black). Newborn infants whose birthing parent is infected should be examined clinically and their blood should be tested for trypanosomes; breastfeeding may continue during treatment.

American Trypanosomiasis

(Chagas Disease)

CLINICAL MANIFESTATIONS: The acute phase of *Trypanosoma cruzi* infection (Chagas disease) lasts 2 to 3 months, followed by the chronic phase that, in the absence of successful antiparasitic treatment, is lifelong. The acute phase commonly is asymptomatic or characterized by mild, nonspecific symptoms. When disease is acquired by oral transmission, patients are more likely to exhibit symptoms of febrile illness with higher morbidity and mortality. In the minority of patients with symptomatic acute-phase infection, fever, edema, cutaneous rash, myalgia, pallor, malaise, lymphadenopathy, and hepatosplenomegaly may develop. Meningoencephalitis and/or acute myocarditis are rare manifestations. Unilateral edema of the eyelids, known as the Romaña sign, may occur if the portal of entry is the conjunctiva. The edematous skin may be violaceous and associated with conjunctivitis and enlargement of the ipsilateral preauricular lymph node. In some patients, a red, indurated nodule known as a chagoma develops at the site of the original inoculation, usually on the face or arms.

Symptoms of acute Chagas disease can resolve without treatment within 3 months, and patients pass into the chronic phase of the infection. Most people with chronic *T cruzi* infection have no signs or symptoms and are said to have the indeterminate form of chronic Chagas disease. Serious progressive sequelae affecting the heart and/or gastrointestinal tract develop in an estimated 20% to 30% of cases years to decades after the initial infection (called determinate forms of chronic Chagas disease). Chagas cardiomyopathy is characterized by conduction system abnormalities, especially right bundle branch block and ventricular arrhythmias, and may progress to dilated cardiomyopathy and congestive heart failure. Patients with Chagas cardiomyopathy may die suddenly from ventricular arrhythmias, complete heart block, or embolic phenomena; death also may occur from intractable congestive heart failure. Less commonly, patients with chronic Chagas disease may develop digestive disease with dilatation of the colon and/or esophagus with swallowing difficulties accompanied by severe weight loss.

Congenital Chagas disease occurs in an estimated 1% to 5% of infants born to infected people in the United States and may be characterized by low birth weight,

hepatosplenomegaly, and anemia. Myocarditis, pneumonitis, and/or meningoencephalitis with seizures and tremors are rare. Most infants with congenital *T. cruzi* infection have no signs or symptoms of disease.

Reactivation of chronic *T. cruzi* infection with parasitemia may be life threatening and may occur in immunocompromised people, including people infected with human immunodeficiency virus and those who are immunosuppressed after transplantation.

ETIOLOGY: *Trypanosoma cruzi*, a protozoan hemoflagellate, causes American trypanosomiasis (Chagas disease). Chagas disease is named after the Brazilian physician Carlos Chagas, who discovered it in 1909.

EPIDEMOLOGY: Parasites are transmitted in feces of infected triatomine insects (sometimes called “kissing bugs,” a type of reduviid; local Spanish/Portuguese names include vinchuca, chinche picuda, or barbeiro). When found indoors, they tend to be located in pet areas, under bedding, and in areas of rodent infestation. The bugs defecate during or after taking a blood meal. The bitten person is inoculated through inadvertent rubbing of insect feces containing the parasite into the site of the bite through the harmed skin or mucous membranes of the eye. The parasite also can be transmitted congenitally, during solid organ transplantation, through blood transfusion, and by ingestion of food or drink contaminated by the vector’s excreta. Accidental laboratory infections can result from handling parasite cultures or blood from infected people or laboratory animals, usually through needlestick injuries. Vector-borne transmission of the disease is limited to the Western Hemisphere, predominantly Mexico and Central and South America.

In the United States, 11 species of kissing bugs have been identified, and most have been found to be infected naturally with *T. cruzi*. Triatomines have been found throughout the southern half of the United States, from California to Florida and as far north as Illinois and Pennsylvania. Significant numbers of wild animals are infected, including opossums, armadillos, wood rats, and raccoons. Animals usually acquire the parasite by eating infected triatomines. Rare vector-borne cases of Chagas disease have been noted in the United States. Most *T. cruzi*-infected individuals in the United States are immigrants from areas of Latin America with endemic infection.

It is estimated that more than 300 000 individuals with *T. cruzi* infection live in the United States, including about 40 000 people capable of becoming pregnant. Assuming a 1% to 5% risk of congenital transmission, based on estimates of infection in pregnant people, approximately 63 to 315 infants are born with Chagas disease in the United States every year. Transfusion- and transplantation-associated cases have been documented in the United States.

The disease is an important cause of morbidity and death in Latin America, where as many as 6 million people may be infected, of whom approximately 20% to 30% either have or will develop cardiomyopathy and/or gastrointestinal tract disorders (www.paho.org/en/topics/chagas-disease). Many individuals with the disease remain undiagnosed, with some estimates as high as 95%.

The **incubation period** for the acute phase of disease is 1 to 2 weeks or longer. Chronic manifestations do not appear for years to decades.

DIAGNOSTIC TESTS: During the acute phase of disease, the parasite is demonstrable in blood specimens by Giemsa staining after a concentration technique or in direct wet-mount or buffy coat preparations. Molecular detection techniques (available at the Centers for Disease Control and Prevention [CDC]) also have high sensitivity

in the acute phase. Next-generation diagnostic techniques using cell-free pathogen DNA are commercially available. The chronic phase of *T. cruzi* infection is characterized by low-level intermittent parasitemia. Diagnosis in the chronic phase relies on serologic tests to demonstrate immunoglobulin (Ig) G antibodies against *T. cruzi*. Serologic tests include indirect immunofluorescence, enzyme-linked immunosorbent assays, immunochromatographic testing, hemagglutination inhibition, and chemiluminescence microparticle immunoassays (CMIA); no single serologic test is sufficiently sensitive or specific to confirm a diagnosis of chronic *T. cruzi* infection. The Pan American Health Organization and the World Health Organization recommend that samples be tested using 2 diagnostic assays of different formats before treatment decisions are made.

The diagnosis of congenital Chagas disease can be made during the first 3 months of life by identification of motile trypomastigotes by direct microscopy of fresh anticoagulated blood specimens or by a nucleic acid amplification test (NAAT), which is a useful tool in infants and has higher sensitivity than serologic testing. If an infant is not tested before 3 months of age, serologic testing should be performed after 9 months of age once serum immunoglobulin (Ig) G measurements are expected to reflect infant response rather than transplacentally acquired antibody. The CDC has developed algorithms for evaluation of Chagas disease in infants <3 months (Fig 3.20) and ≥3 months (Fig 3.21).

FIG 3.20. EVALUATION OF CONGENITAL CHAGAS DISEASE (CCD): INFANT <3 MONTHS OF AGE^a

^aInfant whose birthing parent has suspected or confirmed Chagas disease **OR** infant with symptoms of congenital Chagas disease in at-risk birthing parent whose serologic status is unknown.

FIG 3.21. EVALUATION OF CONGENITAL CHAGAS DISEASE (CCD): INFANT ≥ 3 MONTHS OF AGE

Adapted from: www.cdc.gov/parasites/chagas/health_professionals/congenital_chagas.html.

Some countries have congenital Chagas disease screening programs that combine (1) screening of the birthing parent; and (2) microscopic examination of cord blood from infants whose birthing parent is seropositive.

Low sensitivity of some screening tests and low rates of follow-up likely lead to underestimation of infection rates. Diagnostic testing and consultation are available from the CDC Division of Parasitic Diseases and Malaria (phone: 404-718-4745; email: parasites@cdc.gov; CDC Emergency Operator [after business hours and on weekends]: 770-488-7100).

TREATMENT: The only drugs with proven efficacy are benznidazole and nifurtimox (see *Drugs for Parasitic Infections*, p 1068). Benznidazole was approved in 2017 by the US Food and Drug Administration (FDA) for use in children 2 to 12 years of age and nifurtimox in 2020 for treatment of Chagas disease in children from birth to 18 years of age. The recommended treatment courses are 60 days.

Antitrypanosomal treatment is recommended for all cases of acute and congenital Chagas disease, reactivated infection attributable to immunosuppression, and chronic *T. cruzi* infection in children younger than 18 years. Treatment of chronic *T. cruzi* infection in adults without advanced cardiomyopathy generally is recommended. The efficacy of either agent appears high if given soon after infection, but wanes in the setting of longer infection or advancing age, during which adverse medication effects are also more common.

Trypanocidal therapy with benznidazole in patients with established Chagas cardiomyopathy significantly reduces serum parasite detection by NAAT but does not reduce cardiac clinical deterioration or death significantly through 5 years of follow-up

and, therefore, is not recommended. Both drugs have significant adverse event profiles. The only currently recognized test of cure is reversion to negative serologic status, which may take years in chronic infection. Careful consideration of potential risks and benefits in consultation with an expert in treatment of the disease or with CDC may be necessary, especially for patients in whom chronic infection is diagnosed and/or who do not fall under a clearly recommended treatment category.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions should be followed.

CONTROL MEASURES: Risk to travelers is low. Travelers to areas with endemic infection should avoid contact with triatomine bugs by avoiding habitation in buildings vulnerable to infestation, particularly those constructed of mud, palm thatch, or adobe brick. The use of insecticide-impregnated bed nets, tucked under the mattress on all sides, also may be beneficial. Camping or sleeping outdoors in areas with endemic transmission is not recommended. Travelers to regions with endemic infection also should avoid ingestion of unpasteurized juices, such as sugar cane, guava, or açai palm fruit juice, which have been linked to oral transmission of Chagas disease. Diagnostic testing should be performed on members of households with an infected patient if they have had exposure to the vector similar to that of the patient. All children of a birthing parent with *T. cruzi* infection should be tested for Chagas disease.

Education about the mode of spread and methods of prevention is warranted in areas with endemic infection. Homes should be examined for the presence of the vectors, and if found, measures to eliminate the vector should be taken.

People with known *T. cruzi* infection should not donate blood. Most US blood collection agencies started screening for *T. cruzi* infection in 2007; final guidance to all blood collection agencies for appropriate use of serologic tests to screen blood donors for *T. cruzi* infection was issued by the FDA in December 2010.

Tuberculosis

CLINICAL MANIFESTATIONS: Tuberculosis (TB) disease is caused by organisms of the *Mycobacterium tuberculosis* complex. Most infections caused by *M. tuberculosis* complex in children and adolescents are asymptomatic. When pulmonary TB occurs, clinical manifestations most often appear 1 month to 2 years after infection and include fever, weight loss or poor weight gain, cough, night sweats, and chills. Chest radiographic findings rarely are specific for TB and include lymphadenopathy of the hilar, subcarinal, paratracheal, or mediastinal nodes; atelectasis or infiltrate of a segment or lobe; pleural effusion that can conceal small interstitial lesions; interstitial cavities; or miliary-pattern infiltrates. In selected instances, computed tomography or magnetic resonance imaging of the chest can clarify nonspecific or subtle radiographic findings. Although cavitation is a typical presentation of TB in adults (and sometimes in adolescents), cavitation is uncommon in childhood TB. Necrosis and cavitation, however, can result from a progressive primary focus in very young or immunocompromised patients and in patients with lymphobronchial disease. Extrapulmonary manifestations include meningitis and granulomatous inflammation of the lymph nodes, bones, joints, skin, and middle ear and mastoid. Gastrointestinal tract TB can mimic inflammatory bowel disease. Renal TB is unusual in younger children but can occur in adolescents. In addition, chronic abdominal pain with peritonitis and intermittent partial intestinal

obstruction can be present in disease caused by *Mycobacterium bovis*. Congenital TB can mimic neonatal sepsis, or the infant may come to medical attention in the first 90 days of life with bronchopneumonia and/or hepatosplenomegaly. Clinical findings in patients with drug-resistant TB disease are indistinguishable from manifestations in patients with drug-susceptible disease.

ETIOLOGY: The causative agent is *M tuberculosis* complex, a group of closely related acid-fast bacilli: *M tuberculosis*, *M bovis*, *Mycobacterium africanum*, and a few additional species infrequently associated with human infection. *M africanum* is rare in the United States, so clinical laboratories do not distinguish it routinely, and treatment recommendations are the same as for *M tuberculosis*. *M bovis* can be distinguished from *M tuberculosis* in reference laboratories, and although the spectrum of illness caused by *M bovis* is similar to that of *M tuberculosis*, the epidemiology, treatment, and prevention are different, as detailed later in the chapter.

Definitions:

- **Bacille Calmette-Guérin (BCG)** is a live attenuated vaccine strain of *M bovis*. BCG vaccine rarely is administered to children in the United States but is one of the most widely used vaccines in the world. An isolate of BCG can be distinguished from wild-type *M bovis* only in a reference laboratory.
- **Positive tuberculin skin test (TST) result.** A positive TST result (see Table 3.79) indicates possible infection with *M tuberculosis* complex. Tuberculin reactivity appears 2 to 10 weeks after initial infection; the median interval is 3 to 4 weeks (see Tuberculin Skin Test, p 892). BCG immunization can produce a positive TST result (see Diagnostic Tests, Testing for *M tuberculosis* Infection, p 892).
- **Positive interferon-gamma release assay (IGRA) result.** A positive IGRA result indicates possible infection with *M tuberculosis* complex. IGRAs measure ex vivo interferon-gamma production from T lymphocytes in response to stimulation with antigens mostly specific to *M tuberculosis* complex, including *M tuberculosis* and *M bovis*. The antigens used in IGRAs are not found in BCG or most pathogenic nontuberculous mycobacteria (eg, are not found in *Mycobacterium avium* complex, but are found in *Mycobacterium kansasii*, *Mycobacterium szulgai*, and *Mycobacterium marinum*).
- **TB infection (TBI)** is defined as *M tuberculosis* complex bacteria present in the body. Most commonly, TBI is used to describe infection in a person who has no symptoms or signs of disease and chest radiograph findings that are normal or reveal evidence of healed infection (eg, calcification in the lung, lymph nodes, or both) and a positive TST or IGRA result. This situation is also referred to as latent TB infection.
- **TB disease** is illness in a person with infection attributable to *M tuberculosis* complex in whom symptoms, signs, or radiographic manifestations caused by *M tuberculosis* complex are apparent; disease can be pulmonary, extrapulmonary, or both.
- **Multidrug-resistant (MDR) *M tuberculosis*** is a strain of *M tuberculosis* that is resistant to at least isoniazid and rifampin.
- **Extensively drug-resistant (XDR) *M tuberculosis*** is a strain of *M tuberculosis* that is resistant to isoniazid, rifampin, any fluoroquinolone, and either bedaquiline or linezolid (or both).
- **Pre-XDR *M tuberculosis*** is defined by the Centers for Disease Control and Prevention (CDC) as a strain of *M tuberculosis* that fulfills the definition of multidrug resistant and that is resistant to any fluoroquinolone.

Table 3.79. Definitions of Positive Tuberculin Skin Test (TST) Results in Infants, Children, and Adolescents^{a,b}

Induration 5 mm or greater

Children in close contact with known or suspected contagious people with tuberculosis (TB) disease

Children suspected to have TB disease:

- Findings on chest radiograph consistent with active or previous TB disease
- Clinical evidence of TB disease^c

Children receiving immunosuppressive therapy^d or with immunosuppressive conditions, including human immunodeficiency (HIV) infection

Induration 10 mm or greater

Children at increased risk of disseminated TB disease:

- Children younger than 4 y
- Children with other medical conditions, including Hodgkin disease, lymphoma, diabetes mellitus, chronic renal failure, or malnutrition (see Table 3.80)
- Children born in high-prevalence regions of the world
- Children with significant travel to high-prevalence regions of the world^e
- Children frequently exposed to adults who are living with HIV, lacking housing, or incarcerated, or to people who inject or use drugs

Induration 15 mm or greater

Children without any risk factors

^aSee www.cdc.gov/tb/publications/guidelines/pdf/ciw778.pdf.

^bThese definitions apply regardless of previous bacille Calmette-Guérin (BCG) immunization (see Testing for *M tuberculosis* Infection, p 892); erythema alone at TST site does not indicate a positive test result. Tests should be read at 48 to 72 hours after placement.

^cEvidence by physical examination or laboratory assessment that would include tuberculosis in the working differential diagnosis (eg, meningitis).

^dIncluding immunosuppressive doses of corticosteroids (see Corticosteroids, p 913) or tumor necrosis factor- α antagonists or blockers (see Biologic Response-Modifying Drugs Used to Decrease Inflammation, p 104) or immunosuppressive drugs used in transplant recipients (see Solid Organ Transplantation, p 107).

^eSome experts define significant travel as travel or residence in a country with an elevated TB rate for at least 1 month.

- **Drug-resistant (DR) *M tuberculosis*** is a strain of *M tuberculosis* that is resistant to any drug used to treat drug-susceptible tuberculosis and includes isoniazid-resistant, rifampin-resistant, MDR, pre-XDR, and XDR strains.
- **Directly observed therapy (DOT)** is an intervention by which medications are taken by the patient while a health care professional or trained third party (not a relative or friend) observes and documents that the patient ingests each dose of medication and assesses for possible adverse drug effects. DOT can be in person or via video.
- **Exposed person** is anyone who has had contact with another person with suspected or confirmed contagious TB disease (ie, pulmonary, laryngeal, tracheal, or endobronchial disease). Recently (<3 months) exposed people may have an initially negative TST or IGRA result, normal physical examination findings, and chest radiographic findings that are normal or not compatible with TB. Some recently exposed people are or become infected (and subsequently develop a positive TST or IGRA result), and others do not become infected after exposure; the 2 groups cannot be distinguished initially.
- **Source person** is the person who has transmitted *M tuberculosis* complex to another person who subsequently develops TB infection or disease.

EPIDEMIOLOGY: Case rates of TB in all ages in North America are higher in urban, low-income areas. In recent years, more than 70% of all US cases have occurred in people born outside the United States. Almost 80% of childhood TB disease in the United States is associated with some form of foreign contact of the child, parent, or a household member. Specific groups with greater rates of TB include immigrants, international adoptees, refugees from or travelers to high-prevalence regions (eg, Asia, Africa, Latin America, and countries of the former Soviet Union), people lacking housing or those with unstable housing, people who inject or use drugs, and residents of some correctional facilities and other congregate settings. Secondhand smoke exposure increases the risk of TB disease developing in infected children.

Infants and postpubertal adolescents are at increased risk of progression from TBI to TB disease. Other predictive factors for development of disease include recent infection (within the past 2 years); immunodeficiency, especially from uncontrolled human immunodeficiency virus (HIV) infection; use of immunosuppressive drugs, such as prolonged or high-dose corticosteroid therapy or chemotherapy and drugs for preventing transplant organ rejection (see Solid Organ Transplantation, p 107); and certain diseases or medical conditions, including Hodgkin disease, lymphoma, diabetes mellitus, chronic renal failure, and malnutrition. Patients with TBI who are being treated with tumor necrosis factor (TNF)-alpha antagonists or blocking agents (see Biologic Response-Modifying Drugs Used to Decrease Inflammation, p 104) are at higher risk of progressing to TB disease. A positive TST or IGRA result should be accepted as indicative of infection in individuals receiving or soon to receive immunosuppressive medications,^{1,2} and the patient should be evaluated and treated accordingly.

A diagnosis of TBI or TB disease in a young child is a public health sentinel event often representing recent transmission. Transmission of *M tuberculosis* is airborne, with inhalation of droplet nuclei usually produced by an adult or adolescent with contagious pulmonary, endobronchial, or laryngeal TB disease. The probability of transmission increases if the person has a positive acid-fast sputum smear, productive cough, or pulmonary cavities or is a household contact. Although contagiousness usually lasts only a few days to weeks after initiation of effective drug therapy, it can last longer if the source patient does not adhere to medical therapy or is infected with a drug-resistant strain. If the sputum smear becomes negative for acid-fast bacilli (AFB) on 3 separate specimens at least 8 hours apart after treatment is initiated and the patient has improved clinically, the treated patient can be considered at low risk of transmitting *M tuberculosis*. Children younger than 10 years with only adenopathy in the chest or small pulmonary lesions (paucibacillary disease) and nonproductive cough are not contagious. Rare cases of pulmonary disease in young children, particularly with lung cavities or presence of AFB on sputum microscopy, and infants with congenital TB disease can be contagious.

M bovis is transmitted most often by unpasteurized dairy products, but airborne human-to-human transmission can occur.

² Nolt D, Starke JR; American Academy of Pediatrics, Committee on Infectious Diseases. Clinical report. Tuberculosis infection in children: testing and treatment. *Pediatrics*. 2021;148(6):e2021054663

The **incubation period** from infection to development of a positive TST or IGRA result is 2 to 10 weeks. The risk of developing TB disease is highest during the 12 months after infection and remains high for 2 years; however, many years can elapse between initial *M tuberculosis* infection and subsequent disease.

DIAGNOSTIC TESTS:

Testing for M tuberculosis Infection

Tuberculin Skin Test. The TST is one of two indirect methods for detecting *M tuberculosis* complex infection, the other method being IGRA (p 893). Both methods rely on specific lymphocyte sensitization after infection. Conditions that decrease lymphocyte numbers or function, including severe TB disease, can reduce the sensitivity of these tests. Tuberculin is a purified protein derivative (PPD) from heat-inactivated *M tuberculosis*. The routine (ie, Mantoux) technique of administering the skin test consists of 5 tuberculin units of solution (PPD; 0.1 mL) injected intradermally using a 27-gauge needle and a 1.0-mL syringe into the volar aspect of the forearm. Creation of a palpable wheal 6 to 10 mm in diameter is crucial to accurate testing.

Administration of TSTs and interpretation of results should be performed by trained and experienced health care personnel because administration and interpretation by unskilled people or family members are unreliable. The standardized time for assessing the TST result is 48 to 72 hours after administration. The **induration** is measured transversely at its widest diameter and the result should be recorded in millimeters. Positive TST results, as defined in Table 3.79 (p 890), can persist for several weeks.

Lack of reaction to a TST does not exclude TBI or TB disease. Approximately 10% to 40% of immunocompetent children with culture-documented TB disease do not react initially to a TST. Host factors, such as young age, poor nutrition, immunosuppression, viral infections (especially measles, varicella, and influenza), and disseminated TB disease, can decrease TST reactivity.

Classification of TST results is based on epidemiologic and clinical factors. Interpretation of the size of induration (mm) as a positive result varies with the person's epidemiologic risk of TBI and likelihood of progression to TB disease. Current guidelines from the CDC, the American Thoracic Society, and the American Academy of Pediatrics (AAP) recommend interpretation of TST findings on the basis of an individual's risk stratification and are summarized in Table 3.79 (p 890). Prompt clinical and radiographic evaluation of all children and adolescents with a positive TST result is recommended (see Assessing for *M tuberculosis* Disease, p 896).

BCG immunization, because of cross-reacting antigens present in the PPD, can result in induration of a TST. Distinguishing between a positive TST result caused by *M tuberculosis* complex infection and that caused by BCG requires a qualitative assessment of several factors. Reactivity of the TST (ie, mm of induration) attributable to prior BCG immunization may be absent or variable and depends on many factors, including age at BCG immunization, quality and strain of BCG vaccine used, number of doses of BCG vaccine received, nutritional and immunologic status of the vaccine recipient, frequency of TST administration, and time between immunization and TST. Evidence that increases the probability that a positive TST result is attributable to TBI or TB disease includes known contact with a person with contagious TB disease, a family history of TB disease, more than 2 years since neonatal BCG

immunization, and a TST reaction 15 mm or greater. Generally, interpretation of TST results in BCG recipients who are known contacts of a person with TB disease or who are at high risk of developing TB disease is the same as for people who have not received BCG vaccine.

Blood-Based Testing With IGRAs.^{1–3} IGRAs measure ex vivo interferon-gamma production from T lymphocytes in response to stimulation with proprietary polypeptide mixtures that simulate antigens specific to *M tuberculosis* complex. The IGRA antigens used are not found in BCG or most pathogenic nontuberculous mycobacteria (eg, *M avium* complex) but are found in the nontuberculous mycobacteria *M kansasii*, *M szulgai*, and *M marinum*. Examples of IGRAs are the T-SPOT.TB assay and the QuantiFERON-TB Gold Plus assay. As with TSTs, IGRAs cannot distinguish between TBI and TB disease, and a negative IGRA result cannot exclude infection with *M tuberculosis* complex or the possibility of TB disease in a patient with suggestive clinical findings. The sensitivity of IGRA tests is similar to that of TSTs in adults and children who have untreated culture-confirmed TB disease. In many clinical settings, the specificity of IGRAs is higher than that for the TST, because the antigens used are not found in BCG or most pathogenic nontuberculous mycobacteria. The published experience on testing children with IGRAs demonstrates that IGRAs consistently perform well in children of all ages. The negative predictive value of IGRAs is not clear, but in general, if the IGRA result is negative and the TST result is positive in an asymptomatic child with no known TB exposure, the diagnosis of TBI is unlikely, especially if the child has received a BCG vaccine.

TST Versus IGRA. Either TST or IGRA testing is acceptable for children of any age. IGRA is preferred for children who have received a BCG vaccine or who are unlikely to return for the TST reading. Low-grade, false-positive IGRA results occur in some individuals. For children without specific TB risk factors other than foreign birth or travel who have an unexpected low-level positive IGRA result (QuantiFERON-TB Gold Plus <1.00 IU/mL, T-SPOT.TB with 5–7 spots), a second diagnostic test, either an IGRA or a TST, should be performed; the child is considered infected only if both tests are positive. Indeterminate or invalid IGRA results have several possible causes that could be related to the patient, the assay itself, or its performance; these results do not exclude *M tuberculosis* infection and may necessitate repeat testing, possibly with a different test. Indeterminate/invalid IGRA results should not be used to make clinical decisions.

Specific recommendations for TST and IGRA use are provided in Table 3.80 (p 894).

Use of Tests for *M tuberculosis* Infection. The most reliable strategies for identifying TBI and preventing TB disease in children are based on identification of known risk factors for TBI or progression to TB disease and thorough and expedient contact tracing associated with cases of TB disease, rather than nonselective testing of large populations.

Table 3.80. Tuberculin Skin Test (TST) and IGRA Recommendations for Infants, Children, and Adolescents^a

Children for whom immediate TST or IGRA is indicated^b:

- Contacts of people with confirmed or suspected contagious tuberculosis (contact tracing)
- Children with radiographic or clinical findings suggesting TB disease
- Children immigrating from countries with endemic infection (eg, Asia, Middle East, Africa, Latin America, countries of the former Soviet Union), including international adoptees
- Children with history of significant^c travel to countries with endemic infection who have substantial contact with the resident population^d

Children who should have annual TST or IGRA:

- Children living with HIV

Children at increased risk of progression of TB infection to TB disease: Infants (age <1 year) and children with other medical conditions, including diabetes mellitus, chronic renal failure, malnutrition, congenital or acquired immunodeficiencies, and children receiving tumor necrosis factor (TNF) antagonists, deserve special consideration. Underlying immune deficiencies associated with these conditions theoretically would enhance the possibility for rapid progression to severe disease. Initial histories of potential exposure to tuberculosis should be included for all these patients. If these histories or local epidemiologic factors suggest a possibility of exposure, immediate and periodic TST or IGRA should be considered.

A TST or IGRA should be performed before initiation of immunosuppressive therapy, including prolonged systemic corticosteroid administration, organ transplantation, use of TNF-alpha antagonists or blockers, or other immunosuppressive therapy in any child requiring these treatments.

IGRA indicates interferon-gamma release assay; HIV, human immunodeficiency virus; TBI, *M tuberculosis* infection.

^aBacille Calmette-Guérin (BCG) immunization is not a contraindication to a TST; IGRA is generally preferred for BCG-vaccinated children.

^bBeginning as early as 3 months of age for TST; IGRA may be used at all ages.

^cSome experts define significant travel as birth, travel, or residence in a country with an elevated tuberculosis rate for at least 1 month.

^dIf the child is well and has no history of exposure, the TST or IGRA should be delayed for 8 to 10 weeks after return.

Contact tracing is an intervention that should be coordinated through the local public health department. Universal testing with TST or IGRA, including programs based at schools, child care centers, and camps that include populations at low risk, is discouraged because it results in either a low yield of positive results or a large proportion of false-positive results, leading to an inefficient use of health care resources. However, using a questionnaire to determine risk factors for infection with *M tuberculosis* and identifying who should have a TST or IGRA performed can be useful (see Table 3.81). Risk assessment for TB should be performed at the first medical home encounter with a child and then annually if possible. Testing children for infection with *M tuberculosis* and clinical evaluation for possible TB disease is indicated whenever a TST or IGRA result of a household member converts from a negative to positive result (indicating recent infection) or after travel for >1 month to a country with endemic disease.

HIV Infection. In the United States, annual testing for infection with *M tuberculosis* is recommended for children living with HIV beginning at ages 3 to 12 months and annually thereafter for those who test negative, depending on the local epidemiology

Table 3.81. Validated Questions for Determining Risk of Infection with *M tuberculosis* in Children in the United States

-
- Has a family member or contact had tuberculosis disease?
 - Has a family member had a positive tuberculin skin test result?
 - Was your child born in a high-prevalence country (countries other than the United States, Canada, Australia, New Zealand, or Western and North European countries)?
 - Has your child traveled to a high-prevalence country? How much contact did your child have with the resident population?
-

and the child's region of birth and travel history. Conversely, children who have TB disease should be tested for HIV infection. The clinical manifestations and radiographic appearance of TB disease in children living with HIV tend to be similar to those in immunocompetent children, but manifestations in these children can be more severe, unusual, and more often include extrapulmonary involvement of multiple organs. In people living with HIV, a TST induration of ≥ 5 mm is considered a positive result (see Table 3.79, p 890); however, a false-negative TST or IGRA result attributable to HIV-related immunosuppression also can occur. Confirming TB disease in a child living with HIV using microbiological specimens is challenging, given the paucibacillary nature of TB in this population. Antituberculosis therapy for children living with HIV must be selected with careful consideration of antiretroviral drug interactions, which are very common with the rifamycins.

Organ Transplant Recipients. The risk of TB disease in organ transplant recipients is several-fold greater than in the general population. A careful history should be taken from all transplant candidates, including details about previous TST or IGRA results and exposure to individuals with TB disease. All transplant candidates should undergo evaluation by TST or IGRA before the initiation of immunosuppressive therapy. A positive result of either test should be taken as evidence of infection with *M tuberculosis* complex. In addition, donor-derived TB disease can be transmitted via an infected organ and should be considered as a possible cause of post-transplant fever and related symptoms.

Patients Receiving Immunosuppressive Therapies Including Biologic Response Modifiers. In addition to a detailed history of risk factors for infection with *M tuberculosis*, all patients should have a TST or IGRA performed before the initiation of therapy with high-dose systemic corticosteroids, antimetabolite agents, TNF antagonists or blockers, and some other biologic response-modifying drugs (see Biologic Response-Modifying Drugs Used to Decrease Inflammation, p 104). Some experts recommend that if the child has at least 1 TB risk factor, both a TST and an IGRA should be performed to maximize sensitivity; a positive result of either test should be taken as evidence of *M tuberculosis* infection.

Other Considerations. Testing for infection with *M tuberculosis* complex at any age is not required before administration of live-virus vaccines. Live attenuated measles, mumps, and rubella vaccines temporarily can suppress tuberculin reactivity for at least 4 to 6 weeks, and data suggest a similar suppression with varicella and yellow fever vaccines. The effect of live attenuated influenza vaccines on TST reactivity is not known. If indicated, a TST can be performed or blood drawn for an IGRA at the same visit

during which these vaccines are administered (ie, before substantial replication of the vaccine virus). The effects of live-virus vaccination on IGRA characteristics have not been determined; the same precautions as for TST should be followed.

Sensitivity to PPD tuberculin antigen persists for years in most instances, even after effective treatment. The durability of positive IGRA results has not been determined but is likely similar. Repeat testing with either TST or IGRA has no known clinical utility for assessing the effectiveness of treatment or for diagnosing newly acquired infection in patients who previously were infected with *M tuberculosis*.

Assessing for *M tuberculosis* Disease. Although both IGRA and TST provide evidence for infection with *M tuberculosis* complex, they cannot distinguish TBI from TB disease. Therefore, patients testing positive for *M tuberculosis* infection by IGRA or TST should be assessed for TB disease before therapeutic intervention is undertaken. This assessment should include: (1) asking about symptoms of TB disease and exposure to a possible source person; (2) physical examination for signs of TB disease; and (3) a chest radiograph. If radiographic signs of TB disease (eg, airspace opacities, pleural effusions, cavities, or changes on serial radiographs) are seen, then sputum, gastric aspirate, or nasopharyngeal aspirate sampling should then be performed, as described below. Most experts recommend that children younger than 12 months who are suspected of having pulmonary or extrapulmonary TB disease (eg, have a positive TST result **and** symptoms, physical examination signs, or chest radiograph abnormalities consistent with TB disease), with or without neurologic symptoms, should have a lumbar puncture to evaluate for tuberculous meningitis. Children 12 months and older with TB disease require a lumbar puncture only if they have neurologic signs or symptoms.

Laboratory Confirmation of *M tuberculosis*. Laboratory isolation of *M tuberculosis* complex by culture from a specimen of sputum (expectorated or induced), gastric aspirate, nasopharyngeal aspirate, bronchial washing, pleural fluid, cerebrospinal fluid (CSF), urine or other body fluid, or a tissue biopsy specimen confirms the diagnosis of TB disease. Positive results from a rapid molecular method (eg, nucleic acid amplification tests [NAATs]) increasingly are also considered confirmatory, but culture isolation of the organism is still required for phenotypical susceptibility testing, genotyping, most rapid molecular detection of drug-resistance genes, and species identification with the *M tuberculosis* complex. Children older than 2 years and adolescents frequently produce sputum spontaneously or by induction with aerosolized hypertonic saline. Studies have demonstrated successful collection of induced sputum from infants with pulmonary TB disease, but this requires special expertise. The best specimen for diagnosis of pulmonary TB disease in any child or adolescent in whom cough is absent or nonproductive and sputum cannot be induced is an early-morning gastric aspirate, which is best obtained with a nasogastric tube on awakening the child and before ambulation or feeding. Aspirates collected on 3 separate mornings should be submitted for AFB staining and culture. Nasopharyngeal aspirates (multiple specimens or in addition to other specimen types) are an acceptable specimen for children particularly when gastric aspirates are difficult to obtain, but sensitivity may be lower compared to gastric aspirate samples. Stool has been recommended by the World Health Organization (WHO) as a specimen for young children because it is easier to obtain than gastric aspirates, and swallowed sputum passes through the gastrointestinal tract. The WHO has released guidance on processing stool for NAAT for the diagnosis of pulmonary TB disease in young children (www.who.int/publications/i/item/9789240042650).

Fluorescent staining methods for specimen smears are more sensitive than the traditional Kinyoun acid fast smears and are preferred. The overall diagnostic yield of microscopy of gastric aspirates, induced sputum, or nasopharyngeal aspirates is low in children with clinically suspected pulmonary TB disease, and false-positive stain results caused by the presence of nontuberculous mycobacteria occur rarely. Histologic examination for and demonstration of AFB and granulomas in biopsy specimens from lymph node, pleura, mesentery, liver, bone marrow, or other tissues can be useful, but *M tuberculosis* complex organisms cannot be distinguished reliably from other mycobacteria in stained specimens. The CDC and several reference laboratories offer molecular species identification of mycobacteria including *M tuberculosis* in fixed tissues. Regardless of results of the AFB smears, each specimen should be cultured.

Because *M tuberculosis* complex organisms are slow growing, detection of these organisms may take as long as 10 weeks using solid media; use of liquid media and continuous monitoring systems allows detection within 1 to 6 weeks and usually within 3 weeks. Even with optimal culture techniques, *M tuberculosis* complex organisms are isolated from fewer than 75% of infants and less than 50% of children with pulmonary TB disease diagnosed by clinical criteria; the culture yields for most forms of extrapulmonary TB disease are even lower. Current methods for species identification of isolates from culture include molecular probes, NAATs, genetic sequencing, mass spectrometry, and biochemical tests. *M bovis* usually is suspected because of isolated pyrazinamide resistance, which is characteristic of almost all *M bovis* isolates, but further biochemical or molecular testing is required to distinguish *M bovis* from *M tuberculosis*.

For a child with clinically suspected TB disease, finding the culture-positive source person supports the child's presumptive diagnosis and provides the likely drug susceptibility of the child's organism. Culture material should be collected from children with evidence of TB disease, especially when (1) an isolate from a source person is not available; (2) the presumed source person has drug-resistant TB; (3) the child is immunocompromised or ill enough to require hospital admission; or (4) the child has extrapulmonary disease. Traditional methods of determining drug susceptibility require bacterial isolation. Several molecular methods that rapidly detect drug resistance directly from clinical samples are available.

NAATs cleared by the US Food and Drug Administration (FDA) are available for rapid detection of *M tuberculosis* complex organisms from smear-positive and smear-negative sputum specimens, and other laboratory-developed tests for rapid molecular detection are available locally. Some tests have been validated for specimens other than sputum; expert consultation is recommended for test availability and interpretation of results. Molecular methods, such as Xpert MTB/RIF that find *M tuberculosis* genetic markers associated with drug resistance, are supplementing the culture-based (ie, phenotypic) methods for drug susceptibility testing as they decrease the time to detection of drug resistance from weeks to hours, and in some instances the results could be more reliable for patient care decisions. Some of the methods are verified for direct testing of patient specimens. It is recommended that results from molecular susceptibility testing are confirmed through culture-based testing. Molecular methods continue to evolve and consultation with an expert is useful to determine a testing strategy when drug resistance is suspected.

TREATMENT (SEE TABLE 3.82)¹:

Specific Drugs. Regimen and dosage recommendations and the more commonly reported adverse reactions of first-line antituberculosis drugs are summarized in Tables 3.82, 3.83 (p 902), and 3.84 (p 904). The less commonly used antituberculosis drugs, their doses, and adverse effects are listed in Table 3.85 (p 906). Some of these drugs have less effectiveness and greater toxicity or they are reserved for treating MDR, pre-XDR, or XDR TB disease; they should be used only in consultation with a specialist familiar with treatment of childhood TB disease. For treatment of TB disease, drugs always must be used in recommended combination and dosage to minimize emergence of drug-resistant strains. Use of nonstandard regimens for any reason (eg, drug allergy, drug resistance) should be undertaken only by an expert in treating TB disease.

Occasionally, a patient cannot tolerate oral medications. Isoniazid, rifampin, linezolid, fluoroquinolones, and aminoglycosides can be administered parenterally.

Treatment Regimens for Tuberculosis Infection (TBI). Several regimens are recommended for TBI (without evidence of TB disease), depending on the circumstances for individual patients. Dosages and intervals are provided in Table 3.83.

Isoniazid-Rifapentine Therapy for TBI.² A 3-month course, comprising a once-weekly dose of isoniazid and rifapentine, is a regimen that is safe, well tolerated, and at least as efficacious as 9 months of isoniazid taken daily. Extensive published and unpublished experience with this combination in children has demonstrated excellent results. Isoniazid-rifapentine is a preferred regimen for treatment of TBI for children ≥ 2 years of age, although the pill burden in younger children is substantial and sometimes not well tolerated. Isoniazid-rifapentine should not be used in children < 2 years of age because of a lack of pharmacokinetic data in this age group.

Rifampin Therapy for TBI. A 4-month course of rifampin given daily also is a preferred regimen for the treatment of TBI, and especially when isoniazid resistance is present or likely, as judged from the exposure history. The data supporting the efficacy and safety of this regimen are from randomized controlled trials and case control studies in adults, and several studies that included children. The regimen has been as effective as 9 months of daily isoniazid, the rates of adverse effects have been low, and the completion rates of therapy have been much higher than for 9 months of isoniazid. There has been extensive published and unpublished experience with this regimen in children demonstrating safety, tolerability, and high rates of completion.

Isoniazid-Rifampin Therapy for TBI. An additional possible regimen for treatment of TBI is 3 months of daily isoniazid and rifampin, with no age restriction on its use. This regimen is quite similar in principle to the isoniazid-rifapentine option; however, the medications are given daily because of the relatively short half-life of rifampin compared with rifapentine. Efficacy and rates of completion are comparable or better when compared with isoniazid monotherapy.

Isoniazid Therapy for TBI. Isoniazid monotherapy has been the most widely recommended and utilized treatment for pediatric TBI. The efficacy of isoniazid

Table 3.82. Recommended Usual Treatment Regimens for Drug-Susceptible TB Infection and TB Disease in Infants, Children, and Adolescents

Infection or Disease Category	Regimen	Remarks
TB infection (positive TST or IGRA result, no disease) ^a		
• Isoniazid susceptible	3 mo of isoniazid plus rifapentine, once a week	Isoniazid-rifapentine is a preferred regimen for treatment of TBI for children ≥2 years.
	OR	
	4 mo of rifampin, once a day	Continuous daily therapy is required. Intermittent therapy even by DOT is not recommended.
	OR	
	3 mo of isoniazid plus rifampin, once a day	To be considered if above 2 regimens are not feasible.
	OR	
	6 or 9 mo of isoniazid, once a day	9 months preferred (see text for discussion, Isoniazid Therapy for TBI, p 898). If daily therapy is not possible, DOT twice a week can be used; medication doses differ with daily and twice-weekly regimens.
• Isoniazid resistant	4 mo of rifampin, once a day	Continuous daily therapy is required. Intermittent therapy even by DOT is not recommended.
• Isoniazid-rifampin resistant	Consult a tuberculosis specialist	Moxifloxacin or levofloxacin, with consideration of a second drug based on drug susceptibility testing of presumed source isolate and consultation with a tuberculosis specialist.

Table 3.82. Recommended Usual Treatment Regimens for Drug-Susceptible TB Infection and TB Disease in Infants, Children, and Adolescents, continued

Infection or Disease Category	Regimen	Remarks
Pulmonary and extrapulmonary TB disease (except meningitis and osteoarticular disease)^{b,c}	If nonsevere pulmonary disease, ^d 2 mo of rifampin, isoniazid, pyrazinamide, and ethambutol (RIPE) daily, followed by 2 mo of isoniazid and rifampin daily for drug-susceptible <i>M tuberculosis</i>	Some experts recommend a 3-drug initial regimen (isoniazid, rifampin, and pyrazinamide) if the risk of drug resistance is low. DOT is highly desirable and, in many jurisdictions, DOT is required for all regimens.
	If severe pulmonary disease, 2 mo of rifampin, isoniazid, pyrazinamide, and ethambutol (RIPE) daily, followed by 4 mo of isoniazid and rifampin daily for drug-susceptible <i>M tuberculosis</i>	In many public health jurisdictions, DOT is recommended for all regimens. If a cavity is present, or sputum culture takes longer than 2 months to become negative, treatment should be extended to 9 months.
	If severe or nonsevere pulmonary disease in a patient ≥12 years of age (and ≥40 kg), an alternative is a 4 month regimen with isoniazid, rifapentine, moxifloxacin and pyrazinamide (8 weeks of the 4 drugs given daily, followed by 9 weeks of isoniazid, rifapentine, and moxifloxacin given daily by DOT) ^e	DOT is required for 4-month regimen containing isoniazid, rifapentine, moxifloxacin and pyrazinamide. Patients with a positive culture at completion of 2 months of therapy, with or without ongoing symptoms, should be evaluated to identify cause of delayed response.
	For <i>Mycobacterium bovis</i> disease, at least 9 mo of isoniazid and rifampin, with or without ethambutol, when the organism is susceptible to these drugs	

Table 3.82. Recommended Usual Treatment Regimens for Drug-Susceptible TB Infection and TB Disease in Infants, Children, and Adolescents, continued

Infection or Disease Category	Regimen	Remarks
Meningitis	2 mo of isoniazid, rifampin, pyrazinamide, and ethionamide or a fluoroquinolone (levofloxacin or moxifloxacin) ^f followed by 4–10 mo of isoniazid and rifampin, once a day or 3 times per week (6–12 mo total) for drug-susceptible <i>M tuberculosis</i> ^g	See text for information on corticosteroids (Corticosteroids, p 913). High-dose rifampin (30 mg/kg/day) for TB meningitis is recommended.
	At least 9 mo of therapy without pyrazinamide for <i>M bovis</i> susceptible to isoniazid and rifampin	

TST indicates tuberculin skin test; IGRA, interferon-gamma release assay; DOT, directly observed therapy.

^aSee text for comments and additional acceptable/alternative regimens.

^bDuration of therapy may be longer for people living with HIV, and additional drugs and dosing intervals may be indicated (see Tuberculosis Disease and HIV Infection, p 913).

^cConsultation with an expert is recommended. Susceptible osteoarticular tuberculosis is generally treated with a 4- drug regimen of isoniazid, rifampin, pyrazinamide, and ethambutol for 2 months and isoniazid and rifampin for another 10 months.

^dNonsevere pulmonary disease is defined as tuberculosis confined to one lobe with no cavities or isolated intrathoracic adenopathy, no signs of miliary tuberculosis, no complex pleural effusion, and no clinically significant airway obstruction.

^eFor patients 12 and older receiving isoniazid, rifampine, pyrazinamide, and moxifloxacin for treatment of susceptible pulmonary tuberculosis, the daily dose for patients 40 kg and over of isoniazid is 300 mg, rifampine 1200 mg, and moxifloxacin 400 mg. Dosing for pyrazinamide in patients weighing 40 to <55 kg is 1000 mg; for patients weighing 55 to 75 kg is 1500 mg, and for patients weighing >75 kg is 2000 mg daily. Isoniazid, rifampine, moxifloxacin, and pyrazinamide are administered by DOT daily for 8 weeks followed by isoniazid, rifampine, and moxifloxacin daily by DOT for another 9 weeks (www.cdc.gov/mmwr/volumes/71/wr/mm7108a1.htm).

^fConsultation with an expert in tuberculosis is recommended. When susceptibility to first-line drugs is established, the ethionamide or fluoroquinolone can be discontinued.

^gIn children and adolescents with TB meningitis presumed to be drug susceptible, the WHO states that 6 months of isoniazid, rifampin, pyrazinamide, and ethionamide daily may be used, but the longer treatment regimen in this table is preferred.

Table 3.83. Regimens and Dosages Used in Pediatric Patients With TB Infection (TBI)

Agent(s)	Dose and Age Group	Administration	Duration (months)	Age Restriction	Comments
INH + Rifapentine (3HP)	Age ≥12 y INH: 15 mg/kg, rounded up to nearest 50 or 100 mg (max 900 mg) Rifapentine (by weight): 10–14 kg: 300 mg 14.1–25 kg: 450 mg 25.1–32 kg: 600 mg 32.1–49.9 kg: 750 mg ≥50.0 kg: 900 mg	Weekly (SAT or DOT)	3	Not for children <2 y	Take with food, containing fat if possible; pyridoxine for selected patients ^a
	Age 2–11 y INH: 25 mg/kg, rounded up to nearest 50 or 100 mg (max 900 mg) Rifapentine: see above				

Table 3.83. Regimens and Dosages Used in Pediatric Patients With TB Infection (TBI), continued

Agent(s)	Dose and Age Group	Administration	Duration (months)	Age Restriction	Comments
Rifampin (4R)	Adult: 10 mg/kg (max 600 mg) Child: 15–20 mg/kg (max 600 mg)	Daily (SAT)	4	None	Drug-drug interactions
INH + Rifampin	Same doses as when drugs are used individually for SAT	Daily (SAT)	3	None	Not considered unless 3HP or 4R are not feasible
INH	Adult: 5 mg/kg (max dose 300 mg) Child: 10–20 mg/kg (max 300 mg)	Daily (SAT)	6 or 9	None	Seizures with overdose; pyridoxine for selected patients ^a
	Adult: 15 mg/kg (max dose 900 mg) Child: 20–40 mg/kg (max 900 mg)	Twice weekly (DOT)			

INH indicates isoniazid; DOT, directly observed therapy; SAT, self-administrated therapy.

^aExclusively breastfed infants and for children and adolescents on meat- and milk-deficient diets; children with nutritional deficiencies, including all symptomatic children living with HIV infection; and pregnant adolescents and pregnant adults.

Table 3.84. Drugs for Treatment of Drug-Susceptible Pulmonary TB Disease in Infants, Children, and Adolescents^a

Drugs	Dosage Forms	Daily Dosage (Range), mg/kg	Three Times per Week Dosage, mg/kg per Dose	Maximum Dose	Most Common Adverse Reactions
Ethambutol	Tablets 100 mg 400 mg	20 (15–25)	50	Daily, 1 g Twice a week, 2.5 g	Optic neuritis (usually reversible), decreased red-green color discrimination, gastrointestinal tract disturbances, hypersensitivity
Isoniazid ^b	Scored tablets 100 mg 300 mg	10 (10–15) ^b	20–30	Daily, 300 mg Twice a week, 900 mg	Mild hepatic enzyme elevation, hepatitis, ^c peripheral neuritis, hypersensitivity
Pyrazinamide	Scored tablets 500 mg	35 (30–40)	50	2 g	Hepatotoxic effects, hyperuricemia, arthralgia, gastrointestinal tract upset, pruritus, rash
Rifampin	Capsules 150 mg 300 mg Syrup formulated from capsules	15–20 ^d 30 ^e	15–20 ^d	600 mg	Orange discoloration of secretions or urine, staining of contact lenses, vomiting, hepatitis, hyperbilirubinemia, influenza-like reaction, thrombocytopenia, pruritus; oral contraceptives may be ineffective
Rifapentine	Tablets 150 mg			1200 mg dose for age ≥12 years as part of a multidrug 4- month regimen for pulmonary tuberculosis disease ^f	Orange discoloration of secretions or urine, staining of contact lenses, vomiting, hepatitis, hyperbilirubinemia, influenza-like reaction, anemia, lymphopenia, pruritus; oral contraceptives may be ineffective

Table 3.84. Drugs for Treatment of Drug-Susceptible Pulmonary TB Disease in Infants, Children, and Adolescents,^a continued

Drugs	Dosage Forms	Daily Dosage (Range), mg/kg	Three Times per Week Dosage, mg/kg per Dose	Maximum Dose	Most Common Adverse Reactions
Moxifloxacin [§]	Tablet: 400 mg Intravenous: 400 mg/ 250 mL	Adults: 400 mg (once daily) Children: 10 mg/kg (once daily)		400 mg	Hypersensitivity reactions; theoretical effect on growing cartilage; tendonitis, gastrointestinal tract disturbances, cardiac disturbances, peripheral neuropathy, rash, headache, restlessness, confusion; can prolong QTc interval

^aRifamate is a capsule containing 150 mg of isoniazid and 300 mg of rifampin. Two capsules provide the usual adult (greater than 50 kg) daily doses of each drug. Rifater, in the United States, is a capsule containing 50 mg of isoniazid, 120 mg of rifampin, and 300 mg of pyrazinamide. Isoniazid and rifampin also are available for parenteral administration.

^bConcomitant administration of pyridoxine is recommended for breastfeeding infants and for children or adolescents at risk for nutritional deficiency

^cWhen isoniazid in a dosage exceeding 10 mg/kg/day is used in combination with rifampin, the incidence of hepatotoxic effects may be increased.

^dMany experts recommend using a daily rifampin dose of 20–30 mg/kg/day for infants and toddlers and for serious forms of tuberculosis, such as disseminated disease.

^eA dose of 30 mg/kg/day of rifampin is recommended for TB meningitis and has been shown to improve mortality and neurodevelopmental outcomes.

^f4-drug therapy for susceptible pulmonary tuberculosis disease in ≥12 years includes isoniazid, rifapentine, pyrazinamide, and moxifloxacin daily by DOT for 8 weeks followed by isoniazid, rifapentine, and moxifloxacin daily by DOT for 9 weeks (see www.cdc.gov/mmwr/volumes/71/wr/mm7108a1.htm).

[§]Moxifloxacin does not have an FDA indication for the treatment of TB infection or disease and is not approved for use in children younger than 18 years; its use in younger children necessitates assessment of the potential risks and benefits (see Antimicrobial Agents and Related Therapy, p 973). The Centers for Disease Control and Prevention recommends moxifloxacin use for drug susceptible pulmonary TB disease in persons ≥12 years, with body weight of ≥40 kg.

Table 3.85. Additional Drugs for Treatment of Drug-Resistant TB Disease in Infants, Children, and Adolescents^a

Drugs	Dosage, Forms	Daily Dosage	Maximum Daily Dose	Adverse Reactions
Amikacin ^{b,c}	Vials, 500 mg and 1 g	15–20 mg/kg (intravenous or intramuscular administration)	1 g	Auditory and vestibular toxic effects, nephrotoxic effects.
Bedaquiline ^d	Tablets, 100 mg Dispersible tablets, 20 mg	Children age ≥5 years: 15 kg <30 kg: 200 mg daily for first 2 wk, then 100 mg 3 times/wk with 48 h between doses for wk 3–24	200 mg	Can prolong QTc interval, hepatotoxicity, arthralgia, nausea, abdominal pain, headache. Bedaquiline has an FDA “black box warning” regarding unexplained mortality imbalance noted in placebo-controlled trial in adults (based on the 120-week visit window).
		≥30 kg: 400 mg daily for first 2 wk, then 200 mg 3 times/wk with 48 h between doses for wk 3–24	400 mg	Bedaquiline is metabolized by CYP3A4, and its systemic exposure and therapeutic effect may be reduced during coadministration with inducers of CYP3A4 such as rifamycins and efavirenz.
Clofazimine ^e	Capsules, 50 mg	2–5 mg/kg given in 1 daily dose	300 mg	Investigational in United States. Limited data in children. Photosensitivity, skin discoloration, ichthyosis; can prolong QTc interval; gastrointestinal tract disturbance; avoid in pregnancy; cross-resistance with bedaquiline.
Cycloserine	Capsules, 250 mg	10–20 mg/kg/day, given in 1 dose or in 2 divided doses	1 g	Psychosis, personality changes, seizures, rash.
Delamanid	Tablets, 50 mg Dispersible tablet, 25 mg	<7 kg consult a specialist 7–23 kg: 50 mg/day in 2 divided doses 24–34 kg: 100 mg/day given in 2 divided doses ≥35 kg: 200 mg/day given in 2 divided doses	200 mg	Investigational in United States; gastrointestinal tract disturbances; can prolong QTc interval; paresthesia, tremor, anxiety, depression, insomnia, tinnitus, blurred vision; nightmares and hallucinations in children.

Table 3.85. Additional Drugs for Treatment of Drug-Resistant TB Disease in Infants, Children, and Adolescents,^a continued

Drugs	Dosage, Forms	Daily Dosage	Maximum Daily Dose	Adverse Reactions
Ethionamide ^f	Tablets, 250 mg	15–20 mg/kg/day, given in 1 dose or in 2–3 divided doses	1 g	Gastrointestinal tract disturbances, hepatotoxic effects, hypersensitivity reactions, hypothyroidism.
Levofloxacin ^{b,g}	Tablets 250 mg 500 mg 750 mg Oral solution 25 mg/mL Vials 5 mg/mL 25 mg/mL	Adults: 750–1000 mg (once daily) Children: 15–20 mg/kg (for those 6 months and older, but <50 kg given in 2 divided doses)	1 g	Hypersensitivity reactions; theoretical effect on growing cartilage, tendonitis, gastrointestinal tract disturbances, cardiac disturbances, peripheral neuropathy, rash, headache, restlessness, confusion; can prolong QTc interval.
Linezolid ^{b,h}	Tablets, 600 mg Oral suspension, 20 mg/mL	Adults: 600 mg (once daily) Children <15 kg: 15 mg/kg given once daily Children ≥15 kg: 10–12 mg/kg given once daily	600 mg	Bone marrow suppression, peripheral neuropathy.

Table 3.85. Additional Drugs for Treatment of Drug-Resistant TB Disease in Infants, Children, and Adolescents,^a continued

Drugs	Dosage, Forms	Daily Dosage	Maximum Daily Dose	Adverse Reactions
Para-aminosalicylic acid (PAS)	Packets, 3 g	200–300 mg/kg/day (given in 2–4 divided doses)	12 g	Gastrointestinal tract disturbances, hypersensitivity, hepatotoxic effects, hypothyroidism.

^aThese drugs should be used in consultation with a TB specialist.

^bThese drugs do not have an indication from the US Food and Drug Administration (FDA) for treatment of TB infection or disease.

^cDose adjustment needed with renal insufficiency.

^dBedaquiline is not FDA-approved for use in children <5 years, but the World Health Organization has suggested dosing for children <5 years of age (www.who.int/publications/i/item/9789240055193). Use with caution in end-stage renal impairment. Refer to product information and consult with pharmacist regarding drug interactions with CYP3A4 inhibitors.

^eAvoid if hepatic impairment present unless benefits outweigh risks. May administer higher dose every other day if needed based on dosage form constraints (particularly an issue for children weighing <10 kg; 50-mg capsule is difficult to manipulate). Clofazimine is not commercially available, and the healthcare provider needs to contact manufacturer (Novartis: 1-888-NOW-NOVA). Subsequently, health care provider will need to obtain single-patient expanded access investigational new drug approval from the Center for Drug Evaluation and Research, Division of Anti-Infective Products at the FDA (301-796-1400) and www.fda.gov/drugs/investigation-al-new-drug-ind-application/physicians-how-request-single-patient-expanded-access-compassionate-use.

^fWhen ethionamide is used, concomitant administration of pyridoxine (vitamin B₆) is recommended.

^gLevofloxacin is not approved for use in children younger than 18 years; its use in younger children necessitates assessment of the potential risks and benefits (see Antimicrobial Agents and Related Therapy, p 973).

^hLinezolid pharmacokinetics have not been well established in children. The doses listed will yield a drug exposure approximately equal to that in adults taking 600 mg daily.

monotherapy reaches 98% against development of TB disease, but many studies have shown that the long duration of isoniazid monotherapy results in poor adherence and low completion rates. The WHO recommends a treatment duration of 6 months to provide high coverage of the population in countries with a high disease burden. A 9-month regimen gives an additional 20% to 30% increase in efficacy. The CDC and National TB Controllers Association recommend 6-month or 9-month durations of isoniazid monotherapy for adults, if shorter-course rifamycin-based regimens cannot be used. This option may be very unattractive to patients and families because of its long duration. Many TB care providers and clinics use this regimen only when a rifamycin-containing regimen cannot be used because of drug interactions or rifamycin intolerance.

For infants, children, and adolescents, including those living with HIV or other immunocompromising conditions, the recommended duration of isoniazid therapy in the United States is 9 months for those for whom isoniazid is selected for treatment of TBI. Although there have been no formal trials of interrupted 9-month courses, many experts in North America accept 6 months of uninterrupted treatment as adequate. When adherence with daily therapy with isoniazid cannot be ensured, twice-a-week DOT on the basis of expert opinion and published experience can be considered, but each dose should be observed. Determination of serum aminotransferase concentrations before or during therapy is not indicated except in patients with underlying liver or biliary disease, during pregnancy or the first 12 weeks postpartum, with concurrent use of other potentially hepatotoxic drugs (eg, anticonvulsant or HIV agents), or if there is clinical concern of possible hepatotoxicity.

Therapy for TBI and Contacts of Patients With Isoniazid-Resistant *M tuberculosis* and When Isoniazid Cannot Be Administered. The incidence of isoniazid resistance among *M tuberculosis* complex isolates from US patients in 2020 was 4.8% among cases born in the United States and 9.5% among cases born outside the United States. Risk factors for drug resistance are listed in Table 3.86. If the source person is found to have isoniazid-resistant, rifampin-susceptible organisms, isoniazid should be discontinued, and rifampin should be administered daily to contacts with TBI for a total course of 4 months.

Table 3.86. People at Increased Risk of Drug-Resistant Tuberculosis Infection or Disease^a

- People with a history of prior treatment for tuberculosis disease (or whose source person for the contact received prior treatment)
- Contacts of a patient with drug-resistant contagious tuberculosis disease
- People who resided in countries or areas with high prevalence of drug-resistant tuberculosis, such as Russia and certain nations of the former Soviet Union, Asia, Africa, and Latin America^{a,b}
- Infected people whose source person has positive smears for acid-fast bacilli or cultures after 2 months of appropriate antituberculosis therapy and patients who do not respond to a standard treatment regimen

^aSee wwwnc.cdc.gov/travel/page/yellowbook-home.

^bFor current information on countries with high prevalence of drug resistant tuberculosis disease refer to the most recent WHO Global Tuberculosis Report (eg, www.who.int/publications/i/item/9789240037021).

Optimal therapy for children with TBI caused by organisms with resistance to isoniazid and rifampin (ie, MDR) is not known. In these circumstances, a fluoroquinolone alone and multidrug regimens have been used in observational studies, but the safety and the efficacy of these empiric regimens have not been assessed in controlled clinical trials. A common approach is to give 6 to 12 months of treatment with a later-generation fluoroquinolone (levofloxacin or moxifloxacin), alone or with a second drug, based on the drug susceptibility of the source person's *M tuberculosis* isolate. On the basis of evidence of increased toxicity, adverse events, and discontinuations, pyrazinamide should not be routinely used as the second drug. Consultation with a TB specialist is indicated.

Treatment of Tuberculosis Disease.¹⁻⁶ The goal of treatment is to achieve killing of replicating organisms in the tuberculous lesions in the shortest possible time. Achievement of this goal minimizes the possibility of development of resistant organisms. The major problem limiting successful treatment is poor adherence to prescribed treatment regimens. The use of DOT decreases the rates of relapse, treatment failures, and drug resistance; therefore, DOT is strongly recommended for treatment of all children and adolescents with TB disease in the United States. Intervals and dosages are provided in Tables 3.82, 3.84, and 3.85.

Therapy for Presumed or Known Drug-Susceptible Pulmonary Tuberculosis Disease. Recent clinical trials have shown efficacy of shorter treatment regimens for children with pulmonary tuberculosis disease. For nonsevere pulmonary disease in children 3 months to 16 years of age, defined as tuberculosis confined to 1 lobe with no cavities or isolated intrathoracic adenopathy, no signs of miliary tuberculosis, no complex pleural effusion, and no clinically significant airway obstruction, a 4-month, 4-drug regimen consisting initially of rifampin, isoniazid, pyrazinamide, and ethambutol (RIPE) daily for the first 2 months and isoniazid and rifampin daily for the remaining 2 months is recommended.

If criteria are not met for the 4-month course of RIPE (ie, patient has severe pulmonary disease or extrapulmonary TB disease other than peripheral lymph node TB), at least 6 months of treatment should be given. RIPE should be administered daily for the first 2 months, followed by isoniazid and rifampin daily for 4 months. For either the 4- or 6-month regimen, some experts administer 3 drugs (isoniazid, rifampin, and

pyrazinamide) as the initial regimen if a presumed source person has been identified with known pansusceptible *M tuberculosis* or has no risk factors for drug-resistant *M tuberculosis*.

If the chest radiograph shows one or more pulmonary cavities and/or the sputum culture result remains positive after 2 months of therapy, the duration of therapy should be extended to at least 9 months.

An alternative regimen for patients ≥ 12 years of age (and ≥ 40 kg) with nonsevere or severe, susceptible pulmonary disease is a 4-month regimen with isoniazid, rifapentine, moxifloxacin, and pyrazinamide; all 4 drugs are given daily for 8 weeks, followed by daily isoniazid, rifapentine, and moxifloxacin for 9 weeks (www.cdc.gov/mmwr/volumes/71/wr/mm7108a1.htm).

Therapy for Drug-Resistant Pulmonary Tuberculosis Disease. Consultation with an expert is strongly recommended when drug-resistant TB disease is suspected or confirmed. Guidance is also available from the WHO (<https://apps.who.int/iris/rest/bitstreams/1280998/retrieve>), the Sentinel Project (http://sentinel-project.org/wp-content/uploads/2022/04/DRTB-Field-Guide-2021_v5.1.pdf), and the CDC (www.cdc.gov/tb/topic/drtb/default.htm). Drug resistance is more common in certain groups (Table 3.86). When resistance to drugs other than isoniazid is likely (see Table 3.86), initial therapy should be adjusted by adding at least 2 drugs to match the presumed drug susceptibility pattern until drug susceptibility results are available. If an isolate from the child under treatment is not available, drug susceptibilities can be inferred by the drug susceptibility pattern of isolates from the presumed source person. Data for guiding drug selection may not be available for foreign-born children or in circumstances of international travel or adoption. If this information is not available, consultation with an expert should occur to determine a multidrug oral regimen that includes close monitoring for clinical response.

Most pulmonary TB disease in children that is caused by an isoniazid-resistant but rifampin- and pyrazinamide-susceptible strain of *M tuberculosis* complex can be treated with a 6-month regimen of rifampin, pyrazinamide, and ethambutol. If disease is extensive, many experts add a fluoroquinolone to this regimen. For MDR TB disease, the treatment regimen needed for cure should include multiple antituberculosis drugs to which the organism is susceptible, and consultation with an expert is strongly recommended as new regimens are being evaluated and new guidance developed. There is now a strong emphasis on the use of all-oral regimens whenever possible to avoid the toxicity of the injectable drugs. Bedaquiline is approved by the US Food and Drug Administration as part of combination therapy in the treatment for children ages 5 years and older with MDR pulmonary TB disease. Currently, there are limited safety, tolerability, efficacy, and pharmacokinetic data on its use in children < 5 years of age. However, the WHO has recommended its use in children of all ages and has made provisional dosing recommendations for children of all weights, based on preliminary data from pediatric trials and other emerging evidence (www.who.int/publications/i/item/9789240055193). Delamanid is another new oral drug for treatment of MDR, pre-XDR, and XDR TB disease; this drug is available in the United States under a compassionate use protocol. Regimens in which drugs are administered intermittently are not recommended for drug-resistant disease; daily DOT is critical to prevent emergence of additional resistance.

Extrapulmonary Tuberculosis Disease.¹ In general, extrapulmonary TB disease, with the exception of meningitis and osteoarticular TB, can be treated with the same regimens as used for pulmonary TB disease. Peripheral lymph node TB disease has been successfully treated with the 4-month, 4-drug regimen used for nonsevere pulmonary TB disease (rifampin, isoniazid, pyrazinamide, and ethambutol daily for the first 2 months, and isoniazid and rifampin daily for the remaining 2 months). For suspected drug-susceptible tuberculous meningitis, daily treatment with isoniazid, rifampin, pyrazinamide, and ethionamide or a fluoroquinolone (levofloxacin or moxifloxacin) should be initiated. For CNS TB disease, rifampin should be given at a dose of 30 mg/kg/day to ensure adequate CNS penetration and because this dose has been shown to improve neurodevelopmental outcomes. When susceptibility to first-line drugs is established, ethionamide or fluoroquinolone can be discontinued. Pyrazinamide is given for a total of 2 months, and isoniazid and rifampin are given for a total of 6 to 12 months (the longer therapy is preferred by many experts). In children and adolescents with TB meningitis presumed to be drug susceptible, the WHO now states that 6 months of isoniazid, rifampin, pyrazinamide, and ethionamide daily may be used, but the longer treatment regimen of at least 9 months is preferred. Osteoarticular tuberculosis is generally treated with a 4-drug regimen of isoniazid, rifampin, pyrazinamide, and ethambutol for 2 months and isoniazid and rifampin for an additional 10 months (sensitivities should be obtained and treatment adjusted if needed). Consultation with an expert in tuberculosis is advised for treatment of meningitis and osteoarticular disease.

Evaluation and Monitoring of Therapy in Children and Adolescents. Careful monthly monitoring of clinical and bacteriologic responses to therapy is important. With DOT, clinical evaluation is an integral component of each visit (which may be accomplished virtually by video) for drug administration. For patients with pulmonary TB disease, chest radiographs often are obtained after 2 months of therapy to evaluate response. After initiation of treatment, alveolar or interstitial infiltrates may start to decrease within 1 to 2 weeks but take much longer to resolve completely. Pleural effusions are slower to resolve and may require drainage for symptom relief; partial reaccumulation is common as an isolated finding but does not indicate treatment failure. Even with successful 4- to 6-month treatment regimens, hilar adenopathy can persist for 2 to 3 years; normal radiographic findings are not necessary to discontinue therapy. Follow-up chest radiography beyond termination of successful therapy usually is not necessary unless clinical deterioration occurs.

If therapy has been interrupted, the date of completion should be extended. Although guidelines cannot be provided for every situation, factors to consider when establishing the date of completion include the following: (1) length of interruption of therapy; (2) time during therapy (early or late) when interruption occurred; and (3) the patient's clinical, radiographic, and bacteriologic status before, during, and after interruption of therapy. The total doses administered by DOT should be calculated to guide the duration of therapy.

Untoward effects of TB therapy, including severe hepatitis in otherwise healthy infants, children, and adolescents, are rare. Routine determination of serum

¹ World Health Organization. Consolidated Guidelines on Tuberculosis. Module 5: Management of tuberculosis in children and adolescents. World Health Organization; 2022. Available at: www.who.int/publications/i/item/9789240046764

aminotransferase concentrations is not recommended (see Isoniazid Therapy for TBI, p 898) during treatment of TBI or in most cases of TB disease unless the child develops symptoms suggestive of hepatotoxicity or has additional risks for hepatotoxicity such as preexisting liver disease or coadministration of other potentially hepatotoxic drugs. For most children, monthly clinical evaluations to observe for signs or symptoms of hepatitis and other adverse effects of drug therapy without routine monitoring of aminotransferase concentrations is appropriate follow-up. Regular patient contact to assess drug adherence, effectiveness, and adverse effects is an important aspect of management. DOT encounters also are opportunities for checking on well-being and treatment tolerance. Patients should be provided with written instructions and advised to call a physician or clinic immediately if symptoms of adverse events, in particular hepatotoxicity (ie, nausea, vomiting, abdominal pain, jaundice), develop.

Other Treatment Considerations

Corticosteroids. Corticosteroids are given when the host inflammatory response is contributing significantly to organ dysfunction or tissue damage. The evidence supporting adjuvant treatment with corticosteroids for children with TB disease is incomplete. Corticosteroids are definitely indicated for children with tuberculous meningitis, because corticosteroids decrease rates of mortality and long-term neurologic impairment. Corticosteroids can be considered for children with pleural and pericardial effusions (to hasten reabsorption of fluid), severe miliary disease (to mitigate alveolocapillary block), endobronchial disease (to relieve obstruction and atelectasis), and abdominal TB (to decrease the risk of strictures). Corticosteroids should be given only when accompanied by appropriate antituberculosis drug therapy. Most experts give 2 mg/kg per day of prednisone (maximum, 60 mg/day) or its equivalent for 4 to 6 weeks followed by tapering.

Tuberculosis Disease and HIV Infection.¹ Most adults living with HIV with drug-susceptible TB disease respond well to standard treatment regimens. However, optimal therapy for TB disease in children living with HIV has not been established. Treating TB disease in a child living with HIV is complicated by antiretroviral drug interactions with the rifamycins and overlapping toxicities. Therapy always should include at least 4 drugs initially, should be administered daily via DOT, and should be continued for at least 6 months unless it is nonsevere pulmonary disease (defined as tuberculosis confined to 1 lobe with no cavities or isolated intrathoracic adenopathy, no signs of miliary tuberculosis, no complex pleural effusion, and no clinically significant airway obstruction), in which case a 4-month treatment course is acceptable. Rifampin, isoniazid, pyrazinamide, and ethambutol (RIPE) should be administered for at least the first 2 months. Ethambutol can be discontinued once drug-resistant TB disease is excluded. Coadministration of rifampin and antiretroviral therapy may be contraindicated or require antiretroviral therapy dose adjustments, depending on the antiretroviral agents used. Rifabutin is substituted for rifampin in some circumstances. Consultation with a specialist who has experience in managing patients living with HIV with TB disease is strongly advised. If pulmonary disease TB is diagnosed in a person living with HIV

¹ Panel on Opportunistic Infections in Children with and Exposed to HIV. Guidelines for the Prevention and Treatment of Opportunistic Infections in Children with and Exposed to HIV. Department of Health and Human Services. Available at: <https://clinicalinfo.hiv.gov/en/guidelines/pediatric-opportunistic-infection>

who is not yet receiving antiretroviral therapy, even in the presence of severe immune suppression, antiretroviral therapy can be safely initiated within 2 weeks of antituberculosis therapy, despite the risk of inciting immune reconstitution syndrome.

Immunizations. Patients who are receiving treatment for TB disease can receive measles and other age-appropriate attenuated live-virus vaccines unless they are receiving high-dose systemic corticosteroids, are severely ill, or have other specific contraindications to immunization.

Tuberculosis During Pregnancy and Breastfeeding. Pregnant people who have a positive TST or IGRA result, are asymptomatic, have a normal chest radiograph, and have had recent contact with a contagious person should be considered for TBI therapy with isoniazid, which usually should begin after the first trimester; consultation with an expert in TB is recommended. If there has been no recent contact with a contagious person, TBI therapy can be delayed until after delivery. Pyridoxine supplementation is indicated for all pregnant and breastfeeding people receiving isoniazid.

If TB disease is diagnosed during pregnancy, a standard 6-month regimen for drug-susceptible TB is usually initiated; however, 9 months of therapy is indicated if pyrazinamide is not used initially. Prompt initiation of therapy is mandatory to protect the pregnant person and fetus.

There are few adequate and well-controlled studies evaluating the adverse effects of isoniazid, rifampin, ethambutol, and pyrazinamide on the fetus. Isoniazid, ethambutol, and rifampin are believed (based on extensive clinical experience) to be relatively safe for the fetus. The benefit of ethambutol and rifampin for therapy of TB disease in the pregnant person outweighs the risk to the infant. Because aminoglycosides (streptomycin, kanamycin, amikacin) or capreomycin may cause ototoxic effects in the fetus, they should not be used unless administration is essential for effective treatment. Ethionamide has been demonstrated to be teratogenic, so its use during pregnancy is contraindicated. The effects of other antituberculous drugs on the fetus are unknown.

Although isoniazid is secreted in human milk, no adverse effects of isoniazid on breastfeeding infants have been demonstrated. Breastfed infants do not require pyridoxine supplementation unless they are receiving isoniazid, but breastfeeding people who are taking isoniazid should take pyridoxine. The isoniazid dosage of a breastfed infant whose lactating parent is taking isoniazid does not require adjustment for the small amount of drug in the milk.

Congenital Tuberculosis. Congenital TB disease is rare, but in utero infections can occur after bacilleemia in the pregnant person and have been reported following in vitro fertilization of persons from countries with endemic disease in whom infertility likely was related to subclinical genitourinary tract TB disease. The affected neonate is rarely ill at birth, more often becoming ill at 2 to 4 weeks of life.

None of the possible signs of congenital TB disease, such as fever, tachypnea, lethargy, organomegaly, or pulmonary infiltrates, distinguish it from other systemic infections of the newborn infant. The prognosis is poor without prompt treatment. If a newborn infant is suspected of having congenital TB disease, a TST and IGRA test (both are recommended in order to increase sensitivity), chest radiography, abdominal ultrasound, lumbar puncture, and appropriate cultures and radiography should be performed promptly. The TST result usually is negative in newborn infants with congenital or perinatally acquired infection; IGRA sensitivity in this context is not known but is likely to be low. Regardless of the TST or IGRA results, treatment of

the infant should be initiated promptly with rifampin, isoniazid, pyrazinamide, and ethambutol (RIPE). If meningitis is confirmed, corticosteroids should be added (see Corticosteroids, p 913). The placenta should be examined histologically for granulomata and AFB, and a specimen should be cultured for *M tuberculosis* complex. The parent who gave birth should be evaluated for presence of pulmonary or extrapulmonary disease, including genitourinary tuberculosis. HIV testing of the birth parent is essential.

Management of the Newborn Infant Whose Birth Parent Has TBI or TB Disease. Management of the newborn infant is based on categorization of the infection in the parent who gave birth to the newborn. Although protection of the infant from exposure and infection is of paramount importance, contact between infant and birth parent should be allowed when possible. Differing circumstances and resulting recommendations are as follows:

- **Birth parent has a positive TST or IGRA result and normal chest radiographic findings.** If the birthing parent is asymptomatic, no separation is required. The birthing parent usually is a candidate for treatment of TBI during the postpartum period. The newborn infant needs no special evaluation or therapy. Because of the young infant's high susceptibility for TB disease and because the birthing parent's positive TST or IGRA result could be a marker of an unrecognized person with contagious TB disease within the household, other household members should be questioned about having symptoms of TB and have a TST or IGRA and further evaluation as indicated; this should not delay the infant's discharge from the hospital. These birthing parents can breastfeed their infants.
- **Birth parent has clinical signs and symptoms or abnormal findings on chest radiograph consistent with TB disease.** Birthing parents with suspected or proven TB disease should be reported immediately to the local health department, and evaluation of all household members should be initiated as soon as possible. If the birthing parent has TB disease, the infant should be evaluated for congenital TB (see Congenital Tuberculosis, p 914), and the birthing parent should be tested for HIV infection. The birthing parent and the infant should be separated until the birthing parent has completed TB evaluation and, if TB disease is suspected, until the birthing parent and infant are receiving appropriate antituberculosis therapy, the birthing parent wears a mask, the birthing parent understands and is willing to adhere to infection control measures, and contact is in a well-ventilated space. A birthing parent with proven or likely drug-susceptible TB disease who has been treated appropriately for 2 or more weeks and who is not considered contagious (smear-negative sputum) may breastfeed; a birthing parent with TB disease suspected of being contagious or with risk factors for drug-resistant TB disease should refrain from breastfeeding and from other close contact with the infant because of potential spread of *M tuberculosis* through respiratory tract droplets or airborne transmission (see Tuberculosis During Pregnancy and Breastfeeding, p 914). During separation, expressed human milk can be fed to the infant unless the birthing parent has signs of tuberculous mastitis, which is rare. Once the infant is receiving isoniazid or rifampin (see next paragraph), separation is not necessary unless the birthing parent has possible drug-resistant TB disease or has poor adherence to treatment and DOT is not possible. If the birthing parent is suspected of having isoniazid-resistant TB disease, an expert in TB disease management should be consulted.

If congenital TB is excluded, isoniazid or rifampin is administered until the infant is 3 or 4 months of age (or adjusted age if the infant was born prematurely), when a TST or IGRA should be performed. If the result is negative at 3 to 4 months of age and the birthing parent has good adherence and response to treatment and no longer is contagious, the treatment can be discontinued in the infant. If the result is positive, the infant should be reassessed for TB disease. If TB disease is excluded, isoniazid should be continued for a total of 9 months, or a 4-month course of rifampin can be completed. The infant should be evaluated monthly during treatment for signs of illness or poor growth.

- **Birthing parent has a positive TST or IGRA result and abnormal findings on chest radiography but no evidence of TB disease.** If the chest radiograph of the birthing parent appears abnormal but is not suggestive of TB disease and the history, physical examination, and sputum smear indicate no evidence of TB disease, the infant can be assumed to be at low risk of *M tuberculosis* infection and need not be separated from the birthing parent. The birthing parent and infant should receive follow-up care, and the birthing parent should be treated for TBI. Other household members should have a TST or IGRA and further evaluation.

TUBERCULOSIS CAUSED BY *M BOVIS*: Infections with *M bovis* account for approximately 1% to 2% of TB cases in the United States, with higher rates along the border with Mexico. Children who come from countries where *M bovis* is prevalent in cattle or whose parents come from those countries are more likely to be infected. Most infections in humans are transmitted from cattle by unpasteurized milk and its products, such as fresh cheese,¹ although human-to-human transmission by the airborne route has been documented rarely. In children, *M bovis* more commonly causes cervical lymphadenitis, intestinal TB disease and peritonitis, and meningitis. In adults, *M bovis* infection can progress to advanced pulmonary disease with a risk of transmission to others.

The TST result typically is positive in a person infected with *M bovis*; IGRAs have not been studied systematically for diagnosing *M bovis* infection in particular, but theoretically they should have acceptable test characteristics (see Blood-Based Testing With IGRAs, p 893). The definitive diagnosis of *M bovis* infection requires an isolate. The commonly used methods for identifying a microbial isolate as *M tuberculosis* complex do not distinguish *M bovis* from *M tuberculosis*, *M africanum*, and BCG, which is a live attenuated vaccine strain of *M bovis*; *M bovis* is suspected in clinical laboratories by its typical resistance to pyrazinamide. This approach can be unreliable, and species confirmation at a reference laboratory should be requested when *M bovis* is suspected. Molecular genotyping through the state health department may assist in identifying *M bovis*. BCG rarely is isolated from pediatric clinical specimens in the United States; however, it should be suspected from localized BCG suppurative or draining lymphadenitis in children who recently (within several months) received BCG vaccine, or in infants with selected congenital immunodeficiency syndromes who received a BCG vaccine. Only a reference laboratory can distinguish an isolate of BCG from an isolate of *M bovis*.

¹ American Academy of Pediatrics, Committee on Infectious Diseases and Committee on Nutrition. Consumption of raw or unpasteurized milk and milk products by pregnant women and children. *Pediatrics*. 2014;133(1):175-179 (Reaffirmed November 2019)

Therapy for *M bovis* Disease. Controlled clinical trials for treatment of *M bovis* disease have not been conducted, and treatment recommendations for *M bovis* disease in adults and children are based on results from treatment trials for *M tuberculosis* disease. Although most strains of *M bovis* are pyrazinamide-resistant and resistance to other first-line drugs has been reported, MDR strains are rare. Initial therapy for disease caused by *M bovis* should include 3 or 4 drugs, excluding pyrazinamide, that would be used to treat disease attributable to *M tuberculosis*. For isoniazid- and rifampin-susceptible strains, a total treatment course of at least 9 months is recommended.

Parents should be counseled about the many infectious diseases transmitted by unpasteurized milk and its products,¹ and parents who might import traditional, unpasteurized dairy products from countries where *M bovis* infection is prevalent in cattle should be advised against giving those products to their children. When people are exposed to an adult who has pulmonary disease caused by *M bovis* infection, they should be evaluated by the same methods as for *M tuberculosis*.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Most children with TB disease, especially children younger than 10 years, are not contagious. Possible exceptions are the following: (1) children with pulmonary cavities; (2) children with positive sputum AFB smears; (3) children with laryngeal involvement; (4) children with extensive pulmonary disease; or (5) neonates or infants with congenital TB disease undergoing procedures that involve the oropharyngeal airway (eg, endotracheal intubation). In these instances, airborne infection isolation precautions for TB are indicated until effective therapy has been initiated, specimen smears are negative, and coughing has abated. Additional criteria apply to suspected or known MDR TB disease.

Children with no cough and smear-negative sputum AFB smears can be hospitalized in an open ward. Infection prevention measures for hospital personnel and visitors exposed to contagious patients should include the use of personally “fit tested” and “sealed” N95 or higher respirators for all patient contacts (see Infection Prevention and Control for Hospitalized Children, p 163). If the patient has or is suspected to have drug-resistant TB disease, consultation regarding infection prevention and control should be made with public health authorities.

The major concern in infection control relates to adult household members and contacts who can be the source of infection. Visitation should be limited to people who have been evaluated by symptom screening and chest radiograph and do not have TB disease.

CONTROL MEASURES^{2,3}: Control of TB disease in the United States requires collaboration between health care providers and health department personnel, obtaining a thorough history of exposure(s) to people with contagious TB disease, timely and

effective contact tracing, proper interpretation of TST or IGRA results, and appropriate antituberculosis therapy, including DOT services. A plan to control and prevent XDR TB disease has been published.¹ Eliminating ingestion of unpasteurized dairy products will prevent most *M bovis* infection.²

Management of Contacts, Including Epidemiologic Investigation.^{3,4} Children with a positive TST or IGRA result or TB disease ideally should be the starting point for epidemiologic investigation by the local health department. Close contacts of a TST- or IGRA-positive child, if the test was performed because the child has 1 or more risk factors, should have a TST or IGRA, and people with a positive TST or IGRA result or with symptoms consistent with TB disease should be investigated further. Because children with TB disease usually are not contagious unless they have an adult-type multibacillary form of pulmonary or laryngeal disease, their contacts are not likely to be infected unless they also have been in contact with an adult source person. After the presumptive adult source of the child's TBI or TB disease is identified, other contacts of that adult should be evaluated.

Therapy for Contacts. Children and adolescents recently exposed to a contagious person with TB disease should have a TST or IGRA test performed and should be evaluated for TB disease (history and physical examination, as well as chest radiography if symptomatic or positive TST or IGRA results). For exposed contacts with impaired immunity (eg, HIV infection) and all contacts younger than 5 years, treatment for presumptive TBI should be initiated with either isoniazid or rifampin, even if the initial TST or IGRA result is negative, once TB disease is excluded (see Treatment Regimens for TBI, p 898). Children with TBI can have a negative TST or IGRA result because a cellular immune response has not yet developed or because of anergy. Children with a negative TST or IGRA result should be retested 8 to 10 weeks after the last exposure to a source of infection. If the TST or IGRA result still is negative in an immunocompetent person, treatment can be discontinued. If the contact is immunocompromised and TBI cannot be excluded, after an evaluation for TB disease, treatment should be continued to the completion of the regimen. If a TST or IGRA result of a contact becomes positive, the regimen for TBI should be completed after an evaluation for TB disease.

Child Care and Schools. Children with TB disease can attend school or child care if they are receiving therapy (see Children in Group Child Care and Schools, p 145). They can return to regular activities as soon as effective therapy has been instituted, adherence to therapy has been documented, and clinical symptoms have diminished. Children with TBI can participate in all activities whether they are receiving treatment or not.

BCG Vaccines. BCG vaccine is a live vaccine originally prepared from attenuated strains of *M. bovis*. Use of BCG vaccine¹ is recommended by the Expanded Programme on Immunization of the World Health Organization for administration at birth in countries with endemic TB (see Table 1.7, p 40). BCG is used in more than 100 countries to reduce the incidence of disseminated and other life-threatening manifestations of TB disease in infants and young children. Although BCG immunization decreases the risk of serious complications of TB disease in young children, the various BCG vaccines used throughout the world differ in composition and efficacy.

Two meta-analyses of published clinical trials and case-control studies concerning the efficacy of BCG vaccines concluded that BCG vaccine has relatively high protective efficacy (approximately 80%) against meningeal and miliary TB disease in children. The protective efficacy against pulmonary TB disease differed significantly among the studies, precluding a specific conclusion. Protection against pulmonary TB disease by BCG vaccine in one meta-analysis was estimated to be 50%. Comparative evaluations of the BCG vaccine that is licensed in the United States (TICE strain) for the prevention of TB disease versus other BCG vaccines globally have not been performed.

Indications. In the United States, administration of BCG vaccine should be considered only in limited and select circumstances, such as unavoidable risk of exposure to *M. tuberculosis* and failure or unfeasibility of other control methods. Recommendations for use of BCG vaccine for control of TB disease among children and health care personnel have been published by the Advisory Committee on Immunization Practices of the CDC and the Advisory Council for the Elimination of Tuberculosis.² For infants and children, BCG immunization should be considered only for those who have a negative TST result and who do not have contraindications in the following circumstances:

- The child is exposed continually to a person or people with contagious pulmonary TB disease arising from a strain that is resistant to isoniazid and rifampin and the child cannot be removed from this exposure; OR
- The child is exposed continually to a person or people with untreated or ineffectively treated contagious pulmonary TB disease and the child cannot be removed from such exposure or given antituberculosis therapy.

Careful assessment of the potential risks and benefits of BCG vaccine and consultation with personnel in local TB control programs are strongly recommended before use of BCG vaccine.

Adverse Reactions. Uncommonly (1%–2% of immunizations), BCG vaccine can result in local adverse reactions, such as subcutaneous abscess and regional lymphadenopathy, which generally are not serious. One rare complication, osteitis affecting the epiphysis of long bones, can occur as long as several years after BCG immunization. Disseminated fatal infection occurs rarely (approximately 2 per 1 million people), primarily in people who are severely immunocompromised, such as children with poorly controlled HIV infection or severe combined immunodeficiency. Antituberculosis

¹ www.bcgatlas.org

² Centers for Disease Control and Prevention. The role of BCG vaccine in the prevention and control of tuberculosis in the United States: a joint statement by the Advisory Committee for the Elimination of Tuberculosis and the Advisory Committee on Immunization Practices. *MMWR Recomm Rep*. 1996;45(RR-4):1–18

therapy is recommended to treat osteitis and disseminated disease caused by BCG vaccine.

Children with complications caused by BCG vaccine should be referred for management by a TB expert and should be evaluated for an underlying immune deficiency.

Contraindications. People with burns, skin infections, and most primary or secondary immunodeficiencies should not receive BCG vaccine. Children living with HIV who are vaccinated with BCG at birth in the absence of antiretroviral therapy (ART) are at increased risk for disseminated disease attributable to BCG. BCG vaccine should not routinely be administered to infants and children with HIV in the United States. Use of BCG vaccine is contraindicated for people receiving immunosuppressive medications including high-dose corticosteroids (see Corticosteroids, p 913). Although no untoward effects of BCG vaccine on the fetus have been observed, immunization of people during pregnancy is not recommended.

Public Health Reporting. Reporting of suspected and confirmed cases of TB disease is mandated by law in all states. TB disease is a nationally notifiable condition. TBI (latent tuberculosis) is reportable in some states.

Nontuberculous Mycobacteria

(Environmental Mycobacteria, Mycobacteria Other Than *Mycobacterium tuberculosis*)

CLINICAL MANIFESTATIONS: Several syndromes are caused by nontuberculous mycobacteria (NTM).

- In children, the most common of these syndromes is cervical lymphadenitis.
- Cutaneous infection may follow soil- or water-contaminated traumatic wounds, surgeries, or cosmetic procedures (eg, tattoos, pedicures, body piercings).
- Less common syndromes include skin and soft tissue infection, osteomyelitis, otitis media, central catheter-associated bloodstream infections, and pulmonary infections, especially in adolescents with cystic fibrosis.
- NTM, especially *Mycobacterium avium* complex (MAC [including *Mycobacterium avium* and *Mycobacterium avium-intracellulare*]) and *Mycobacterium abscessus*, can be recovered from sputum in 10% to 20% of adolescents and young adults with cystic fibrosis and can be associated with fever and declining clinical status.
- Disseminated infections almost always are associated with impaired cell-mediated immunity, as found in children with congenital immune defects (eg, interleukin-12 deficiency, cytokine–JAK–STAT pathways abnormalities, NF-kappa-B essential modulator [NEMO] mutation and related disorders, and interferon-gamma receptor defects), hematopoietic cell transplants, or advanced human immunodeficiency virus (HIV) infection. Disseminated NTM infection, most commonly MAC, is rare in children living with HIV during the first year of life. The frequency of disseminated MAC increases with increasing age and declining CD4+ T-lymphocyte counts, typically less than 50 cells/mm³, in children 6 years or older.¹ Manifestations of disseminated NTM infections depend on the species and route of infection and

¹ Panel on Opportunistic Infections in Children with and Exposed to HIV. Guidelines for the Prevention and Treatment of Opportunistic Infections in Children with and Exposed to HIV. Department of Health and Human Services. Available at: <https://clinicalinfo.hiv.gov/en/guidelines/pediatric-opportunistic-infection>

include fever, night sweats, weight loss, abdominal pain, fatigue, diarrhea, and anemia. These signs and symptoms also are found in advanced immunosuppressed children living with HIV infection without disseminated MAC. For children living with HIV infection who have disseminated MAC, respiratory symptoms and isolated pulmonary disease are uncommon. In patients living with HIV infection who develop immune restoration with initiation of antiretroviral therapy, local NTM symptoms can worsen temporarily. This immune reconstitution syndrome usually occurs 2 to 4 weeks after initiation of antiretroviral therapy. Symptoms can include worsening fever, swollen lymph nodes, local pain, and laboratory abnormalities.

ETIOLOGY: Of the close to 200 species of NTM that have been identified, only a few species cause most human infections. The species most commonly infecting children in the United States are MAC, *Mycobacterium fortuitum*, *M. abscessus*, and *Mycobacterium marinum* (Table 3.87). Several new species, which can be detected by nucleic acid amplification tests (NAATs) but cannot be grown by routine culture methods, have been identified in lymph nodes of children with cervical adenitis. NTM disease in patients living with HIV infection usually is caused by MAC. *M. fortuitum*, *Mycobacterium chelonae*, *Mycobacterium smegmatis*, and *M. abscessus* are referred to as “rapidly growing” mycobacteria, because visible growth can be detected in subculture usually within 7 days on solid media, whereas MAC, *M. marinum*, and *Mycobacterium szulgai* require several weeks before sufficient growth occurs and are referred to as “slow growing” mycobacteria. Rapidly growing mycobacteria have been implicated most often in wound, soft tissue, bone, pulmonary, central venous catheter, and middle-ear infections. Other mycobacterial species that usually are not pathogenic have caused infections in immunocompromised hosts or have been associated with the presence of a foreign body.

EPIDEMIOLOGY: NTM are ubiquitous in nature, being found in soil, food, water, and animals. Tap water is the major reservoir for *M. avium* (included in MAC), *Mycobacterium chimaera* (belonging to MAC), *Mycobacterium kansasii*, *Mycobacterium lentiflavum*, *Mycobacterium xenopi*, *Mycobacterium simiae*, and health care-associated infections attributable to *M. abscessus* and *M. fortuitum*. Outbreaks have been associated with contaminated water used for acupuncture and pedicures and inks used for tattooing. Health care-associated outbreaks have occurred among children undergoing pulpotomy or other dental procedures associated with improperly maintained dental unit water lines. Outbreaks of otitis media caused by *M. abscessus* have been associated with polyethylene ear tubes and use of contaminated equipment or water. Health care-associated outbreaks of *M. chelonae* have been associated with the use of commercial-grade misting humidifiers and nonsterile ice for invasive procedures. For *M. marinum*, water in a fish tank or aquarium or an injury in a salt-water environment are the major sources of infection. A waterborne route of transmission has been implicated for MAC infection in some immunocompromised hosts. A variety of other outbreaks associated with contaminated medical equipment, inoculation through injections, surgery, and other procedures have been reported, particularly in settings of poor infection control practices. Pseudo-outbreaks associated with contamination of specimens or reagents have also been reported.

An international outbreak of *M. chimaera* infection (including prosthetic valve endocarditis, vascular graft infection, and disseminated infection) has been associated with heater-cooler devices used in heart surgery requiring cardiopulmonary bypass and is

	<i>M. kansasii</i>
	<i>Mycobacterium genavense</i>
	<i>M. haemophilum</i>
	<i>M. chelonae</i>

^aNot endemic in the United States.
^bFound primarily in Northern Europe.

attributable to aerosolization of *M chimera* from contaminated devices. Clinical presentation is indolent and includes fever, myalgia, arthralgia, fatigue, and weight loss, with diagnosis in patients often occurring up to several years after exposure. The US Food and Drug Administration (FDA) has determined that all heater-cooler devices have common design features that could lead to bioaerosol formation.

Although many people are exposed to NTM, it is unknown why some exposures result in acute or chronic infection. Usual portals of entry for NTM infection are believed to be abrasions in the skin, such as cutaneous lesions caused by *M marinum*; penetrating trauma such as needles and organic material most often associated with *M abscessus* and *M fortuitum*; surgical sites, especially for cosmetic surgery and central vascular or peritoneal dialysis catheters; oropharyngeal mucosa, which is the presumed portal of entry for cervical lymphadenitis; tooth eruption, which is the presumed portal of entry for submandibular lymphadenitis; gastrointestinal or respiratory tract, for disseminated MAC; and respiratory tract, including tympanostomy tubes for otitis media. Pulmonary disease and rare cases of mediastinal adenitis and endobronchial disease occur. NTM are important pathogens in patients with cystic fibrosis and are emerging pathogens in individuals receiving biologic response modifiers, such as anti-tumor necrosis factor- α agents (see Biologic Response-Modifying Drugs Used to Decrease Inflammation, p 104). Most infections remain localized at the portal of entry or in regional lymph nodes. Dissemination to distal sites primarily occurs in severely immunocompromised hosts.

No definitive evidence of person-to-person transmission of NTM exists outside of reports of possible occurrence in cystic fibrosis care centers.

Buruli ulcer disease is a skin and bone infection caused by *Mycobacterium ulcerans*, an emerging disease causing significant morbidity and disability in tropical areas such as Africa, Asia, South America, Australia, and the western Pacific.

The **incubation periods** for NTM are variable.

DIAGNOSTIC TESTS: Routine screening of respiratory or gastrointestinal tract specimens for NTM is not recommended except in the setting of cystic fibrosis, where respiratory specimens should be cultured for mycobacteria annually in those with a stable course who are spontaneously expectorating. Definitive diagnosis of NTM disease generally requires isolation of the organism, although molecular diagnostic tests are becoming more widely available. Consultation with the laboratory should occur to ensure that cultures and other specimens are handled correctly. For example, isolation of *Mycobacterium haemophilum* requires that the culture is maintained at 30°C and that heme-containing medium is added for isolation. Because NTM commonly are found in the environment, contamination of cultures or transient colonization can occur. Caution must be exercised in interpretation of cultures obtained from nonsterile sites, such as gastric washing specimens, endoscopy material, a single expectorated sputum sample, or urine specimens, and when the species cultured usually is nonpathogenic (eg, *Mycobacterium terrae* complex or *Mycobacterium goodii*). An acid-fast bacilli smear-positive sample and repeated isolation on culture media of a single species from any site are more likely to indicate disease rather than culture contamination or transient colonization. Diagnostic criteria for NTM lung disease in adults include 2 or more separate sputum samples or 1 bronchial alveolar lavage or bronchial wash specimen that grows NTM. These criteria have not been validated in children and apply best to MAC, *M kansasii*, and *M abscessus*. NTM isolates from draining sinus tracts or wounds

almost always are clinically significant. Recovery of NTM from sites that usually are sterile, such as cerebrospinal fluid, pleural fluid, bone marrow, blood, lymph node aspirates, middle ear or mastoid aspirates, or surgically excised tissue, is very likely to be clinically significant. However, rare instances of sample or laboratory contamination leading to a false-positive culture result have been reported. With radiometric or non-radiometric broth techniques, blood cultures are highly sensitive in recovery of MAC and other bloodborne NTM species. If disseminated MAC disease is confirmed, the patient should be evaluated for underlying immunodeficiency conditions. Polymerase chain reaction-based assays for some NTM have been developed but are not yet widely available in commercial diagnostic laboratories. Matrix-assisted laser desorption/ionization–time-of-flight (MALDI-TOF) instruments have been approved for the identification of mycobacteria species and may allow for more NTM isolates to get species identification faster than traditional methods.

Patients with NTM infections can have positive tuberculin skin test (TST) result, because the purified protein derivative preparation, derived from *Mycobacterium tuberculosis*, shares a number of antigens with these NTM species. These TST reactions usually measure less than 10 mm of induration but can measure more than 15 mm (see Tuberculosis, p 888). The interferon-gamma release assays (IGRAs) use 2 or 3 antigens more specific to *M tuberculosis* complex and result in less cross-reactivity from MAC and most other NTM species compared with TST. However, cross-reactions can occur with infection caused by *M kansasii*, *M marinum*, and *M szulgai* (see Tuberculosis, p 888).

TREATMENT^{1,2}: NTM are relatively resistant in vitro to antimycobacterial drugs, but this does not necessarily correlate with clinical response, especially with MAC infections. Only limited controlled trials of drug treatment have been performed in adults with NTM infections, and none have been conducted in children. The approach to initial therapy for an NTM infection should be directed by the following: (1) the species causing the infection; (2) the results of drug-susceptibility testing, especially to macrolides and amikacin; (3) the site(s) of infection; (4) the patient's immune status; and (5) the need to treat a patient presumptively for tuberculosis while awaiting culture reports that subsequently reveal NTM.

For NTM lymphadenitis in otherwise healthy children, especially when the disease is caused by MAC, complete surgical excision is curative and limits scar formation. Published reports of antimicrobial therapy without surgical incision have had variable success rates. Therapy with azithromycin or clarithromycin combined with either a rifamycin (eg, rifampin or rifabutin) or ethambutol may be beneficial for children in whom surgical excision is not possible or is incomplete and for children with recurrent disease; use of a 3-drug regimen consisting of a macrolide, a rifamycin, and ethambutol can be considered for children with more extensive disease (see Table 3.88).

Table 3.88. Treatment of Nontuberculous Mycobacteria Infections in Children^a

Organism	Disease	Initial Treatment
Slowly Growing Species^a		
<i>Mycobacterium avium</i> complex (MAC); <i>Mycobacterium haemophilum</i> ; <i>Mycobacterium lentiflavum</i>	Lymphadenitis	Complete excision of lymph nodes; if excision incomplete or disease recurs, azithromycin or clarithromycin plus either a rifamycin (rifampin or rifabutin) or ethambutol; children with more extensive disease may require a 3-drug regimen consisting of a macrolide, a rifamycin, and ethambutol.
	Pulmonary infection	Azithromycin or clarithromycin plus ethambutol and rifampin (or rifabutin); pulmonary resection may be needed in some patients who fail to respond to drug therapy. For severe disease, an initial course of amikacin or streptomycin often is included. Clinical data in adults with mild to moderate disease support that 3-times-weekly therapy is as effective as daily therapy, with less toxicity. For patients with advanced or cavitary disease, or those with cystic fibrosis drugs should be given daily.
<i>Mycobacterium chimaera</i> (belonging to MAC)	Prosthetic valve endocarditis	Valve removal, prolonged antimicrobial therapy based on susceptibility testing, but generally azithromycin or clarithromycin, ethambutol, and rifampin (or rifabutin). Additional drugs including amikacin and/or clofazimine are often used.
	Disseminated	See text.
<i>Mycobacterium kansasii</i>	Pulmonary infection	Azithromycin or clarithromycin plus rifampin and ethambutol daily or three times a week. Alternatively, isoniazid plus rifampin and ethambutol daily. If rifampin resistance is detected, a 3-drug regimen based on drug susceptibility testing should be used.
	Osteomyelitis	Surgical débridement and prolonged antimicrobial therapy using the regimen above.
<i>Mycobacterium marinum</i>	Cutaneous infection	None, if minor; rifampin, trimethoprim-sulfamethoxazole, clarithromycin, or doxycycline ^b for moderate disease; extensive lesions may require surgical débridement. Susceptibility testing not routinely required.
<i>Mycobacterium ulcerans</i>	Cutaneous and bone infections	Rifampin and clarithromycin for 8 weeks; excision to remove necrotic tissue, if present; potential response to thermotherapy.

Table 3.88. Treatment of Nontuberculous Mycobacteria Infections in Children,^a continued

Organism	Disease	Initial Treatment
Rapidly Growing Species^a		
<i>Mycobacterium fortuitum</i> complex	Cutaneous infection	Initial therapy for serious disease is amikacin plus imipenem (or meropenem), IV. When starting oral therapy, options often include doxycycline, ^b trimethoprim-sulfamethoxazole, or ciprofloxacin. ^c Antimicrobial selection should be based on in vitro susceptibility testing. May require surgical excision.
	Catheter infection	Catheter removal; amikacin plus meropenem, IV; oral options often include trimethoprim-sulfamethoxazole or ciprofloxacin. ^c Antimicrobial selection should be based on in vitro susceptibility testing.
<i>Mycobacterium abscessus</i>	Otitis media; cutaneous infection	For macrolide-susceptible isolates, 3 or more drugs guided by drug susceptibility test results. Example regimen include azithromycin or clarithromycin plus initial course of amikacin, imipenem or meropenem, cefoxitin, or tigecycline ^d for at least 2 months, followed by 2 or more oral drugs guided by drug susceptibility test results. For macrolide resistant (mutational or inducible) isolates, 4 or more drugs guided by drug susceptibility test results. May require surgical débridement; expert consultation is advised.
	Pulmonary infection (in cystic fibrosis)	Regimen options as above; may include inhaled drugs; may require surgical resection although rarely performed in people with cystic fibrosis; expert consultation advised.
<i>Mycobacterium chelonae</i>	Catheter infection, prosthetic valve endocarditis	Catheter removal; débridement, removal of infected foreign material; valve replacement; and tobramycin (initially), imipenem or meropenem, plus azithromycin or clarithromycin, and linezolid or clofazimine.
	Disseminated cutaneous infection	Tobramycin (initially), imipenem or meropenem, plus azithromycin or clarithromycin, and linezolid or clofazimine.

IV indicates intravenously; MIC, minimum inhibitory concentration.

^aTreatment always includes 2 or more drugs.

^bDoxycycline can be used without regard to patient age.

^cSee Fluoroquinolones, p 973.

^dExperience with using tigecycline in children is limited; it should not be used in children younger than 8 years if there are effective alternatives, because there may be reversible inhibition of bone growth and adverse effects on tooth development. Tigecycline also has a black box warning for an increase in all-cause mortality and should be reserved for situations where alternative agents are not suitable.

The natural history of NTM lymphadenitis without curative surgical excision is slow resolution but with a high risk of spontaneous drainage through the skin and resulting scarring, even when antimicrobial management is used. Joint decision making with the parent(s) and possibly the child depending on age, and the surgeon and pediatric infectious disease consultant are important in developing the best treatment plan for each patient.

The choice of drugs, dosages, and duration should be reviewed with a consultant experienced in the management of NTM infections but always includes 2 or more drugs to which the organism is susceptible (see Table 3.88). Infected indwelling foreign bodies must be removed, and surgical débridement for serious localized disease is optimal, especially for infections caused by *M abscessus*. Clinical isolates of MAC usually are resistant to many of the approved antituberculosis drugs, including isoniazid but generally are susceptible to azithromycin and clarithromycin with variable susceptibility to ethambutol, rifabutin or rifampin, amikacin, or streptomycin. Secondary agents include moxifloxacin and linezolid; susceptibility testing to these other agents has not been correlated with clinical outcomes, so they are not recommended routinely. Isolates of rapidly growing mycobacteria (*M fortuitum*, *M abscessus*, and *M chelonae*) should be tested in vitro against drugs to which they commonly are susceptible and that have been used with some therapeutic success (eg, amikacin, imipenem, sulfamethoxazole or trimethoprim-sulfamethoxazole, cefoxitin, ciprofloxacin, clarithromycin, linezolid, clofazimine, doxycycline, and tigecycline, although tigecycline has a black box warning for an increase in all-cause mortality and should be reserved for situations in which alternative agents are not suitable). Additionally, evidence of inducible macrolide resistance should be investigated by extending the culture incubation to 14 days or identifying the *erm* gene with sequencing or line-probe assay.

Patients receiving therapy should be monitored for evidence of treatment response and adverse drug reactions. Patients receiving clarithromycin plus rifabutin or high-dose rifabutin (with another drug) should be observed for rifabutin-related development of leukopenia, uveitis, polyarthralgia, and pseudojaundice.

The duration of therapy for NTM infections depends on host status, site(s) of involvement, severity of disease, and response to therapy. Most patients who respond ultimately show substantial clinical improvement in the first 4 to 6 weeks of therapy. Elimination of the organisms from blood cultures can take longer, often up to 12 weeks. Most experts recommend a minimum treatment duration of 3 to 6 months, but longer therapy is often required. In patients with cystic fibrosis who have NTM pulmonary disease, the duration of therapy is 12 months beyond achievement of culture negativity.

For patients with cystic fibrosis and isolation of MAC species, treatment is suggested only for those with clinical symptoms not attributable to other causes, worsening lung function, and chest radiographic progression. The decision to initiate therapy should take into consideration susceptibility testing results and should involve consultation with a specialist in cystic fibrosis care.

In children with living with HIV infection and in other immunocompromised patients with disseminated MAC infection, multidrug therapy is recommended. Treatment of disseminated MAC infection should be undertaken in consultation with

an expert because the infections are life threatening and drug-drug interactions may occur between medications used to treat disseminated MAC and HIV.

The optimal time to initiate antiretroviral therapy in a child in whom HIV infection and disseminated MAC are newly diagnosed is not established. Many experts provide treatment of disseminated MAC for 2 weeks before initiating antiretroviral therapy in an attempt to minimize occurrence of the immune reconstitution syndrome and minimize confusion relating to the cause of drug-associated toxicity.

Chemoprophylaxis. The most effective way to prevent disseminated MAC in children living with HIV infection is to preserve their immune function through use of antiretroviral therapy. Children living with HIV infection who have advanced immunosuppression should be offered prophylaxis against disseminated MAC with azithromycin or clarithromycin based on their CD4+ T-lymphocyte counts, provided disseminated MAC has been excluded by a negative blood culture in AFB-specific blood culture bottles.¹ Combination therapy for prophylaxis should be avoided in children, if possible, because it has not been shown to be cost-effective and increases rates of adverse events. Children with a history of disseminated MAC and continued immunosuppression should receive lifelong prophylaxis to prevent recurrence. Prophylaxis can be discontinued in some children living with HIV infection after immune reconstitution as detailed in the guidelines for opportunistic infections in children.¹ For adolescents who are diagnosed with HIV infection, MAC prophylaxis does not need to be started if antiretroviral therapy is immediately started after the HIV diagnosis. Adolescents who are not receiving antiretroviral therapy or are viremic on antiretroviral therapy with no current options for a fully suppressive antiretroviral therapy regimen should receive MAC prophylaxis if they have CD4+ T-lymphocyte counts <50 cells/mm³. MAC prophylaxis can be discontinued for adolescents after immune reconstitution, as detailed in the HIV guidelines for opportunistic infections.²

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended. For patients with cystic fibrosis see recommendations from the Cystic Fibrosis Foundation.³

CONTROL MEASURES: Control measures include chemoprophylaxis for high-risk patients living with HIV infection (see Treatment, p 924) and avoidance of tap water contamination of central venous catheters, dental procedures, surgical procedures and

Available at: <https://clinicalinfo.hiv.gov/en/guidelines/adult-andadolescent-opportunistic-infection>

³ The Cystic Fibrosis Foundation has additional recommendations for infection prevention and control in patients with cystic fibrosis, regardless of respiratory tract culture results: Saiman L, Seigel JD, LiPuma JJ, et al. Infection prevention and control guideline for cystic fibrosis: 2013 update. *Infect Control Hosp Epidemiol*. 2014;35(Suppl 1): S1-S67. Available at: www.cff.org/Care/Clinical-Care-Guidelines/Infection-Prevention-and-Control-Clinical-Care-Guidelines/Infection-Prevention-and-Control-Clinical-Care-Guidelines/

wounds, injections and injectable medications, skin, or endoscopic equipment and other medical devices.

FDA instructions are available regarding the use of filtered water (not tap water) for heater-cooler devices and other recommendations related to these devices (www.fda.gov/medical-devices/what-heater-cooler-device/recommendations-use-any-heater-cooler-device). If heater-cooler devices are implicated in *M. chimaera* infection or have been or are to be used in cardiac surgeries, patients should be informed (preferably before their surgery) of the risk and monitored after surgery for signs and symptoms suggestive of infection. These devices are also used for extracorporeal membrane oxygenation (ECMO), but to date no cases related to use in this setting have been reported. If *M. chimaera* or any NTM is suspected or documented to be potentially associated with a device, an FDA medical device report should be filed with MedWatch (see MedWatch – the FDA Safety Information and Adverse Event-Reporting Program, p 1113).

Tularemia

CLINICAL MANIFESTATIONS: There are several common presentations of tularemia in children, with ulceroglandular disease being the most frequently identified. Characterized by a maculopapular lesion at the entry site with subsequent ulceration and slow healing, the ulceroglandular variant is associated with tender regional lymphadenopathy that can drain spontaneously. The glandular variant (regional lymphadenopathy with no ulcer) also is common. Less common disease variants include oculoglandular (severe conjunctivitis with preauricular lymphadenopathy), oropharyngeal (exudative stomatitis, painful pharyngitis, or tonsillitis with cervical lymphadenopathy), typhoidal (high fever, septicemia, possible splenomegaly or hepatomegaly), and meningitis. Secondary skin eruptions, which can include vesicular skin lesions, can be mistaken for herpes simplex virus or varicella zoster virus cutaneous infections. Pneumonic tularemia presents with fever, dry or productive cough, chest pain, and hilar adenopathy with or without chest abnormalities. Pneumonic tularemia is normally caused by inhalation of contaminated dust or aerosols often associated with farming or lawn maintenance activities; it can also occur when other forms of tularemia remain untreated and spread through the bloodstream to the lungs. Pneumonic tularemia would be the anticipated variant after intentional release of aerosolized organisms.

ETIOLOGY: *Francisella tularensis* is a small, weakly staining, gram-negative pleomorphic coccobacillus. Two subspecies cause human infection in North America: *F. tularensis* subspecies *tularensis* (type A), and *F. tularensis* subspecies *holarctica* (type B). Type A is generally considered more virulent, especially if inhaled. In the absence of effective chemotherapy, inhalation of small numbers of type A bacteria has a mortality rate of >30%. Therefore, in this situation, rapid diagnosis and chemotherapy is critical.

EPIDEMIOLOGY: *F. tularensis* can infect more than 100 animal species; the vertebrate species considered most important in enzootic cycles are lagomorphs (rabbits and hares) and rodents (especially muskrats, voles, beavers, and prairie dogs). Domestic cats and dogs are an additional but uncommon source of infection. In the United States, most human cases are attributed to tick bites but may also result from bites of other arthropod vectors, such as deer flies, or direct contact with any of the aforementioned

animal species. Infections attributable to tick and deer fly bites usually take the form of ulceroglandular or glandular tularemia. *F tularensis* bacteria can be transmitted to humans via the skin when handling infected animal tissue, as can occur when hunting or skinning infected rabbits, muskrats, prairie dogs, and other rodents. Infection has been reported in commercially traded hamsters and prairie dogs. Infection also can be acquired following ingestion of contaminated water (including contaminated well water) or inadequately cooked meat, or by inhalation of contaminated aerosols generated during lawn mowing, brush cutting, or certain farming activities (eg, baling contaminated hay). At-risk people have occupational or recreational exposure to infected animals or their habitats; this includes rabbit hunters and trappers, people exposed to certain ticks or biting insects, and laboratory technicians working with *F tularensis*, which is highly infectious and may be aerosolized when grown in culture. In the United States, most cases occur from May through September. Approximately two thirds of cases occur in male individuals, and one quarter of cases occur in children younger than 15 years of age.

Tularemia has been reported in all US states except Hawaii. It is most common in central and western states and parts of Massachusetts (particularly Martha's Vineyard). In 2019, a total of 274 cases in the United States were reported.

Organisms can be present in blood during the first 2 weeks of disease and in cutaneous lesions for as long as 1 month if untreated. Person-to-person transmission has not been reported.

The **incubation period** usually is 3 to 5 days, with a range of 1 to 21 days.

DIAGNOSTIC TESTS: Because of its propensity for causing laboratory-acquired infections, laboratory personnel should be alerted immediately when *F tularensis* infection is suspected. Isolation of *F tularensis* confirms infection and is most successful from specimens of ulcers, lymph node aspirates or biopsies, pleural fluid and/or other respiratory tract specimens, pharyngeal swabs, or blood depending on the form of illness, and is best achieved by inoculation of cysteine-enriched media. Blood cultures are often negative. Biosafety level 2 practices are recommended for initial activities involving clinical specimens. If tularemia is suspected on the basis of clinical and epidemiological history or Gram stain identification of tiny gram-negative coccobacilli, biological safety level (BSL)-3 practices, containment equipment, and facilities are recommended for all manipulations of suspect cultures. All isolates suspected to be *F tularensis* should be discussed with the state public health agency and forwarded for confirmation to local reference laboratories (usually the state laboratory) that are part of the Laboratory Response Network.

F tularensis in clinical samples can be identified by a laboratory-developed and validated nucleic acid amplification test (NAAT). Immunohistochemical staining is specific for detection of *F tularensis* in fixed tissues; however, this method is not available in most clinical laboratories.

Diagnosis is established most often by serologic testing. Patients do not develop antibodies until the second week of illness. Serologic assays include microagglutination, tube agglutination, enzyme-linked immunosorbent assay, and indirect immunofluorescence assay. Confirmatory serologic laboratory evidence includes a fourfold or greater change in serum antibody titer to *F tularensis* antigen between acute and convalescent specimens. Seroconversion from negative to positive immunoglobulin (Ig) M and/or IgG antibodies in paired sera is also indicative of infection. A single elevated

serum antibody titer to *F tularensis* antigen, collected at least 14 days after illness onset, is supportive of the diagnosis, but can also occur with past infection. Additional information on confirmatory and supportive laboratory diagnosis is available at www.cdc.gov/tularemia/clinicians/index.html.

TREATMENT: Gentamicin (2.5 mg/kg/dose, administered 3 times daily, intravenously or intramuscularly, with the dose adjusted to maintain the desired peak serum concentrations of at least 5 µg/mL) is the drug of choice for the treatment of tularemia in children because of the limited availability of streptomycin and the fewer adverse effects of gentamicin. Gentamicin administered as a once daily dose, rather than divided, may be considered in consultation with an expert in infectious diseases. The usual duration of therapy is 10 to 14 days. A 7-day course may be sufficient in mild disease, but a longer course is required for more severe illness (eg, meningitis). Because of the difficulty in achieving adequate cerebrospinal fluid concentrations of gentamicin, combination therapy of gentamicin plus ciprofloxacin or gentamicin plus doxycycline may be considered for patients with tularemia meningitis (see Tables of Antibacterial Drug Dosages, p 987, and www.cdc.gov/tularemia/clinicians/index.html). Suppuration of lymph nodes can occur despite antimicrobial therapy.

Oral ciprofloxacin is an alternative for mild to moderate disease, but it is not approved by the US Food and Drug Administration for the treatment of tularemia. Doxycycline is associated with a higher rate of relapse compared with other therapies and is not recommended for definitive treatment; if doxycycline is used, some experts recommend extending treatment to 21 days. *F tularensis* is not susceptible to beta-lactam drugs, including carbapenems.

Because treatment delay is associated with therapeutic failure, treatment should be initiated as soon as tularemia is suspected. Clinically relevant resistance to antimicrobials recommended for treatment of tularemia has not been identified in the United States; when treatment failures occur, they are likely related to delays in treatment or inadequate antimicrobial penetration of infected tissue.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS: Standard precautions are recommended.

CONTROL MEASURES:

- People should protect themselves against arthropod bites by wearing protective clothing, by frequent inspection for and removal of ticks from the skin and scalp, and by using insect repellents (see Prevention of Mosquito-borne and Tick-borne Infections, p 207).
- Drinking untreated surface water should be avoided.
- Gloves should be worn by those handling the carcasses of wild rabbits, muskrats, prairie dogs, and other potentially infected animals. Children should not handle sick or dead animals, including pets.
- People should avoid mowing over live or dead animals because this may aerosolize infective material.
- Game meats should be cooked thoroughly.
- Primary clinical specimens may be handled in the laboratory using BSL-2 precautions. BSL-3 precautions are recommended for all manipulations of suspect cultures. Note that *F tularensis* is a tier 1 select agent and must be handled as such after it has been identified. Additional information on laboratory safety can be found in the Centers for

Disease Control and Prevention (CDC) Biosafety in Microbiological and Biomedical Laboratories manual (www.cdc.gov/biosafety/publications/bmbl5/).

- Standard precautions should be used for handling clinical materials.
- Oral doxycycline or ciprofloxacin for 10 to 14 days is recommended for children and adults after exposure to an intentional release of tularemia (eg, a bioterrorism attack) and for laboratory workers with inadvertent exposure to *F tularensis*.

Public Health Reporting. Tularemia is a nationally notifiable condition; a suspected case should be reported immediately to the state or local health department.

Louse-borne Typhus (Epidemic or Sylvatic Typhus)

CLINICAL MANIFESTATIONS: Louse-borne or epidemic typhus is an uncommon disease that is spread through contact with infected human body lice. Patients develop abrupt onset of high fever, chills, and myalgia accompanied by severe headache and malaise. A rash often develops by day 4 to 7 after the start of illness but may not always be present and should not be relied on for diagnosis. When present, the rash usually begins on the trunk and axilla, spreads centrifugally to the limbs, and generally spares the face, palms, and soles. The rash typically is macular to maculopapular but in advanced stages can become petechial or hemorrhagic. The rash can be difficult to observe on patients with darkly pigmented skin and is absent in up to 40% of patients. There is no eschar, as might be present in many other rickettsial diseases. Abdominal complaints (stomach pain, nausea) and changes in mental status are common, including delirium, drowsiness, seizures, and coma. Cough and tachypnea may be present. Myocardial and renal failure can occur when disease is severe. The fatality rate in untreated people can exceed 30%, particularly among persons who are malnourished and those without access to supportive care. Mortality is less common in children and increases with advancing age. Untreated patients who recover typically have an illness lasting 2 weeks.

Brill-Zinsser disease is a recrudescent form of epidemic typhus that is unrelated to louse infestation. It can occur years after the initial episode, and generally occurs when the body's immune system is weakened from illness, medications, advanced age, or stress. The symptoms of Brill-Zinsser disease generally are milder in nature and shorter in duration than the initial infection.

Laboratory abnormalities in epidemic typhus may include thrombocytopenia, increased hepatic enzymes, hyperbilirubinemia, and elevated blood urea nitrogen.

ETIOLOGY: Epidemic typhus is caused by *Rickettsia prowazekii*, which are gram-negative obligate intracellular bacteria.

EPIDEMIOLOGY: Epidemic typhus is transmitted by the human body louse (*Pediculus humanus corporis*), which is infected through feeding on patients with acute typhus fever. Humans are the primary reservoir of the organism. Infected lice generally defecate during feeding and excrete the bacteria in their feces. Disease transmission can occur when infected louse feces are rubbed into broken skin or mucous membranes or are inhaled. All ages can be affected. Poverty, crowding, and poor sanitary conditions such as those found in war, famine, drought, and other natural disasters contribute to the spread of body lice and, hence, the disease. Cases have occurred throughout the world, including the colder, mountainous areas of Asia, Africa, some parts of Europe,

and Central and South America, particularly in refugee camps and jails in resource-limited countries. Epidemic typhus is most common during winter months, when conditions favor person-to-person transmission of the vector. The last known epidemic of louse-borne typhus in the United States occurred in 1921. Sporadic human cases associated with close contact with infected flying squirrels (*Glaucomys volans*), their nests, or their ectoparasites occasionally are reported in the eastern United States. Cases have been reported in people who reside or work in flying squirrel-infested dwellings, even when direct contact is not reported. Flying squirrel-associated disease, called sylvatic typhus, typically presents with a similar but generally milder illness to that observed with body louse-transmitted infection. Untreated illness can be severe, although no fatal cases of sylvatic typhus have been reported; the later development of Brill-Zinsser disease has been confirmed in at least 1 case of untreated sylvatic typhus.

People with Brill-Zinsser disease harbor active *R prowazekii* and, therefore, may pose a risk for reintroduction of the organism and new outbreaks. Rickettsiae are present in the blood and tissues of patients during the early febrile phase but are not found in secretions. Direct person-to-person spread of the disease does not occur in the absence of the louse vector.

The **incubation period** is 1 to 2 weeks.

DIAGNOSTIC TESTS: Louse-borne typhus may be diagnosed via indirect immunofluorescence antibody (IFA) assay; immunohistochemistry (IHC); a nucleic acid amplification test (NAAT) of blood, plasma, or tissue samples; or isolation by culture. Serologic tests are the most common means of confirmation and can be used to detect either immunoglobulin (Ig) G or IgM antibodies. The specimen preferably should be obtained within the first week of symptoms and before (or within 24 hours of) doxycycline administration. Detectable levels of IgG and IgM antibodies generally do not appear until around 7 to 10 days after onset of symptoms, so a negative test result early in the disease does not rule out infection. The gold standard for serologic diagnosis of louse-borne typhus is a fourfold increase in IgG antibody titer by the IFA test between acute sera obtained in the first week of illness and convalescent sera obtained 2 to 4 weeks later. Low-level antibody titers may persist in persons for years; therefore, only a change in titer in paired samples is diagnostic of recent infection. People with Brill-Zinsser disease generally show an elevation in their IgG but not IgM antibody concentrations to *R prowazekii*. Cross-reactivity may be observed to antibodies to *Rickettsia typhi* (the agent of endemic typhus) and, to a lesser degree, *Rickettsia rickettsii* (the etiologic agent of Rocky Mountain spotted fever) and other spotted fever group rickettsiae. *R prowazekii* also may be cultured and identified through submission to specific reference laboratories that are equipped to culture and identify epidemic typhus. Cell culture cultivation of the organism must be confirmed by molecular methods. NAATs can detect *Rickettsia prowazekii* in acute whole blood, serum, or tissue specimens, but sensitivity is lower during the first few days of the illness or following 48 hours of doxycycline therapy. Treatment should never be withheld pending results of diagnostic tests. Because epidemic typhus is not common in the United States, testing generally is not available at commercial laboratories but can be performed at the Centers for Disease Control and Prevention through submission by state health departments.

TREATMENT: Because of the rapid progression of louse-borne typhus, treatment should not be delayed pending diagnostic results in patients who present with clinically

and epidemiologically compatible disease. Doxycycline is the drug of choice to treat louse-borne typhus, regardless of patient age. The recommended dosage of doxycycline for adults is 100 mg, twice per day, intravenously or orally, and for children weighing less than 45 kg (100 lb) is 2.2 mg/kg per dose, administered twice a day (maximum 100 mg/dose [see Tetracyclines, p 975]). Treatment should be continued for at least 3 days after clinical defervescence and evidence of clinical improvement is documented; the total treatment course usually is 7 to 10 days. Some patients may relapse if not treated for the full 7 to 10 days. Patients treated early may experience less severe illness and shorter recovery time. Chloramphenicol, where available, may be used in cases of absolute contraindication of doxycycline (life-threatening allergy) but also carries significant risks (ie, aplastic anemia). In epidemic situations in which antimicrobial agents have limited availability (eg, refugee camps), a single 200-mg dose of doxycycline in adults (or 4.4 mg/kg, maximum dose 200 mg, as a single dose for children) may provide effective treatment and facilitate outbreak control when combined with delousing efforts.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended after delousing has been completed. Precautions should be taken when delousing hospitalized patients infected with *R. prowazekii* using pediculicide, because aerosolized louse feces associated with these patients pose an exposure risk. Therefore, health care providers initially caring for these patients and handling potentially contaminated clothing should consider wearing an N95 or higher respirator (or similar respiratory protection) and eye protection.

CONTROL MEASURES: Thorough delousing in epidemic situations, particularly among exposed contacts of cases, is recommended. Several applications of pediculicides may be needed, because lice eggs are resistant to most insecticides. Washing clothes in hot water kills lice and eggs. During epidemics, insecticides dusted onto clothes of louse-infested populations are effective. In situations involving outbreaks of epidemic typhus in prisons and refugee settings, active surveillance for fever is important to assess efficacy of control measures and to ensure rapid and effective treatment. To halt the spread of disease to other people, louse-infested patients should be treated with cream or gel pediculicides containing pyrethrins or permethrin; malathion is prescribed most often when pyrethroids fail. Prevention and control of flying squirrel-associated typhus requires application of insecticides and precautions to prevent contact with these animals and their ectoparasites and to exclude them from nesting in, or entering into, human dwellings. No prophylaxis is recommended for people exposed to flying squirrels.

Public Health Reporting. *R. prowazekii* is considered a select agent and a category B potential biological terrorism agent requiring additional regulation and oversight for its storage, use, and transfer. Cases should be reported to local, state, regional, or national public health departments.

Murine Typhus

(Endemic or Flea-borne Typhus)

CLINICAL MANIFESTATIONS: Murine typhus, also known as endemic typhus or flea-borne typhus, resembles epidemic (louse-borne) typhus but usually has a less abrupt onset with less severe systemic symptoms. The disease can be mild in young children. Fever, present in almost all patients, can be accompanied by myalgia and a

persistent, usually severe, headache. Nausea, vomiting, anorexia, and abdominal pain and tenderness also develop in approximately half of patients. A macular or maculopapular rash appears by day 4 to 7 of illness in approximately 50% of patients and lasts 4 to 8 days. The rash often is distributed on the patient's trunk, although extremities also can be involved. Untreated illness seldom lasts longer than 2 weeks. The clinical course is usually uncomplicated, but severe manifestations, such as sepsis or central nervous system abnormalities (eg, meningitis), are possible. Laboratory findings can include thrombocytopenia, elevated liver aminotransferases, hypoalbuminemia, hypocalcemia, and hyponatremia. Fatal outcome is rare but has been reported in up to 4% of hospitalized patients.

ETIOLOGY: Murine typhus is caused by *Rickettsia typhi*, which are gram-negative obligate intracellular bacteria.

EPIDEMIOLOGY: Rats, in which infection is inapparent, are the natural reservoirs for *R typhi*. The disease is worldwide in distribution and tends to occur most commonly in male adults; male and female children are affected equally. Outside the United States, the primary vector for transmission among rats and transmission to humans is the rat flea, *Xenopsylla cheopis*, although other fleas and mites have been implicated. A suburban cycle has emerged in the United States involving primarily cat fleas (*Ctenocephalides felis*), mouse fleas (*Leptopsylla segnis*), and fleas from opossums (often cat fleas) and other peridomestic species. Infection occurs when infected flea feces are rubbed into broken skin or mucous membranes or are inhaled. Murine typhus is uncommon in most of the United States; most diagnosed cases occur during spring to early fall and in southern California, southern Texas, the southeastern Gulf Coast, and Hawaii.

The **incubation period** is 6 to 14 days.

DIAGNOSTIC TESTS: Serologic testing for *R typhi* by an indirect immunofluorescence antibody (IF) assay is the most common means of diagnosis. Enzyme immunoassay or latex agglutination tests also are available. Antibody concentrations peak at around 4 weeks after infection, but results of antibody tests may be negative early in the course of illness. A fourfold increase in immunoglobulin (Ig) G titer between acute and convalescent serum specimens obtained 2 to 4 weeks apart is confirmatory for laboratory diagnosis. Use of IgM assays alone is not recommended. Because of cross-reactivity, standard serologic tests might not differentiate murine typhus caused by *R typhi* from epidemic (louse-borne) typhus (*Rickettsia prowazekii*) or from infection with spotted fever rickettsiae, such as *Rickettsia rickettsii*. More specific testing with antibody cross-adsorption assay or western blot analyses is not available routinely. Routine hospital blood cultures are not suitable for culture of *R typhi*. Nucleic acid amplification tests (NAATs) can detect *R typhi* and distinguish murine and epidemic typhus and other rickettsioses in acute whole blood, serum, and skin biopsies, but sensitivity is lower during the first few days of illness or following 48 hours of antibiotic treatment. Because murine typhus is not common in many regions of the United States, testing may not be available at commercial labs but can be performed at the Centers for Disease Control and Prevention through submission by state health departments.

TREATMENT: Doxycycline is the treatment of choice for murine typhus, regardless of patient age. The recommended dosage of doxycycline for children weighing less than 45 kg (100 lb) is 2.2 mg/kg per dose, administered intravenously or orally, twice a day (maximum 100 mg/dose) and for adults is 100 mg/dose, twice daily (see Tetracyclines,

p 975). Early diagnosis should be based on clinical suspicion and epidemiology. In a patient with disease that is clinically compatible with murine typhus, treatment should not be withheld because of a negative laboratory result or while awaiting laboratory confirmation, because severe or fatal infection can develop when treatment is delayed. Treatment should be continued for at least 3 days after defervescence and evidence of clinical improvement is documented. The total treatment course usually is 7 to 14 days. Fluoroquinolones or chloramphenicol are alternative medications but may not be as effective; fluoroquinolones are not approved for this use in children younger than 18 years (see Fluoroquinolones, p 973).

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: Fleas should be controlled by appropriate insecticides before use of rodenticides because fleas will seek alternative hosts, including humans.

Suspected animal populations should be controlled by species-appropriate means, such as avoiding leaving food out for stray or wild animals, flea control on pets, and keeping pets indoors. No prophylaxis is recommended for exposed individuals.

Public Health Reporting. Patients infected with murine typhus should be reported to local or state public health departments.

***Ureaplasma urealyticum* and *Ureaplasma parvum* Infections**

CLINICAL MANIFESTATIONS: The role of *Ureaplasma* species in human disease is controversial. There has been an inconsistent association between presence of *Ureaplasma urealyticum* and nongonococcal urethritis (NGU). Without treatment, the urethritis usually resolves within 1 to 6 months. There also has been an inconsistent relationship of infection by *Ureaplasma* species with prostatitis and epididymitis in male individuals and upper genital tract syndromes in female individuals, including salpingitis, endometritis, and pelvic inflammatory disease.¹ *Ureaplasma* organisms commonly are detected in placentas with histologic chorioamnionitis (now known as intra-amniotic infection), and studies suggest that there is an association of upper genital tract infection by *Ureaplasma* species and adverse pregnancy outcomes. Some reports also describe an association between the presence of *Ureaplasma* in the vaginal flora and preterm birth.

Ureaplasma urealyticum and *Ureaplasma parvum* are frequently isolated from the lower respiratory tract and from lung biopsy specimens of preterm infants, and studies have demonstrated an association of *Ureaplasma* species with the development of bronchopulmonary dysplasia in preterm infants. These organisms also have been recovered from respiratory tract secretions of infants 3 months or younger with pneumonia, but their role in development of lower respiratory tract disease in otherwise healthy young infants is unclear. *Ureaplasma* species have been isolated from the bloodstream of newborn infants and from cerebrospinal fluid of infants with meningitis, intraventricular hemorrhage, and hydrocephalus. The contribution of *U. urealyticum* to the outcome of infants with infections of the central nervous system is unclear given the confounding effects of preterm birth and intraventricular hemorrhage.

Cases of *U. urealyticum* or *U. parvum* arthritis, osteomyelitis, pneumonia, pericarditis, meningitis, and progressive sinopulmonary disease have been reported, almost

¹ The terms male, female, men, and women refer to sex assigned at birth.

exclusively in immunocompromised patients. Patients with primary antibody deficiency and solid organ transplants appear to be the major risk groups. A recently described syndrome of *Ureaplasma* sepsis with hyperammonemia (caused by rapid hydrolysis of host urea by the organism) in lung transplant patients appears to be attributable to the introduction of the organism from the transplanted lung into naïve recipients who are immunosuppressed.

ETIOLOGY: *Ureaplasma* organisms are small pleomorphic bacteria that lack a cell wall. The genus contains 2 species capable of causing human infection, *U urealyticum* and *U parvum*. At least 14 serotypes have been described, 4 for *U parvum* and 10 for *U urealyticum*.

EPIDEMOLOGY: The principal reservoir of human *Ureaplasma* species is the genital tract of sexually active adults. Colonization occurs in more than half of sexually active female individuals; the incidence in sexually active male individuals is lower. Colonization is uncommon in prepubertal children and adolescents who are not sexually active, but a positive genital tract culture is not clearly definitive of sexual abuse. *Ureaplasma* species may colonize the throat, eyes, umbilicus, and perineum of newborn infants and may persist for several months after birth. *U parvum* generally is more common than *U urealyticum* as a colonizer in pregnant people and their offspring.

Because *Ureaplasma* species commonly are isolated from the female lower genital tract and neonatal respiratory tract in the absence of disease, a positive culture does not establish its causative role in acute infection. However, recovery of these organisms from an upper genital tract or lower respiratory tract specimen in the appropriate host who has evidence of clinical disease is much more indicative of true infection.

The **incubation period** after sexual transmission is 10 to 20 days.

DIAGNOSTIC TESTS: Specimens for culture require *Ureaplasma* compatible transport media, with refrigeration at 4°C (39°F). If the specimen cannot be transported to the reference laboratory within 24 hours, the sample should be frozen at -70°C (not -20°C). If a vaginal or urethral swab is used for collection, Dacron or calcium alginate swabs should be used to collect and inoculate transport media; cotton swabs should be avoided. Several rapid, sensitive real-time polymerase chain reaction assays for detection of *U urealyticum* and *U parvum* have been developed. Many of these assays have greater sensitivity than culture, but they are not widely available outside of reference laboratories. Transport medium is not necessary for urine to be tested only by polymerase chain reaction (PCR) assay. Such specimens can be concentrated 10-fold and frozen at -70°C immediately after collection and shipped on dry ice. *Ureaplasma* species can be cultured in urea-containing broth and agar in 2 to 4 days. Serologic testing is of limited value for diagnostic purposes and is not available commercially.

TREATMENT: A positive *Ureaplasma* culture or PCR assay result does not indicate need for therapy if the patient is asymptomatic. *Ureaplasma* species generally are susceptible to macrolides, tetracyclines, and quinolones, but because they lack a cell wall they are not susceptible to penicillins or cephalosporins. They also are not susceptible to trimethoprim-sulfamethoxazole or clindamycin. For symptomatic children, adolescents, and adults, doxycycline can be used for treatment. Doxycycline can be used without regard to patient age; azithromycin is the preferred antimicrobial agent for children younger than 8 years or people who are allergic to tetracyclines. Persistent urethritis after doxycycline treatment may be attributable to doxycycline-resistant *U urealyticum*.

or *Mycoplasma genitalium*. Recurrences are common, and tetracycline resistance may occur in up to 50% of *Ureaplasma* isolates in some patient populations. If tetracycline resistance is likely, azithromycin is indicated; a quinolone is an option if azithromycin resistance also is possible. On the basis of very limited data, quinolone and macrolide coresistance remains uncommon, at less than 5% in the United States, but up to 10% elsewhere including Australia and Southeast Asia. Such infections are difficult to treat, but pristinamycin (not approved by the US Food and Drug Administration) has proven effective.

In neonates, antimicrobial treatment with erythromycin has generally failed to prevent chronic pulmonary disease in small randomized trials, possibly because erythromycin does not eliminate *Ureaplasma* organisms from the airways in a large proportion of infants. One small randomized trial suggests that bronchopulmonary dysplasia or death may be reduced by azithromycin (10 mg/kg/day for 7 days followed by 5 mg/kg/day for a maximum of 6 weeks). Another recent randomized clinical trial of azithromycin in mechanically ventilated preterm neonates showed significant benefit with respect to death or oxygen requirement at 28 days in infants who received the drug regardless of the presence of *Ureaplasma* species, highlighting the difficulty in defining a possible pathogenic role for *Ureaplasma* species in preterm infants, given that azithromycin has anti-inflammatory as well as antimicrobial properties. Pharmacokinetic studies suggest that a 3-day course of 20 mg/kg/day of intravenous azithromycin may be more effective in clearance of *Ureaplasma* organisms from preterm infants, although efficacy in improving clinical outcomes needs to be demonstrated. Definitive evidence of efficacy of antimicrobial agents in the treatment of central nervous system infections caused by *Ureaplasma* species in infants and children also is lacking. There are reports of preterm infants with *Ureaplasma* species identified in cerebrospinal fluid who have or have not received antimicrobial therapy and who have had documentation of sterilization of cerebrospinal fluid.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: None recommended.

Varicella-Zoster Virus Infections

CLINICAL MANIFESTATIONS: Primary infection results in varicella (chickenpox), manifesting in unvaccinated people as a generalized, pruritic, erythematous vesicular rash typically consisting of 250 to 500 lesions in varying stages of development (papules, vesicles) and resolution (crusting), low-grade fever, and other systemic symptoms. Complications include bacterial superinfection of skin lesions with or without bacterial sepsis, pneumonia, central nervous system involvement (acute cerebellar ataxia, encephalitis, stroke/vasculopathy), thrombocytopenia, and rarer complications such as glomerulonephritis, arthritis, and hepatitis. Primary viral pneumonia is uncommon among immunocompetent children but is the most common complication in adults. Varicella tends to be more severe in adults, infants, and adolescents than in other children. Breakthrough cases can occur in immunized children, as described in Active Immunization (p 947), but usually are mild and rash presentation is modified. Reye syndrome may follow varicella, although this outcome has become very rare with the recommendation not to use salicylate-containing compounds (eg, aspirin,

bismuth-subsalicylate) in children with chickenpox. In immunocompromised children, progressive, severe varicella may occur with continuing eruption of lesions (sometimes including hemorrhagic skin lesions) along with high fever persisting into the second week of illness and visceral dissemination (ie, encephalitis, hepatitis, and pneumonia). Severe and even fatal varicella has been reported in otherwise healthy children on high-dose corticosteroids (greater than 2 mg/kg/day of prednisone or equivalent) for treatment of asthma and other illnesses.

Varicella-zoster virus (VZV) establishes latency in sensory (dorsal root, cranial nerve, and autonomic including enteric) ganglia during primary VZV infection. This latency occurs with both wild-type VZV and the varicella vaccine strain. Reactivation results in herpes zoster (shingles), typically characterized by grouped vesicular skin lesions on an erythematous base in the unilateral distribution of 1 to 3 contiguous sensory dermatomes, most commonly in the thoracic and lumbar regions, frequently accompanied by localized pain and/or itching. Zoster may also result in cranial neuropathy, particularly in the fifth, seventh, and eighth cranial nerve distributions. Postherpetic neuralgia (PHN), pain that persists after resolution of the zoster rash, may last for weeks to months but is unusual in children. Zoster occasionally becomes disseminated in immunocompromised patients, with lesions appearing outside the primary dermatomes and/or visceral complications. Uncommonly, VZV reactivation occurs in the absence of skin rash (zoster sine herpete); these patients may present with aseptic meningitis, encephalitis, stroke, acute retinal necrosis, or gastrointestinal tract involvement (visceral zoster). Recurrent zoster is rare and should prompt a consideration for an evaluation for immunodeficiency or consideration of an alternative diagnosis. A vesicular rash, especially in the distribution of the trigeminal ganglion or sacral sensory roots, may represent herpes simplex virus infection (so-called zosteriform HSV) and should be assessed virologically (eg, by a nucleic acid amplification test [NAAT] of swabbed material from the base of an unroofed vesicle) to distinguish this from zoster attributable to VZV.

Fetal infection after a pregnant person is infected with varicella during the first or early second trimester of pregnancy occasionally results in fetal death or varicella embryopathy, characterized by limb hypoplasia, cutaneous scarring, eye abnormalities, and damage to the central nervous system (congenital varicella syndrome). The incidence of the congenital varicella syndrome among infants born to persons who experience gestational varicella is approximately 2% when infection occurs between 8 and 20 weeks of gestation. Rarely, cases of congenital varicella syndrome have been reported in infants born to persons infected after 20 weeks of pregnancy, the latest occurring at 28 weeks' gestation. Children infected with VZV in utero may develop zoster early in life without having had extrauterine varicella.

Varicella infection has a higher case fatality rate in infants when varicella infection occurs in the birthing parent from 5 days before to 2 days after delivery, because there is little opportunity for development and transfer of antibody across the placenta prior to delivery, and the infant's cellular immune system is immature.

ETIOLOGY: VZV (also known as human herpesvirus 3) is a member of the *Herpesviridae* family, the subfamily *Alphaherpesvirinae*, and the genus *Varicellovirus*.

EPIDEMIOLOGY: Humans are the only source of infection for this highly contagious virus. Infection occurs when the virus comes in contact with the mucosa of the upper

respiratory tract or the conjunctiva of a susceptible person. Person-to-person transmission occurs from contact with lesions from varicella or herpes zoster or from airborne spread. Varicella is more contagious than herpes zoster. There is no evidence of VZV spread from fomites; the virus is extremely labile and is unable to survive for long in the environment. Varicella infection in a household member usually results in infection of almost all susceptible people in that household. Children who acquire their infection at home (secondary family cases) often have more skin lesions than the index case. Health care-associated transmission is well documented.

In temperate climates in the prevaccine era, varicella was a disease with a marked seasonal distribution, with peak incidence during winter and spring mainly among children younger than 10 years. In tropical climates, acquisition of varicella often occurs later, resulting in a significant proportion of susceptible adults. High rates of vaccine coverage in the United States have eliminated discernible seasonality of varicella. Following implementation of universal immunization in the United States in 1995, varicella incidence declined by approximately 98% in all age groups as a result of personal and herd immunity.

The age of peak varicella incidence has shifted from children younger than 10 years to children 10 through 14 years of age. Immunity to wild-type varicella generally is lifelong. Symptomatic reinfection is uncommon. Asymptomatic primary infection is unusual.

Immunocompromised people with primary (varicella) or reactivated (herpes zoster) infection are at increased risk of severe disease. Severe varicella and disseminated zoster are more likely to develop in children with congenital T-lymphocyte defects or acquired immunodeficiency syndrome (AIDS) than in people with B-lymphocyte abnormalities. Other groups of pediatric patients who may experience more severe or complicated varicella include infants, adolescents, patients with chronic cutaneous or pulmonary disorders, and patients receiving systemic corticosteroids or other immunosuppressive therapy or long-term salicylate therapy.

Patients are considered contagious from 1 to 2 days before onset of the rash until all lesions have dried/crusted.

The **incubation period** usually is 14 to 16 days, with a range of 10 to 21 days after exposure to rash. The **incubation period** may be prolonged for as long as 28 days after receipt of varicella-zoster immune globulin or immune globulin intravenous (IGIV) and may be shortened in immunocompromised patients. Varicella can develop after birth in infants born to people with active varicella around the time of delivery; the usual interval from onset of rash in a birthing parent to onset in the neonate is 9 to 15 days.

DIAGNOSTIC TESTS: Diagnostic tests for VZV are summarized in Table 3.89.

Vesicular fluid or a scab can be used to identify VZV using a NAAT, which currently is the diagnostic method of choice. During the acute phase of illness, VZV also can be identified by a NAAT of saliva or buccal swab specimens, although viral DNA is more likely to be detected in vesicular fluid or scabs. VZV can be demonstrated by direct fluorescent antibody (DFA) assay, using scrapings of a vesicle base early in the eruption, or by viral isolation in cell culture from vesicular fluid. Viral culture and DFA assay both are much less sensitive than a NAAT. NAATs that discriminate between vaccine-strain and wild-type VZV are available free of charge through the specialized reference laboratory at the Centers for Disease Control and Prevention (CDC), through a safety research program sponsored by Merck & Co, and through the Association of

Table 3.89. Diagnostic Tests for Varicella-Zoster Virus (VZV) Infection

Test	Specimen	Comments
NAAT	Vesicular swabs or scrapings, scabs from crusted lesions, biopsy tissue, CSF	Very sensitive method. Specific for VZV. Methods have been designed that distinguish vaccine strain from wild-type (see text).
DFA	Vesicle scraping, swab of lesion base (must include cells)	Specific for VZV. More rapid and more sensitive than culture, less sensitive than NAAT.
Viral culture	Vesicular fluid, CSF, biopsy tissue	Distinguishes VZV from HSV. Limited availability, requires up to a week for result. Least sensitive.
Serology (IgG) ^a	Acute and convalescent serum specimens for IgG	Specific for VZV. Commercial assays generally have low sensitivity to reliably detect vaccine-induced immunity.
Serology (IgM)	Acute serum specimens for IgM	IgM serology is less specific than IgG serology. IgM inconsistently detected. Not reliable method for routine confirmation.

CSF indicates cerebrospinal fluid; DFA, direct fluorescent antibody; HSV, herpes simplex virus; IgG, immunoglobulin G; IgM, immunoglobulin M; NAAT, nucleic acid amplification test.

^aSee Table 1.19, p 122.

Public Health Laboratories/CDC Vaccine Preventable Diseases Reference Centers (www.cdc.gov/od/oc/media/press/2012/s011212a01.htm).

A significant increase (fourfold rise in titer) in serum varicella immunoglobulin (Ig) G antibody between acute and convalescent samples by any standard serologic assay can confirm a diagnosis retrospectively, but this may not reliably occur in immunocompromised people (see Care of Exposed People, p 944). However, diagnosis of varicella by serologic testing seldom is indicated. Commercially available enzyme immunoassay (EIA) tests usually are not sufficiently sensitive to reliably demonstrate a vaccine-induced antibody response, and therefore, routine postvaccination serologic testing is not recommended (see Table 1.19, p 122). Commercial IgM tests are not reliable for routine confirmation or ruling out of acute infection because of potential false-negative and false-positive results.

TREATMENT: Nonspecific therapies for varicella include keeping fingernails short to prevent trauma and secondary bacterial infection from scratching, frequent bathing, application of lotion to reduce pruritus, and acetaminophen for fever. Children with varicella should not receive salicylates or salicylate-containing products (eg, aspirin, bismuth-subsalicylate), because these products increase the risk of Reye syndrome. Salicylate therapy should be stopped, if possible, in an unimmunized child who is exposed to varicella. Treatment with ibuprofen is controversial, because some data suggest an association with life-threatening streptococcal skin infections, perhaps because of delays in recognition, and should be avoided if possible.

The decision to use antiviral therapy and the route and duration of therapy should be determined by host factors and extent of infection. Antiviral drugs have a limited window of opportunity to affect the outcome of VZV infection. In immunocompetent hosts, most virus replication has stopped by 72 hours after onset of rash; the duration of replication may be extended in immunocompromised hosts. Oral acyclovir and valacyclovir are not routinely recommended for otherwise healthy younger children with varicella, because their use results in only a modest decrease in symptoms. Antiviral therapy should be considered for otherwise healthy people at increased risk of moderate to severe varicella, such as unvaccinated people older than 12 years, those with chronic cutaneous or pulmonary disorders, those receiving long-term salicylate therapy, or those receiving short or intermittent courses of corticosteroids. Some experts also recommend use of oral acyclovir or valacyclovir for secondary household cases in which the disease usually is more severe than in the primary case or in children who have immunocompromised household contacts. Acyclovir or valacyclovir therapy should also be considered for children with zoster and the continuing development of new lesions. For recommendations on dosage and duration of therapy, see Non-HIV Antiviral Drugs (p 1044).

The American College of Obstetricians and Gynecologists recommends that pregnant people with varicella should be considered for treatment to minimize morbidity. No controlled data are available that treatment will impact the likelihood or severity of congenital varicella syndrome. Intravenous acyclovir is recommended for pregnant people with serious complications of varicella.

Intravenous acyclovir therapy is recommended for immunocompromised patients, including patients being treated with high-dose corticosteroid therapy for more than 14 days. Therapy initiated early in the course of the illness, especially within 24 hours of rash onset, maximizes benefit. Oral acyclovir should not be used to treat immunocompromised children with varicella because of poor oral bioavailability. In the event of national shortages of intravenous acyclovir (as occurred in 2011–2012 and 2019), intravenous ganciclovir or foscarnet may be reasonable alternatives. Information on current drug shortages in the United States can be found at www.ashp.org/shortages. Valacyclovir (20 mg/kg per dose, with a maximum dose of 1000 mg, administered orally 3 times daily for 5 days) is licensed for treatment of varicella in children 2 through 17 years of age. Some experts have used valacyclovir, with its improved bioavailability compared with oral acyclovir, in selected immunocompromised patients perceived to be at low to moderate risk of developing severe varicella, such as human immunodeficiency virus (HIV)-infected patients with relatively normal concentrations of CD4+ T-lymphocytes and children with leukemia in whom careful follow-up is ensured. Famciclovir is available for treatment of VZV infections in adults, but its efficacy and safety have not been established for children. Although varicella-zoster immune globulin or IGIV, administered shortly after exposure, can prevent or modify the course of disease, immune globulin preparations are not effective treatment once disease is established (see Care of Exposed People, p 944).

Antiviral susceptibility testing is not validated but can be considered in cases of poor response to standard therapy; susceptibility testing requires growth of the virus in cell culture, however, which is challenging with VZV. Infections caused by acyclovir-resistant VZV strains, which generally are rare and limited to immunocompromised hosts with prior prolonged exposure to antiviral therapy or prophylaxis, have been successfully treated with parenteral foscarnet.

CONTROL MEASURES:

Evidence of Immunity to Varicella. Evidence of immunity to varicella includes any of the following:

1. Documentation of age-appropriate immunization
 - Preschool-aged children (ie, age 12 months through 3 years): 1 dose
 - School-aged children, adolescents, and adults: 2 doses
2. Laboratory evidence of immunity or laboratory confirmation of disease¹
3. Birth in the United States before 1980 (should not be considered evidence of immunity for health care personnel, pregnant people, and immunocompromised people)
4. Diagnosis or verification of a history of varicella or zoster by a health care provider

Isolation and Exclusions

Child Care and School. Children with uncomplicated varicella who have been excluded from school or child care may return when the rash has crusted or, in immunized people without crusts, until no new lesions appear within a 24-hour period. Exclusion of children with zoster whose lesions cannot be covered is based on similar criteria. Zoster lesions that are covered pose little risk to susceptible people, although transmission has been reported.

Hospitalized Patients.

VARICELLA. In addition to standard precautions, airborne and contact precautions are recommended for patients with varicella until all lesions are dry and crusted, typically at least 5 days after onset of rash but a week or longer in immunocompromised patients. In patients with varicella pneumonia, precautions are maintained for the duration of illness. For previously immunized patients with breakthrough varicella with only maculopapular lesions, isolation is recommended until no new such lesions appear within a 24-hour period, even if lesions have not resolved completely. For exposed patients without evidence of immunity (see Evidence of Immunity to Varicella, above), airborne and contact precautions from 8 until 21 days after exposure to the index patient also are indicated; these precautions should be maintained until 28 days after exposure for those who received varicella-zoster immune globulin or IGIV.

ZOSTER. Airborne and contact precautions are recommended for both immunocompetent and immunocompromised patients with disseminated zoster for the duration of illness. Immunocompromised patients with localized disease require airborne and contact precautions until disseminated infection is ruled out. For immunocompetent patients with localized zoster, standard precautions and complete covering of the lesions (if possible) are indicated until all lesions are crusted.

NEWBORN INFANTS. For neonates born to persons with varicella or disseminated zoster, airborne and contact precautions are recommended until 21 days of age or until 28 days of age if varicella-zoster immune globulin or IGIV was administered to the infant. To minimize risk of transmission to the infant, the birthing parent and the infant should be isolated separately until the parent's vesicles have dried, even if the infant has received varicella-zoster immune globulin. Neither wild-type VZV nor Oka vaccine-strain virus has been shown to be transmitted by human milk; expressed/pumped milk from a parent with varicella or zoster can be fed to the infant, provided no lesions are evident on the breast. If the infant develops clinical varicella, the birthing parent may care for the infant. If the neonate is born with varicella, the parent and her newborn infant should be isolated together and discharged home when clinically

¹ Commercial assays can be used to assess disease-induced immunity, but they lack sensitivity to detect vaccine-induced immunity (ie, they might yield false-negative results).

stable. Infants whose birthing parent has localized zoster may be in contact with the parent as long as the lesions can be covered. The birthing parent should be advised to practice good hand hygiene before holding the infant.

If an infant is clinically stable for discharge during the potential incubation period and has not yet developed varicella, quarantine to complete the 21- or 28-day period may continue at home after ensuring that all relatives and contacts have evidence of immunity to varicella. If the infant needs to see the health care provider during that period, the office should be notified of the need for airborne and contact precautions.

Infants with congenital varicella do not require isolation if they do not have active skin lesions.

Care of Exposed People. Potential interventions for people without evidence of immunity exposed to a person with varicella or herpes zoster include: (1) varicella vaccine, administered ideally within 3 days but up to 5 days after exposure; (2) when indicated, varicella-zoster immune globulin; or (3) if the child cannot be immunized, preemptive oral valacyclovir or acyclovir starting day 7 after exposure. These options and their use in different settings are discussed in detail below.

Postexposure Immunization. Varicella vaccine should be administered to healthy people without evidence of immunity who are 12 months or older, including adults, as soon as possible, preferably within 3 days and up to 5 days after exposure. This approach may prevent or modify disease. Patients should be counseled that not all close exposures result in infection, so vaccination even after 3 to 5 days following exposure is still warranted.

Passive Immunoprophylaxis. The decision to administer varicella-zoster immune globulin depends on 3 factors: (1) the likelihood that the exposed person is susceptible to varicella; (2) the probability that a given exposure to varicella or zoster will result in infection; (3) the likelihood that complications of varicella will develop if the person is infected. Fig 3.22 identifies what constitutes a significant exposure and people without evidence of immunity who should receive varicella-zoster immune globulin if exposed, including immunocompromised people, pregnant people, and certain newborn infants. Varicella-zoster immune globulin is commercially available in the United States from a broad network of specialty distributors (list available at www.varizig.com).

Data are not available regarding the sensitivity and specificity of serologic tests in immunocompromised patients. Detection of VZV IgG after 1 dose of varicella vaccine might not correspond to adequate protection in immunocompromised people, and false-positive results can occur. Therefore, regardless of serologic test results, careful questioning of the child and parents about potential past disease or exposure to disease can be helpful in determining immunity. Administration of varicella-zoster immune globulin is recommended as soon as possible within 10 days to immunocompromised children without evidence of immunity (see Fig 3.22 for dosing). However, the degree and type of immunosuppression should be considered in making this decision, and consultation with pediatric infectious diseases or immunology specialists can assist in decision making.

Patients receiving monthly high-dose IGIV (400 mg/kg or greater) at regular intervals are likely to be protected if the last dose of IGIV was administered 3 weeks or less before exposure.

Any patient to whom varicella-zoster immune globulin is administered to prevent varicella subsequently should receive age-appropriate varicella vaccine, provided that receipt of live vaccines is not contraindicated. Administration of varicella vaccine; measles, mumps, and rubella (MMR) vaccine; and measles, mumps, rubella,

FIG 3.22. MANAGEMENT OF EXPOSURES TO VARICELLA-ZOSTER VIRUS

FIG 3.22. MANAGEMENT OF EXPOSURES TO VARICELLA-ZOSTER VIRUS, CONTINUED

IGIV indicates immune globulin intravenous.

^aPeople who receive hematopoietic cell transplants should be considered nonimmune regardless of previous history of varicella disease or varicella vaccination in themselves or in their donors.

^bTo verify a history of varicella in an immunocompromised child, health care providers should inquire about an epidemiologic link to another typical varicella case or to a laboratory confirmed case, or evidence of laboratory confirmation. Immunocompromised children who have neither an epidemiologic link nor laboratory confirmation of varicella should not be considered as having a valid history of disease.

^cImmunocompromised children include those with congenital or acquired T-lymphocyte immunodeficiency, including leukemia, lymphoma, and other malignant neoplasms affecting the bone marrow or lymphatic system; children receiving immunosuppressive therapy, including ≥ 2 mg/kg/day of systemic prednisone (or its equivalent) for ≥ 14 days, and certain biologic response modifiers; all children with human immunodeficiency virus (HIV) infection regardless of CD4+ T-lymphocyte percentage; and all hematopoietic cell transplant patients regardless of pretransplant immunity status.

^dIf the exposed person is an adolescent or adult, has chronic illness, or there are other compelling reasons to try to avert varicella, some experts recommend preemptive therapy with oral valacyclovir or acyclovir (see Chemoprophylaxis, below, for dosing). For exposed people ≥ 12 months of age, vaccination is recommended for protection against subsequent exposures.

^eIf 1 prior dose of varicella vaccine has been received, a second dose should be administered at ≥ 4 years of age. If the exposure occurred during an outbreak, a second dose is recommended for preschool-aged children younger than 4 years for outbreak control if at least 3 months have passed after the first dose.

^fSee Chemoprophylaxis, below, for dosing. If varicella-zoster immune globulin and either valacyclovir or acyclovir are not available, IGIV may be administered (400 mg/kg).

and varicella (MMRV) vaccine should be delayed until 5 months after varicella-zoster immune globulin administration (see Table 1.11, p 69). Varicella vaccine is not needed if the patient develops varicella despite receipt of varicella-zoster immune globulin.

Chemoprophylaxis. For immunocompromised patients without evidence of immunity or for immunocompetent patients for whom varicella prevention is desired (eg, healthy older adolescent or adult contacts for whom vaccination is not possible) who have been exposed to varicella or herpes zoster (Fig 3.22), valacyclovir (20 mg/kg per dose, administered orally 3 times per day, with a maximum daily dose of 3000 mg), if available and dosage form is tolerable, or acyclovir (20 mg/kg per dose, administered orally 4 times per day, with a maximum daily dose of 3200 mg) may be used as chemoprophylaxis if passive immunoprophylaxis is not utilized. Antiviral treatment should begin 7 days after exposure and should continue for a total of 7 days. No studies of oral prophylaxis have been performed for adults. VZV-seropositive patients receiving intensive and/or myeloablative chemotherapy should routinely receive antiviral prophylaxis; children receiving antiviral prophylaxis or treatment with valganciclovir, ganciclovir, or foscarnet do not require additional antiviral prophylaxis against VZV.

Postexposure Passive Immunization of Children Living With HIV. Children living with HIV who lack evidence of immunity to varicella (eg, serologic evidence of immunity to varicella, or documentation of receipt of 2 doses of varicella vaccine after initiation of ART, or health care provider-confirmed clinical diagnosis of varicella), **or** who have severe immune suppression (for people ≤ 5 years of age, defined as a CD4+ T-lymphocyte percentage $<15\%$; for people >5 years of age, defined as a CD4+ T-lymphocyte percentage $<15\%$ or a CD4+ T-lymphocyte count <200 lymphocytes/ mm^3) should receive varicella-zoster immune globulin, if available, ideally within 96 hours but potentially beneficial up to 10 days, after close contact with a person who has chickenpox or shingles (see Human Immunodeficiency Virus Infection, p 489). An alternative to varicella-zoster immune globulin for passive immunization is oral valacyclovir or acyclovir beginning 7 days after exposure, and if this is not

available, then IGIV, 400 mg/kg, administered once within 10 days after exposure (see Fig 3.22, p 945). Children who have received IGIV for other reasons within 3 weeks of exposure do not require additional passive immunization.

Hospital Exposures. The CDC recommends health care institutions evaluate employees proactively for evidence of immunity to varicella and establish protocols and recommendations for vaccinating and managing health care personnel following workplace exposures. If exposure to an infected person occurs in the hospital, the following control measures are recommended:

- Health care professionals, patients, and visitors who have been exposed (see Fig 3.22, p 945) and who lack evidence of immunity to varicella should be identified.
- Varicella immunization is recommended for people without evidence of immunity, provided there are no contraindications to vaccine use.
- Varicella-zoster immune globulin should be administered to appropriate candidates (see Fig 3.22, p 945) up to day 10 after exposure.
- If vaccine cannot be administered, varicella-zoster immune globulin or preemptive oral valaciclovir or acyclovir can be considered.
- All exposed patients without evidence of immunity should be discharged as soon as possible. Patients who remain hospitalized should be isolated from day 8 through 21 after exposure or through day 28 if they received varicella-zoster immune globulin.
- Health care professionals who have received 2 doses of vaccine and who are exposed to VZV should self-monitor or be monitored daily during days 8 through 21 after exposure through the employee health program or by infection-control staff to determine clinical status. They should be restricted from work immediately if symptoms such as fever, headache, other constitutional symptoms, or any suspicious skin lesions occur.
- Health care professionals who have received only 1 dose of vaccine and who are exposed to VZV should receive the second dose with a single-antigen live attenuated varicella vaccine (ie, not given in combination as in MMRV vaccine), preferably within 3 to 5 days of exposure, provided at least 4 weeks have elapsed after the first dose. After immunization, management is similar to that of 2-dose vaccine recipients.
- Health care professionals who lack evidence of immunity should receive varicella vaccine as soon as possible and be restricted from work from day 8 through 21 after exposure or through day 28 if they received varicella-zoster immune globulin.
- Previously immunized health care professionals who develop breakthrough infection should be considered infectious until vesicular lesions have crusted or, if they had maculopapular lesions, until no new lesions appear within a 24-hour period.

Exposure of Newborn Infants. Preterm infants and term infants whose birthing parent had varicella in the immediate peripartum period may need varicella-zoster immune globulin (see Fig 3.22, p 945). For healthy term infants exposed postnatally to varicella or zoster outside of the immediate perinatal period, varicella-zoster immune globulin is not indicated. However, some experts advise use of varicella-zoster immune globulin for exposed newborn infants within the first 2 weeks of life whose birthing parent does not have evidence of immunity to varicella.

Active Immunization.¹

Vaccine. Varicella vaccine is a live attenuated vaccine developed in Japan in the early 1970s by Professor Michiaki Takahashi and licensed in 1995 by the US Food and

¹ Centers for Disease Control and Prevention. Prevention of varicella: recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR Recomm Rep*. 2007;56(RR-4):1–40

Drug Administration (FDA) for use in healthy people 12 months or older who have not had varicella illness. Quadrivalent MMRV vaccine was licensed in September 2005 by the FDA for use in healthy children 12 months through 12 years of age.

Dose and Administration. The recommended dose of monovalent or quadrivalent varicella-containing vaccines is 0.5 mL, administered subcutaneously or intramuscularly.

Immunogenicity. Approximately 76% to 85% of immunized healthy children older than 12 months develop a humoral immune response to VZV at levels considered associated with protection after a single dose of varicella vaccine. Seroresponse rates and cell-mediated immune responses approach 100% after 2 doses.

Effectiveness. The effectiveness of 1 dose of varicella vaccine is about 82% against any clinical varicella and 98% against severe disease. Two doses of vaccine demonstrated 92% to 95% effectiveness against any clinical varicella.

Simultaneous Administration With Other Vaccines or Antiviral Agents. Varicella-containing vaccines may be administered simultaneously with other childhood immunizations recommended for children 12 through 15 months of age and 4 through 6 years of age (<https://publications.aap.org/redbook/pages/Immunization-Schedules>). If not administered at the same visit or as MMRV vaccine, the interval between administration of a varicella-containing vaccine and MMR vaccine should be at least 28 days (see Table 1.9, p 60). The minimal interval between MMRV vaccine doses is 3 months. Because of susceptibility of vaccine virus to acyclovir, valacyclovir, or famciclovir, these antiviral agents may interfere with immunogenicity and, thus, should be avoided from 1 day before to 21 days (the outer limit of likely viral replication) after receipt of a varicella-containing vaccine.

Adverse Events. Reactions to varicella vaccine generally are mild and occur with an overall frequency of approximately 5% to 35%. Approximately 20% to 25% of immunized children will experience minor injection site reactions (eg, pain, redness, swelling). In approximately 1% to 3% of immunized children, a localized rash develops, and in an additional 3% to 5%, a generalized varicella-like rash develops. These rashes typically consist of 2 to 5 lesions and may be maculopapular rather than vesicular; lesions usually appear 5 to 26 days after immunization, usually at or near the injection site when localized. After MMRV or monovalent varicella vaccine plus MMR, a measles-like rash was reported in 2% to 3% of recipients. Fever was reported in a higher proportion after the first dose of MMRV than after the first dose of monovalent varicella vaccine plus MMR (22% vs 15%, respectively) in young children. Both fever and measles-like rash usually occurred within 5 to 12 days of immunization, were of short duration, and resolved without sequelae.

A slightly increased risk of febrile seizures is associated with the higher likelihood of fever following the first dose of MMRV compared with MMR and monovalent varicella vaccine. One additional febrile seizure is expected to occur per approximately 2300 to 2600 young children immunized with a first dose of MMRV compared with a first dose of MMR and monovalent varicella vaccine. After the second vaccine dose administered in older children (4 to 6 years of age), there were no differences in incidence of fever, rash, or febrile seizures among recipients of MMRV vaccine compared with recipients of simultaneous MMR and varicella vaccines.¹

¹ Centers for Disease Control and Prevention. Use of combination measles, mumps, rubella, and varicella vaccine: recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR Recomm Rep*. 2010;59(RR-3):1-12

Breakthrough Disease. Breakthrough disease is defined as a case of infection with wild-type VZV occurring more than 42 days after immunization. Varicella in vaccine recipients usually is very mild, with rash frequently atypical (predominantly maculopapular) with a median of fewer than 50 lesions), a lower rate of fever, and faster recovery than disease in unimmunized children. It may be mistaken for other conditions, such as insect bites or poison ivy.

Herpes Zoster After Immunization. Vaccine-strain VZV can cause herpes zoster in immunocompetent and immunocompromised people. However, data from postlicensure surveillance indicate that the age-specific risk of herpes zoster is much lower among immunocompetent children immunized with varicella vaccine than among children who have had natural varicella infection.

Transmission of Vaccine-Strain VZV. Vaccine-strain VZV transmission to contacts is rare. In all cases in which transmission has occurred, the immunized person had a rash following vaccine. Some experts believe that immunocompromised people with skin lesions that are presumed to be attributable to vaccine virus should receive acyclovir or valacyclovir treatment.

Recommendations for Immunization.

Children 12 Months Through 12 Years of Age. Both monovalent varicella vaccine and MMRV have been licensed for use for healthy children 12 months through 12 years of age.¹ Children in this age group should receive two 0.5-mL doses of monovalent varicella vaccine or MMRV administered subcutaneously or intramuscularly, separated by at least 3 months. However, provided the second dose is administered a minimum 28 days after the first dose, it does not need to be repeated.

All healthy children should receive the first dose of varicella-containing vaccine at 12 through 15 months of age. The second dose of vaccine is recommended routinely when children are 4 through 6 years of age (ie, before a child enters kindergarten or first grade) but can be administered at an earlier age. The American Academy of Pediatrics expresses no preference between MMR plus monovalent varicella vaccine or MMRV for toddlers receiving their first immunization of this kind. Parents should be counseled about the rare possibility of their child developing a febrile seizure 1 to 2 weeks after immunization with MMRV for the first immunizing dose. For the second dose at 4 through 6 years of age, MMRV generally is preferred over MMR plus monovalent varicella to minimize the number of injections. A catch-up second dose of varicella vaccine should be offered to all children 7 years and older who have received only 1 dose.

People 13 Years or Older. Immunocompetent individuals 13 years or older without evidence of varicella immunity should receive two 0.5-mL doses of monovalent varicella vaccine, separated by at least 28 days. For people who previously received only 1 dose of varicella vaccine, a second dose is necessary. Only monovalent varicella vaccine is licensed for use in this age group.

Contraindications and Precautions.

Allergy to Vaccine Components. Varicella vaccine should not be administered to people who have had an anaphylactic or severe allergic reaction to any component of the vaccine, including gelatin and neomycin, or to a previous dose of a varicella-containing vaccine.

¹ Centers for Disease Control and Prevention. Use of combination measles, mumps, rubella, and varicella vaccine: recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR Recomm Rep*. 2010;59(RR-3):1-12

Immunization of Immunocompromised Patients.

GENERAL RECOMMENDATIONS.¹ Varicella vaccine (as a 2-dose regimen if there is sufficient time) should be administered to immunocompetent patients without evidence of varicella immunity, if it can be administered ≥ 4 weeks before initiating immunosuppressive therapy. Varicella vaccine should not be administered to highly immunocompromised patients. This includes persons receiving certain immune response mediators (eg, monoclonal antibodies, interleukins, tumor necrosis factor- α inhibitors), who either should be immunized before starting therapy or should wait at least 3 months after such therapies to be immunized. Given the increasing number of such therapies, decisions about immunization with live-virus vaccines should be made in consultation with an infectious disease or immunology specialist.

Certain categories of patients (eg, patients with HIV without severe immunosuppression [see HIV Infection, below] or with a primary immune deficiency disorder without defective T-lymphocyte-mediated immunity, such as primary complement component deficiency disorder, isolated impairment of humoral immunity, or chronic granulomatous disease [CGD]) should receive varicella vaccine. Immunodeficiency should be excluded before immunization in children with a family history of hereditary immunodeficiency.

In people with possible altered immunity, only monovalent varicella vaccine (not MMRV) should be used for immunization against varicella. The Oka vaccine strain remains susceptible to acyclovir, and if a high-risk patient develops vaccine-related rash then acyclovir or valacyclovir may be used as treatment.

MALIGNANCY.¹ The interval until immune reconstitution varies with the intensity and type of immunosuppressive therapy, radiation therapy, underlying disease, and other factors, complicating the ability to make a broadly applicable recommendation for an interval after cessation of immunosuppressive therapy when live-virus vaccines can be administered safely and effectively. Current recommendations are for patients to be vaccinated with varicella vaccine when in remission and at least 3 months after cancer chemotherapy, with evidence of restored immunocompetence. In regimens that included anti-B-lymphocyte antibodies, vaccinations should be delayed at least 6 months.

TRANSPLANT RECIPIENTS.¹ A 2-dose series of varicella vaccine should be administered a minimum of 24 months after hematopoietic cell transplant to varicella-seronegative patients who do not have graft-versus-host disease, are considered immunocompetent, and whose last dose of IGIV was 8 to 11 months previously (see Table 1.11, p 69). Varicella reimmunization generally is not recommended for solid organ transplant recipients after transplantation, although this is an evolving area, especially for certain organs.^{2,3}

³ Suresh S, Upton J, Green M, et al. Live vaccines after solid organ transplant: proceedings of a consensus meeting, 2018. *Pediatr Transplant*. 2019;23(7):e13571

HIV INFECTION.¹ The live-virus MMR vaccine and monovalent varicella vaccine can be administered to children and adolescents living with HIV without severe immunosuppression. Severely immunocompromised infants, children, adolescents, and young adults living with HIV (for people ≤ 5 years of age, defined as a CD4+ T-lymphocyte percentage $<15\%$; for people >5 years of age, defined as a CD4+ T-lymphocyte percentage $<15\%$ **or** a CD4+ T-lymphocyte count <200 lymphocytes/mm³) should not receive measles virus-containing vaccine, because vaccine-related pneumonia has been reported. Eligible children should receive 2 doses of single-antigen varicella vaccine at the appropriate intervals. The quadrivalent MMRV vaccine should not be administered to any infant or child living with HIV, regardless of degree of immunosuppression, because of lack of safety data in this group.

CHILDREN RECEIVING CORTICOSTEROIDS. Varicella vaccine should not be administered to people who are receiving high doses of systemic corticosteroids (2 mg/kg per day or more of prednisone or its equivalent or 20 mg/day of prednisone or its equivalent) for 14 days or more. The recommended interval between discontinuation of high-dose corticosteroid therapy and immunization with varicella vaccine is at least 1 month. Varicella vaccine may be administered to individuals receiving only inhaled, nasal, or topical steroids.

HOUSEHOLDS WITH POTENTIAL CONTACT WITH IMMUNOCOMPROMISED PEOPLE. Household contacts of immunocompromised people should be immunized if they have no evidence of immunity to decrease the likelihood that wild-type VZV will be introduced into the household. No precautions are needed following immunization of healthy people who do not develop a rash. Immunized people in whom a postimmunization rash develops should avoid direct contact with an immunocompromised host who lacks evidence of immunity for the duration of the rash.

Pregnancy and Lactation. Varicella vaccine should not be administered to pregnant people, because the possible effects on fetal development are unknown, although no cases of congenital varicella syndrome or patterns of malformation have been identified after inadvertent immunization of pregnant people. Pregnancy should be avoided for at least 1 month after immunization. A pregnant person or other household member is not a contraindication for immunization of a child in the household. Breastfeeding is not a contraindication to immunization.

Immune Globulin. Whether immune globulin (IG) can interfere with varicella vaccine-induced immunity is unknown, although IG can interfere with immunity induction by measles vaccine. Pending additional data, varicella vaccine should be withheld for the same intervals after receipt of any form of IG or other blood product as for measles vaccine (see Measles, p 570; and Table 1.11, p 69). Additionally, IG should be withheld for at least 2 weeks after receipt of varicella vaccine.

Salicylates. No cases of Reye syndrome have been reported following varicella vaccination, with more than 140 million doses distributed in the United States. However, because use of salicylates during varicella infection is associated with Reye syndrome, the vaccine manufacturer recommends that salicylates be avoided for 6 weeks after administration of varicella vaccine.

VIBRIO INFECTIONS

Cholera

(*Vibrio cholerae*)

CLINICAL MANIFESTATIONS: Cholera is characterized by voluminous watery diarrhea and rapid onset of life-threatening dehydration. Hypovolemic shock may occur within hours of the onset of diarrhea. Stools have a characteristic rice-water appearance, are white-tinged with small flecks of mucus, and contain high concentrations of sodium, potassium, chloride, and bicarbonate. Vomiting is a common feature of cholera. Fever and abdominal cramps usually are absent. In addition to dehydration and hypovolemia, common complications of cholera include hypokalemia, metabolic acidosis, and hypoglycemia, particularly in children. Although severe cholera is a distinctive illness characterized by profuse diarrhea and rapid dehydration, people infected with toxigenic *Vibrio cholerae* may have no symptoms or mild to moderate diarrhea lasting 3 to 7 days.

ETIOLOGY: *V. cholerae* is a curved or comma-shaped motile gram-negative rod. There are more than 200 *V. cholerae* serogroups, some of which carry the cholera toxin (CT) gene and other virulence factors. Although those serogroups with the CT gene and others without the CT gene can cause acute watery diarrhea, only toxin-producing serogroups O1 and O139 have caused epidemic cholera, with the currently circulating 7th pandemic strain of O1 causing the vast majority of cases worldwide. *V. cholerae* O1 is classified into 2 biotypes, classical and El Tor, and 2 major serotypes, Ogawa and Inaba. All other serogroups of *V. cholerae* are known collectively as *V. cholerae* non-O1/non-O139. Toxin-producing strains of *V. cholerae* non-O1/non-O139 can cause sporadic cases of severe dehydrating diarrheal illness but have not caused large outbreaks of cholera. Non-toxin-producing strains of *V. cholerae* non-O1/non-O139 are associated with sporadic cases of gastroenteritis, sepsis, and rare cases of wound infection (discussed in Other *Vibrio* Infections, p 955).

EPIDEMIOLOGY: Cholera is an underreported infection, and estimates of the global burden are imprecise. In areas where the disease is endemic, cholera disproportionately affects young children. Cholera also causes explosive epidemics across all age groups in vulnerable populations. These outbreaks occur frequently in the setting of natural or manmade humanitarian disasters. Examples include large epidemics that occurred after the introduction of pandemic *V. cholerae* into Haiti in 2010 and into Yemen in 2017. In the United States, cholera is a sporadic disease. Cases resulting from travel to or ingestion of contaminated food transported from regions with endemic cholera have been reported. Domestically acquired cases in the United States have been reported from eating Gulf Coast seafood.

Humans are the only documented natural host, but free-living *V. cholerae* organisms can persist in the aquatic environment. Infection primarily is acquired by ingestion of large numbers of organisms from contaminated water or food (particularly raw or undercooked shellfish, raw or partially dried fish, or moist grains or vegetables held at ambient temperature). People with low gastric acidity and those with blood group O are at increased risk of severe cholera infection.

The **median incubation period** usually is 1 to 2 days, with a range of a few hours to 5 days.

DIAGNOSTIC TESTS: *V. cholerae* can be cultured from fecal specimens (preferred) or vomitus plated on thiosulfate citrate bile salts sucrose agar. Because most laboratories in the United States do not culture routinely for *V. cholerae* or other *Vibrio* organisms, clinicians should request appropriate cultures for clinically suspected cases. Isolates of *V. cholerae* should be sent to a state health department laboratory for confirmation and then forwarded to the Centers for Disease Control and Prevention (CDC) for species identification using DNA-based methods, serotyping, and detection of the cholera toxin gene (www.cdc.gov/laboratory/specimen-submission/detail.html?CDCTestCode=CDC-10119). Tests to detect serum antibodies to *V. cholerae*, such as the vibriocidal assay and an anticholera toxin enzyme-linked immunoassay, are available at the CDC, subject to preapproval. Both assays require submission of acute and convalescent serum specimens and, thus, provide a retrospective diagnosis. A fourfold increase in vibriocidal antibody titers between acute and convalescent sera suggests the diagnosis of cholera. Several commercial tests for rapid antigen detection of *V. cholerae* O1 and O139 in stool specimens have been developed. These *V. cholerae* O1 and O139 rapid diagnostic tests have sensitivities ranging from approximately 80% to 97% and specificities of approximately 70% to 90% compared with culture on thiosulfate citrate bile salts sucrose agar. Rapid diagnostic tests are not a substitute for stool culture but might provide an indication of a suspect cholera outbreak in regions where stool culture is not immediately available. Multiplex molecular panels have been cleared by the US Food and Drug Administration for detection of various bacteria, parasites, and viruses associated with gastrointestinal tract infections, and some can specifically detect *V. cholerae* from unpreserved stool specimens and/or stool specimens preserved in Cary Blair transport media. Culture confirmation is recommended following a positive result from these culture-independent diagnostic testing panels, as low levels of contaminating nucleic acid from media have been reported.

TREATMENT: Timely and appropriate rehydration therapy is the cornerstone of management of cholera and reduces the mortality of severe cholera from more than 10% to less than 0.5%. Rehydration therapy should be based on World Health Organization (WHO) standards, with the goal of replacing the estimated fluid deficit within 3 to 4 hours of initial presentation. In patients with severe dehydration, isotonic intravenous fluids should be used, and lactated Ringer solution is the preferred commercially available option.¹ For patients without severe dehydration, oral rehydration therapy using the WHO's reduced-osmolality oral rehydration solution (ORS) has been the standard, but data suggest that rice-based ORS or amylase-resistant starch ORS are more effective.

Antimicrobial therapy decreases the duration and volume of diarrhea as well as the shedding of viable bacteria. Antimicrobial therapy should be considered for people who are moderately to severely ill. The choice of antimicrobial therapy should be made based on the age of the patient (Table 3.90) as well as prevailing patterns of antimicrobial resistance. When local patterns of resistance are unknown, antimicrobial susceptibility testing should be performed on isolates and monitored. Zinc supplementation should be considered as an adjunct to rehydration in children (www.cdc.gov/cholera/treatment/zinc-treatment.html).

¹ World Health Organization. *The Treatment of Diarrhoea, a Manual for Physicians and Other Senior Health Workers*. 4th Rev. World Health Organization; 2005

Table 3.90. Antibiotics for Suspected Cholera

Antibiotic	Pediatric Dose ^a	Adult Dose	Comment(s)
Doxycycline	4.4 mg/kg, single dose	300 mg, single dose	Use should be in epidemics caused by susceptible isolates. Can be used without regard to patient age, but is not recommended for pregnant people.
Ciprofloxacin ^b	15 mg/kg, twice daily for 3 days (single dose 20 mg/kg has been used)	500 mg, twice daily for 3 days	Decreased susceptibility to fluoroquinolones is associated with treatment failure.
Azithromycin	20 mg/kg, single dose	1 g, single dose	
Erythromycin	12.5 mg/kg, 4 times/day for 3 days	250 mg, 4 times/day for 3 days	
Tetracycline ^c	12.5 mg/kg, 4 times/day for 3 days	500 mg, 4 times/day for 3 days	

^aNot to exceed adult dose.

^bFluoroquinolones are not approved for children younger than 18 years for this indication.

^cFor use in children ≥8 y.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, contact precautions are indicated for diapered children or incontinent people for the duration of illness.

CONTROL MEASURES:

Hygiene. Disinfection of drinking water through chlorination or boiling prevents waterborne transmission of *V. cholerae*. Thoroughly cooking crabs, oysters, and other shellfish from the Gulf Coast before eating is recommended to decrease the likelihood of illness. Foods such as fish, rice, or grain gruels should be refrigerated promptly and thoroughly reheated before eating, and fruits and vegetables should be peeled before eating. The use of latrines or burying feces is recommended, and defecation should be avoided near any body of water. Appropriate hand hygiene after defecating and before preparing or eating food is important for preventing transmission.

Treatment of Contacts. Although administration of appropriate antimicrobial agents within 24 hours of identification of the index case may prevent additional cases of cholera among household contacts, chemoprophylaxis of contacts currently is not recommended.

Vaccine. A single-dose, live attenuated monovalent oral vaccine (CVD 103-HgR; Vaxchora), has been approved by the US Food and Drug Administration and is available in the United States for use for travelers 2 through 64 years of age who are traveling to areas where cholera is a risk. In addition to following safe food and water precautions, the Advisory Committee on Immunization Practices of the CDC

recommends cholera vaccine for immunocompetent pediatric and adult travelers 2 through 64 years of age to an area of active cholera transmission.¹ No data exist on use of the currently licensed CVD 103-HgR formulation in immunocompromised populations. An area of active cholera transmission is defined as a province, state, or other administrative subdivision within a country with endemic or epidemic cholera caused by toxigenic *V. cholerae* and includes areas with cholera activity within the past year that are prone to recurrence of cholera epidemics; it does not include areas where only rare sporadic cases have been reported. Information about destinations with active cholera transmission is available at wwwnc.cdc.gov/travel/.

Three non-live oral vaccines are approved by the WHO and available outside the United States. Dukoral is a monovalent inactivated vaccine based on heat-killed whole cells of serogroup O1 plus recombinant cholera toxin B subunit. The vaccine also may provide some protection against heat-labile enterotoxigenic *Escherichia coli* infection and is primarily used by travelers to areas with endemic cholera. Children between 2 and 6 years of age require 3 doses, and adults and children 6 years and older require 2 doses at least 1 week apart. Two bivalent (O1 and O139) vaccines, ShanChol and Euvichol, provide durable protection in older children and adults but do not provide significant protection in young children. In 2011, the WHO initiated a global oral cholera vaccine stockpile, comprised of bivalent vaccine, to allow for its rapid deployment during cholera epidemics and other emergencies. Instructions regarding access to the stockpile are available at www.who.int/groups/Icg/cholera/stockpiles.

Cholera immunization is not required for travelers entering the United States from cholera-affected areas, and the WHO no longer recommends immunization for travel to or from areas with cholera transmission. No country requires cholera vaccine for entry.

Public Health Reporting. Confirmed cases of cholera must be reported to health authorities in any country in which they occur and were contracted. Local and state health departments should be notified immediately of presumed or known cases of cholera.

Other *Vibrio* Infections

CLINICAL MANIFESTATIONS: Vibriosis is illness attributable to more than 20 species of the *Vibrionaceae* family. Species commonly isolated from clinical samples include: (1) *Vibrio parahaemolyticus*, *Vibrio vulnificus*, *Vibrio alginolyticus*, and other *Vibrio* species; (2) nontoxigenic *Vibrio cholerae*; (3) toxigenic *Vibrio cholerae* O75 and O141; and (4) members of the *Vibrionaceae* family that are not in the genus *Vibrio* (eg, *Grimontia*, *Photobacterium*). Associated clinical syndromes include gastroenteritis, wound infection, and septicemia. Gastroenteritis is the most common syndrome and is characterized by acute onset of watery, nonbloody stools and crampy abdominal pain. Approximately half of affected people will have low-grade fever, headache, and chills; approximately 30% will have vomiting. Spontaneous recovery occurs in 2 to 5 days. Wound infections typically start as cellulitis with vesicles and can progress to hemorrhagic bullae, necrosis, and/or necrotizing fasciitis. Septicemia can be primary or follow gastroenteritis or wound infection and often is fulminant and accompanied by development of metastatic skin lesions

¹ Collins JP, Ryan ET, Wong KK, et al. Cholera vaccine: recommendations of the Advisory Committee on Immunization Practices, 2022. *MMWR Recomm Rep*. 2022;71(RR-2):1–8

within 36 hours. Risk factors for severe wound infections and for septicemia include liver disease, iron overload, hemolytic anemia, chronic renal failure, diabetes mellitus, low gastric acidity, and immunosuppression. Various otolaryngologic manifestations attributable to *V alginolyticus* have been linked to swimming in salt water.

ETIOLOGY: *Vibrio* organisms are facultatively anaerobic, motile, gram-negative bacilli that are tolerant of salt. The most commonly reported nontoxigenic *Vibrio* species associated with diarrhea are *V parahaemolyticus* and *V cholerae* non-O1/non-O139. *V vulnificus* typically causes primary septicemia and severe wound infections, but the other species also can cause these syndromes. *V alginolyticus* typically causes wound and ear infections, with ear infections more commonly seen in children.

EPIDEMIOLOGY: *Vibrio* species are natural inhabitants of marine and estuarine environments. In temperate climates, most noncholera *Vibrio* infections occur during summer and fall months, when *Vibrio* populations in seawater are highest due to favorable growth conditions in warm temperatures. Following trends in climate change, global *Vibrio* infections are expected to continue increasing. Gastroenteritis usually follows ingestion of raw or undercooked seafood, especially oysters, clams, crabs, and shrimp. Wound infections usually are attributable to *V vulnificus* and can result from exposure of a preexisting wound to contaminated seawater or from punctures resulting from handling of contaminated fish or shellfish. Exposure to contaminated water during natural disasters, such as hurricanes, has resulted in wound infections. Person-to-person transmission has not been reported. National surveillance for infections associated with noncholera *Vibrio* organisms has been in place since 1997 (www.cdc.gov/vibrio/surveillance.html). It is estimated that 80 000 cases, 500 hospitalizations, and 100 deaths from vibriosis occur each year in the United States.

The **incubation period** is typically 24 hours (with a range of 5 to 92 hours) for gastroenteritis and is 1 to 7 days for wound infections and septicemia.

DIAGNOSTIC TESTS: Depending on the clinical syndrome, *Vibrio* organisms can be isolated from stool, wound exudates, or blood. Because identification of the organism requires special techniques, laboratory personnel should be notified when infection with *Vibrio* species is suspected. Multiplex molecular panels are available, but the specificity of some diagnostic tests is poor. Infection should be confirmed by culture, and isolates (or clinical specimens if isolates are not available on a positive nonculture diagnostic test) should be forwarded as required to the local or state public health laboratory for characterization, outbreak investigation, and surveillance.

TREATMENT: Diarrhea typically is mild and self-limited, and oral rehydration is recommended as treatment. Wound infections require prompt surgical débridement of necrotic tissue, if present. Antimicrobial therapy is recommended for severe diarrhea, wound infection, or septicemia. Septicemia, with or without hemorrhagic bullae, and wound infections should be treated with a third-generation cephalosporin plus either doxycycline or ciprofloxacin. Severe diarrhea should be treated with doxycycline or ciprofloxacin. Doxycycline can be used without regard to patient age. A combination of trimethoprim-sulfamethoxazole and an aminoglycoside is an alternative regimen.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, contact precautions are recommended for diapered or incontinent children.

CONTROL MEASURES: Seafood should be cooked fully and refrigerated if not consumed immediately. Cross-contamination of cooked seafood by contact with surfaces and containers contaminated by raw seafood should be avoided. Uncooked mollusks and crustaceans should be handled with care, and gloves can be worn during preparation. Abrasions suffered by ocean bathers should be rinsed with clean fresh water. All children, immunocompromised people, and people with chronic liver disease should avoid eating raw oysters or clams, and all individuals should be advised of risks associated with seawater exposure if a wound is present or likely to occur.

Public Health Reporting. Vibriosis is a nationally notifiable disease, and cases should be reported to local or state health departments immediately.

West Nile Virus

CLINICAL MANIFESTATIONS: West Nile virus (WNV) is the leading cause of mosquito-borne illness in the United States. An estimated 80% of people infected with WNV are asymptomatic. Most of the 20% of people who are symptomatic experience an acute systemic febrile illness that often includes headache, myalgia, arthralgia, vomiting, diarrhea, or a transient maculopapular rash. Less than 1% of infected people (1 in 150) develop neuroinvasive disease, which typically manifests as meningitis, encephalitis, or acute flaccid myelitis. WNV meningitis is indistinguishable clinically from aseptic meningitis caused by other viruses. Patients with WNV encephalitis usually present with fever, headache, seizures, mental status changes (including disorientation, stupor, or coma), focal neurologic deficits, or movement disorders (including tremor). WNV acute flaccid myelitis often is clinically and pathologically identical to poliovirus-associated poliomyelitis, with damage of anterior horn cells and resulting weakness and paralysis of one or more limbs; this may progress to respiratory paralysis requiring mechanical ventilation. WNV-associated Guillain-Barré syndrome also has been reported and can be distinguished from WNV acute flaccid myelitis by clinical manifestations, findings on cerebrospinal fluid analysis, and electrophysiologic testing. Cardiac dysrhythmias, myocarditis, rhabdomyolysis, optic neuritis, uveitis, chorioretinitis, orchitis, pancreatitis, and hepatitis have been described rarely after WNV infection.

Routine clinical laboratory results are nonspecific in WNV infections. In patients with neuroinvasive disease, cerebrospinal fluid (CSF) examination generally shows lymphocytic pleocytosis, but neutrophils may predominate early in the illness. Brain magnetic resonance imaging frequently is normal, but signal abnormalities may be seen in the basal ganglia, thalamus, and brainstem with WNV encephalitis and in the spinal cord with WNV acute flaccid myelitis.

Most patients with WNV nonneuroinvasive disease or meningitis recover completely, but fatigue, malaise, and weakness can linger for weeks or months. Recovery from WNV encephalitis or acute flaccid myelitis often takes weeks to months, and patients commonly have residual neurologic deficits. Among patients with neuroinvasive disease, the overall case fatality rate is approximately 10% but is significantly higher in WNV encephalitis and acute flaccid myelitis than in WNV meningitis.

Most people known to have been infected with WNV during pregnancy have delivered infants without evidence of infection or clinical abnormalities. Rare cases of congenital infection and probable transmission via human milk (see Breastfeeding

and Human Milk, p 135) have been reported. If WNV disease is diagnosed during pregnancy, a detailed examination of the fetus and of the newborn infant should be performed.¹

ETIOLOGY: WNV is an RNA virus of the *Flaviviridae* family (genus *Flavivirus*) that is related antigenically to St. Louis encephalitis and Japanese encephalitis viruses.

EPIDEMIOLOGY: WNV is an arthropod-borne virus (arbovirus) that is transmitted in an enzootic cycle between mosquitoes and amplified in vertebrate hosts, primarily birds. WNV is transmitted to humans primarily through bites of infected *Culex* mosquitoes. Humans usually do not develop a level or duration of viremia sufficient to infect mosquitoes and, therefore, are dead-end hosts. Person-to-person WNV transmission can occur rarely through blood transfusion and solid organ transplantation. Congenital and perinatal transmission during pregnancy, delivery, or via breastfeeding has been described. Transmission through percutaneous and mucosal exposure has occurred in laboratory workers and occupational settings.

WNV transmission has been documented on every continent except Antarctica. Since the 1990s, the largest outbreaks of WNV neuroinvasive disease have occurred in the Middle East, Europe, and North America. WNV first was detected in the Western Hemisphere in New York City in 1999 and subsequently spread across the continental United States and Canada. From 1999 through 2020, 52 532 cases of WNV infection were reported in the United States, of which 26 683 were nonneuroinvasive disease and 25 849 were neuroinvasive disease, with peaks in national incidence in 2002, 2003, and 2012. WNV is the leading cause of neuroinvasive arboviral disease in the United States. In 2020 (latest finalized data available from the Centers for Disease Control and Prevention [CDC]), there were 559 cases of WNV neuroinvasive disease reported. Although the lower number of cases reported in 2020 likely was associated with the COVID-19 pandemic, WNV caused 4 times more neuroinvasive disease cases than the number reported for all other domestic arboviruses combined (eg, La Crosse [88], Powassan [20], St. Louis encephalitis viruses [14], eastern equine encephalitis [13], and Jamestown Canyon [10]). WNV human cases have been reported from all US states; the states with the highest average annual incidence (>1.0 case per 100 000) of human WNV disease over the period 1999-2020 were Colorado, Louisiana, Mississippi, Nebraska, North Dakota, South Dakota, and Wyoming. Preliminary data from 2021 has shown Arizona to have nearly 10 times the number of cases reported in other states. A map of the distribution of WNV neuroinvasive disease across the United States can be found on the CDC website (www.cdc.gov/westnile/statsmaps/final.html). Climate change likely is one factor associated with the expanded range of mosquito vectors and, therefore, WNV disease.

Most human WNV infections occur in summer or early fall in temperate and subtropical regions. All age groups are susceptible to WNV infection, but incidence of severe disease (eg, neuroinvasive disease and death) is highest among older adults. Overall incidence is 0.05/100 000 in those <20 years of age compared with 1.2/100 000 in those ≥70 years of age. Chronic renal failure, history of cancer, alcohol use disorder, diabetes mellitus, and hypertension have been associated with developing severe WNV disease.

¹ Centers for Disease Control and Prevention. Interim guidelines for the evaluation of infants born to mothers infected with West Nile virus during pregnancy. *MMWR Morb Mortal Wkly Rep*. 2004;53(7):154-157

The **incubation period** usually is 2 to 6 days but ranges from 2 to 14 days and can be up to 21 days in immunocompromised people and up to 37 days in solid organ transplant recipients.

DIAGNOSTIC TESTS: Detection of anti-WNV immunoglobulin (Ig) M antibodies in serum or cerebrospinal fluid (CSF) is the most common method for diagnosis of WNV infection. Presence of anti-WNV IgM usually is good evidence of recent WNV infection but may indicate infection with another closely related flavivirus. WNV IgM antibodies are detectable in most WNV-infected patients within 3 to 8 days of symptom onset and typically remain detectable for months and, in some individuals, years after the acute illness. For patients from whom serum collected within 8 days of illness lacks detectable IgM, testing should be repeated on a convalescent-phase sample. Because anti-WNV IgM can persist in the serum of some patients for longer than 1 year, a positive test result may reflect past infection. Detection of WNV IgM in CSF generally is indicative of recent neuroinvasive infection. IgG antibody generally is detectable shortly after IgM and usually persists for years. Plaque-reduction neutralization tests can be performed to measure virus-specific neutralizing antibodies and to discriminate between cross-reacting antibodies from closely related flaviviruses. A fourfold or greater increase in virus-specific neutralizing antibodies between acute- and convalescent-phase serum specimens collected 2 to 3 weeks apart may be used to confirm recent WNV infection. State and local health departments can assist with diagnostic testing and with determination of whether additional testing is indicated via the CDC Arbovirus Diagnostic Laboratory (www.cdc.gov/ncezid/dvbd/specimensub/arboviral-shipping.html).

Viral culture and WNV nucleic acid amplification tests (including reverse transcriptase-polymerase chain reaction) can be performed on acute-phase serum, CSF, or tissue specimens. By the time most immunocompetent patients present with clinical symptoms, WNV RNA usually no longer is detectable; therefore, polymerase chain reaction assay is not recommended for diagnosis in immunocompetent hosts. Sensitivity of these tests is likely higher in immunocompromised patients. Immunohistochemical staining can detect WNV antigens in fixed tissue, but negative results are not definitive.

WNV disease should be considered in the differential diagnosis of febrile or acute neurologic illnesses associated with recent exposure to mosquitoes, blood transfusion, or solid organ transplantation and of illnesses in neonates whose birthing parent was infected with WNV during pregnancy or while breastfeeding. WNV and other arboviruses should be considered in the differential diagnosis of aseptic meningitis and encephalitis along with other causes such as herpes simplex virus and enteroviruses.

TREATMENT: No specific therapy is available; management of WNV disease is supportive. Although various therapies have been evaluated or used empirically for WNV disease, none has shown specific benefit thus far. A review summarizing potential treatments (including immune globulin intravenous with or without a high titer of WNV antibody, WNV recombinant humanized monoclonal antibody, interferon, corticosteroids, and ribavirin) is available online at www.cdc.gov/westnile/healthcareproviders/healthCareProviders-TreatmentPrevention.html.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS: Standard precautions are recommended.

CONTROL MEASURES: Candidate WNV vaccines are being evaluated, but none are licensed for use in humans. Prevention of WNV disease depends on community-level mosquito control programs to reduce vector densities, personal protective measures to decrease exposure to infected mosquitoes, and screening of blood and organ donors. Successful community-level integrated pest-management strategies combine removing mosquito habitats by eliminating standing water, using structural barriers, and controlling both larval stage and adult mosquitos (www.epa.gov/mosquitocontrol/success-mosquito-control-integrated-approach and www.epa.gov/insect-repellents/using-repellent-products-protect-against-mosquito-borne-illnesses). Personal protective measures include use of mosquito repellents, wearing long-sleeved shirts and long pants, and limiting outdoor exposure from dusk to dawn (see Prevention of Mosquito-borne and Tick-borne Infections, p 207). Using air conditioning, installing window and door screens, and reducing peridomestic mosquito breeding sites can decrease the risk of WNV exposure further. Blood donations in the United States are screened for WNV infection, but physicians should remain vigilant for the possible transmission of WNV through blood transfusion or organ transplantation. Any suspected WNV infections temporally associated with blood transfusion or organ transplantation should be reported promptly to the appropriate state health department and to the United Network for Organ Sharing in the case of suspected organ transmission.

Pregnant people should take precautions to avoid mosquito bites. Products containing N,N-diethyl-meta-toluamide (DEET) can be used in pregnancy without adverse effects. Pregnant people who develop meningitis, encephalitis, acute flaccid myelitis, or unexplained fever in areas of ongoing WNV transmission should be tested for WNV infection. Confirmed WNV infections should be reported to local or state health departments, and infected pregnant people should be followed to determine the outcomes of their pregnancies. Although WNV probably has been transmitted through human milk, such transmission appears rare, and no adverse effects on infants have been described. Because the benefits of breastfeeding outweigh the risk of WNV disease in breastfeeding infants, people should be encouraged to breastfeed even in areas with ongoing WNV transmission.

Yersinia enterocolitica* and *Yersinia pseudotuberculosis

Infections

(Enteritis and Other Illnesses)

CLINICAL MANIFESTATIONS: *Yersinia enterocolitica* causes several age-specific syndromes and a variety of other less commonly reported clinical illnesses. Infection with *Y enterocolitica* typically manifests as fever, diarrhea, and abdominal pain in children younger than 5 years; stool often contains leukocytes, blood, and mucus. Symptoms of *Y enterocolitica* generally resolve within 7 days but diarrhea may persist for more than 2 weeks. Relapsing disease and, rarely, necrotizing enterocolitis and protein-losing enteropathy also have been described. In older children and adults, a pseudoappendicitis syndrome attributable to mesenteric lymphadenitis (fever, abdominal pain, tenderness in the right lower quadrant of the abdomen, and leukocytosis) is common. Bacteremia is the major complication of *Y enterocolitica* infection occurring mostly in children younger than 1 year and in older children with predisposing conditions, such as excessive iron

storage (eg, deferoxamine use, sickle cell disease, and beta-thalassemia) and immunosuppressive states. Extraintestinal manifestations of *Y enterocolitica* are uncommon but include pharyngitis, meningitis, osteomyelitis, pyomyositis, conjunctivitis, pneumonia, empyema, endocarditis, acute peritonitis, abscesses of the liver and spleen, urinary tract infection, and primary cutaneous infection. Postinfectious sequelae with *Y enterocolitica* infection include erythema nodosum, reactive arthritis, uveitis, and glomerulonephritis. These sequelae occur most often in older children and adults, particularly people with HLA-B27 antigen.

Major manifestations of *Y pseudotuberculosis* infection include fever, scarlatiniform rash, acute gastroenteritis, and abdominal symptoms. Acute pseudoappendiceal abdominal pain is common, resulting from ileocecal mesenteric adenitis or terminal ileitis. Other uncommon findings reported have been intestinal intussusception; erythema nodosum; septicemia, mainly among individuals with underlying conditions; acute renal failure with nephritis; and sterile pleural and joint effusions. *Y pseudotuberculosis* infection may cause a severe systemic inflammatory disease called Far East scarlet-like fever (FESLF), which has been reported sporadically and in outbreaks in Russia and Japan.

Although not common, recent case reports suggest that infection with *Y enterocolitica* and *Y pseudotuberculosis* may mimic or contribute to the pathogenesis of Kawasaki disease. In Japan, nearly 10% of children with a diagnosis of Kawasaki disease have serologic or culture evidence of *Y pseudotuberculosis* infection. These patients often require more than 1 dose of intravenous immune globulin (IVIG) and are more likely to develop cardiac sequelae than Kawasaki disease patients without *Y pseudotuberculosis* infection.

ETIOLOGY: The genus *Yersinia* consists of 17 species of gram-negative bacilli belonging to the family *Yersiniaceae*. *Y enterocolitica*, *Y pseudotuberculosis*, and *Yersinia pestis* (see Plague, p 671) are the 3 most recognized human pathogens; however, other *Yersinia* species also have been isolated from clinical specimens. Isolates of *Y enterocolitica* involved in human infections belong to several serotypes (O:3, O:8, O:9, and O:5.27) and are divided into 3 groups according to their pathogenic potential: nonpathogenic biotype 1A, weakly pathogenic biotypes 2 through 5, and highly pathogenic biotype 1B. Strains from biotype 1A can induce infections only in immunocompromised individuals. Serotype O:8, from biotype 1B, is the most virulent and has been responsible for several food poisoning outbreaks in the United States. At present, carriage of pathogenic *Y enterocolitica* serotype O:3, found primarily in pigs, is the most frequent cause of yersiniosis in Europe and North America. The 3 *Yersinia* species have in common a tropism for lymphoid tissue and share factors that promote serum resistance, coordinate gene expression, and facilitate iron acquisition. Differences in virulence gene distribution exist among *Yersinia* species.

EPIDEMIOLOGY: *Y enterocolitica* and *Y pseudotuberculosis* are isolated most often during the cool months of temperate climates because of favorable growth conditions at cooler temperatures (4°C to 43°C). The Foodborne Disease Active Surveillance Network (FoodNet) conducts active surveillance for infections caused by *Yersinia* (see Appendix V: Prevention of Infectious Disease From Contaminated Food Products, p 1145). During 2019, FoodNet identified 681 *Yersinia* cases of infection (21% were hospitalized and 0.6% died), with an average incidence of 1.4 per 100 000 population, which represents

a 153% increase in comparison to 2016-2018.¹ This increased incidence likely resulted from increased use of culture-independent diagnostic tests that detect bacterial antigens and genes for *Y enterocolitica*. *Yersinia* incidence is highest in children younger than 5 years and in Black people; however, in recent years, a significant declining incidence among Black children has been observed. FoodNet data from 1996–2007 indicate that compared with *Y enterocolitica* infection, the average annual incidence of *Y pseudotuberculosis* infection is much lower (0.04 cases per 1 million population), occurs in older people (median age was 47 years), and is more severe and invasive (72% were hospitalized, 11% died, and two thirds of isolates were recovered from blood).

The principal reservoir of *Y enterocolitica* is swine, although it can be isolated from a variety of domestic and wildlife animals; *Y pseudotuberculosis* has been isolated from ungulates (deer, elk, goats, sheep, cattle), rodents (rats, squirrels, beaver), rabbits, and many bird species. Infection with *Y enterocolitica* is reported to be transmitted by ingestion of contaminated food (raw or incompletely cooked pork products, tofu, and unpasteurized or inadequately pasteurized milk²), by contaminated surface or well water, by direct or indirect contact with animals, and rarely by transfusion with contaminated packed red blood cells and by person-to-person transmission. Cross-contamination has been documented to lead to infection in infants if their caregivers handle raw pork intestines (ie, chitterlings) and do not clean their hands or food preparation surfaces adequately before handling the infant or the infant's toys, bottles, or pacifiers. *Y pseudotuberculosis* can follow exposure to well and mountain waters contaminated with animal feces. Household pets can be source of infection for children.

The **incubation period** typically is 4 to 6 days, with a range of 1 to 14 days. Organisms typically are excreted for 2 to 3 weeks and up to 2 to 3 months in untreated cases. Prolonged asymptomatic carriage is possible.

DIAGNOSTIC TESTS: *Y enterocolitica* and *Y pseudotuberculosis* can be recovered from stool, mesenteric lymph nodes, and blood. Stool cultures generally yield bacteria during the first 2 weeks of illness, regardless of the nature of gastrointestinal tract manifestations. Laboratory personnel should be notified when *Yersinia* infection is suspected so that stool can be appropriately stored (eg, Cary-Blair transport media) and cultured on suitable media (eg, blood, chocolate, and MacConkey agars incubated at 25°C to 35°C for 24 to 48 hours in ambient air). Because of relatively slow growth conditions of *Yersinia*, isolation from nonsterile sources (eg, stool) is recommended using selective media.

DNA-based gastrointestinal syndrome panels are commercially available but typically target only *Y enterocolitica* and may cross-react with other *Yersinia* species. In 2018, 68% of yersiniosis cases reported to FoodNet were diagnosed using such culture-independent panels. Reliable species identification using matrix-assisted laser desorption/ionization–time-of-flight (MALDI-TOF) mass spectrometry, DNA-based methods, biotyping, and serotyping of pathogenic strains isolated from clinical, food, and environmental samples are available through public health reference laboratories.

¹ Tack DM, Ray L, Griffin PM, et al. Preliminary incidence and trends of infections with pathogens transmitted commonly through food - Foodborne Diseases Active Surveillance Network, 10 U.S. Sites, 2016-2019. *MMWR Morb Mortal Wkly Rep*. 2020;69(17):509-514

² American Academy of Pediatrics, Committee on Infectious Diseases, Committee on Nutrition. Consumption of raw or unpasteurized milk and milk products by pregnant women and children. *Pediatrics*. 2014;133(1):175-179 (Reaffirmed November 2019)

Infection also can be confirmed by demonstrating increases in serum antibody titer after infection, but these tests generally are available only in reference or research laboratories. Cross-reactions of these antibodies with *Brucella*, *Vibrio*, *Salmonella*, and *Rickettsia* organisms and *Escherichia coli* can lead to false-positive *Y enterocolitica* and *Y pseudotuberculosis* titers. In patients with thyroid disease, persistently increased *Y enterocolitica* antibody titers can result from antigenic similarity of the organism with antigens of the thyroid epithelial cell membrane. Characteristic ultrasonographic features demonstrating edema of the wall of the terminal ileum and cecum with normal appendix help to distinguish pseudoappendicitis from appendicitis and can help avoid exploratory surgery.

TREATMENT: In immunocompetent hosts, yersiniosis is typically self-limited and does not require antibiotic treatment. Although a clinical benefit of antimicrobial therapy for immunocompetent patients with enterocolitis, pseudoappendicitis syndrome, or mesenteric adenitis has not been established, some clinicians consider treatment because it can decrease the duration of shedding of *Yersinia* organisms. Antibiotic treatment is recommended for neonates, immunocompromised hosts, and all patients with severe manifestations like septicemia or extraintestinal disease. Parenteral therapy with a third-generation cephalosporin is appropriate in these situations, and evaluation of cerebrospinal fluid should be performed for infected neonates. In addition to third-generation cephalosporins, trimethoprim-sulfamethoxazole, aminoglycosides, fluoroquinolones, chloramphenicol, tetracycline, and doxycycline may be used. *Y enterocolitica* isolates are usually resistant to first-generation cephalosporins and most penicillins. Antibiotic therapy has no beneficial effect on postinfectious syndromes.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, contact precautions are indicated for diapered or incontinent children for the duration of diarrheal illness.

CONTROL MEASURES: Ingestion of uncooked or undercooked meat (especially pork), unpasteurized milk,¹ or contaminated water should be avoided. People who handle raw meat products should minimize contact with young children and their possessions while handling raw products. Meticulous hand hygiene and proper sanitization of food preparation surfaces should be practiced before and after handling and preparation of uncooked products. No vaccines against *Y enterocolitica* and *Y pseudotuberculosis* are available, although several candidates are under evaluation.

Public Health Reporting. *Yersinia* infections are not nationally notifiable but are reportable in many states (a directory of state and territorial, city and county, and tribal health departments can be found at www.cdc.gov/publichealthgateway/healthdirectories/index.html).

Zika

CLINICAL MANIFESTATIONS: Most Zika virus infections are asymptomatic or result in mild clinical disease with symptoms lasting a few days to a week. Commonly reported signs and symptoms include fever, pruritic maculopapular rash, arthralgia, and conjunctival hyperemia. Other findings include myalgia, headache, edema of the

¹ American Academy of Pediatrics, Committee on Infectious Diseases and Committee on Nutrition. Consumption of raw or unpasteurized milk and milk products by pregnant women and children. *Pediatrics*. 2014;133(1):175-179 (Reaffirmed November 2019)

extremities, vomiting, retro-orbital pain, and lymphadenopathy. Clinical laboratory abnormalities are observed uncommonly in symptomatic patients but can include thrombocytopenia, leukopenia, and increased liver aminotransferase concentrations. Severe disease requiring hospitalization and deaths are rare. However, Guillain-Barré syndrome and rare reports of other neurologic complications (eg, meningoencephalitis, myelitis, and uveitis) have been associated with Zika virus infection.

Congenital Zika virus infection can cause fetal loss, intrauterine growth restriction, premature delivery, microcephaly, and other serious neurologic anomalies. Clinical findings most specific for congenital Zika syndrome include severe microcephaly with partially collapsed skull, cortical hypoplasia with abnormal gyral patterns, intracranial calcifications between the cortex and subcortex), congenital contractures (arthrogryposis), and ocular abnormalities (eg, chorioretinal scarring and pigmentary mottling). Other abnormalities have been reported among infants with congenital infection including other structural brain abnormalities (eg, ventriculomegaly, corpus callosum agenesis, cerebellar hypoplasia, mild microcephaly), other structural eye abnormalities (eg, microphthalmia, cataracts, chorioretinal atrophy, or optic nerve hypoplasia), and neurologic sequelae associated with structural brain abnormalities (eg, hypertonia, dystonia, swallowing dysfunction, seizures, hearing loss). Approximately 5% of infants in the US Zika Pregnancy and Infant Registry had any Zika-associated brain or eye defect; one third of those infants had more than 1 defect reported. The frequency of Zika-associated birth defects in infants was similar among those born to symptomatic (5.3%) and asymptomatic (4.2%) pregnant people. Among pregnancies with confirmed Zika infection, the frequency of any Zika-associated birth defect was higher among those with first (8.0%) and second (6.0%) trimester infections compared with third trimester infections (3.8%). Rare cases of perinatal transmission from birthing parents who were viremic at delivery have been reported. These perinatal transmissions generally result in asymptomatic or mildly symptomatic illness in the neonate.

ETIOLOGY: Zika virus is a single-stranded, RNA virus in the genus *Flavivirus* that is most closely related antigenically to dengue. Two major lineages, African and Asian, have been identified through phylogenetic analyses.

EPIDEMIOLOGY: Zika virus is transmitted to humans primarily by *Aedes aegypti* mosquitoes and less commonly by *Aedes albopictus* and possibly other *Aedes* (*Stegomyia*) species (eg, *Aedes polynesiensis* and *Aedes hensilli*). In the United States, *Ae aegypti* mosquitoes are found primarily in southern states. *Ae albopictus* mosquitoes have a wider distribution (see map at www.cdc.gov/zika/vector/range.html). Both *Aedes* species bite humans primarily during the daytime hours. These are the same vectors that transmit dengue, chikungunya, and yellow fever viruses. Human and nonhuman primates are the main reservoirs of the virus, with humans acting as the primary host in which the virus multiplies, allowing spread to additional mosquitoes and then other humans. Additional modes of transmission have been identified, including perinatal, in utero, sexual, blood transfusion, and laboratory exposure. Although Zika virus has been detected in human milk, and a few possible cases of transmission of Zika virus by breastfeeding have been reported, to date there is no consistent evidence that infants acquire Zika virus through breastfeeding.

Prior to 2007, only sporadic human Zika virus disease cases were reported from countries in Africa and Asia. In 2007, the first documented Zika virus disease outbreak

was reported in the Federated States of Micronesia. In subsequent years, outbreaks of Zika virus disease were identified in countries in Southeast Asia and the Western Pacific. In 2015, Zika virus was identified for the first time in the Western hemisphere and subsequently spread throughout much of the Americas, with 48 countries and territories in the Americas reporting local transmission. During 2016, large outbreaks occurred in Puerto Rico and the US Virgin Islands, and limited local transmission was identified in parts of Florida and Texas. In 2017, Zika virus disease cases started to decline worldwide. Since 2018, there have been no locally acquired cases reported from US states. Current information on Zika virus transmission and travel guidance can be found at www.cdc.gov/zika/geo/index.html and wwwnc.cdc.gov/travel/page/zika-travel-information, respectively.

The **incubation period** is 3 to 14 days after the bite of an infected mosquito.

DIAGNOSTIC TESTS: Zika virus infection should be considered in patients with acute onset of fever, maculopapular rash, arthralgia, or conjunctivitis who live in or have traveled to or had sex with someone who lived in or recently traveled to an area with ongoing transmission in the 2 weeks preceding illness onset. Because dengue and chikungunya virus infections share a similar geographic distribution and symptoms with Zika virus infection, patients with suspected Zika virus infection also should be evaluated and managed for possible dengue or chikungunya virus infection. Other considerations in the differential diagnosis include malaria, rubella, measles, parvovirus, adenovirus, enterovirus, leptospirosis, rickettsiosis, group A streptococcal infections, and COVID-19.

Nucleic acid amplification tests (NAATs) are the preferred method of diagnosis. Zika virus RNA is likely to be detected in serum from approximately 2 days before to 1 week after illness onset; RNA also can be detected in other body fluids (eg, whole blood, urine, saliva, amniotic fluid, semen, and breast milk). Immunoglobulin (Ig) M and neutralizing antibody testing also can be used to identify Zika virus infections, particularly in patients who present after viral nucleic acid is no longer detectable. IgM antibody assays can be conducted on serum, plasma, whole blood, or cerebrospinal fluid (CSF). IgM antibodies develop during the first week of illness and may be detectable for months to years following infection, making it difficult to distinguish the timing of Zika virus infection. Cross-reactivity of the Zika virus IgM antibody tests with other flaviviruses can result in a false-positive test result making it difficult to differentiate between flavivirus infections. Recent epidemiologic data indicate a declining prevalence of Zika virus infection in the Americas; this lower prevalence will result in a lower pretest probability of infection and a higher probability of false-positive test results for both molecular and serologic testing.

Although neutralizing antibody titers can yield cross-reactive results in people with previous flavivirus infections or who were vaccinated against a related flavivirus, they may differentiate flavivirus infections, particularly in individuals who were flavivirus-naïve before their infection. Testing guidance is updated as new information is obtained; for the most recent guidance, visit www.cdc.gov/Zika.

Zika Laboratory Testing in Nonpregnant Symptomatic Individuals. Given the current global arboviral epidemiology, Zika virus testing is currently not recommended for this group unless people live in or have traveled to a country with a current Zika outbreak (wwwnc.cdc.gov/travel/page/zika-travel-information). For individuals

traveling to or living in an area with a current Zika virus outbreak, both Zika and dengue virus NAATs should be performed as soon as possible on serum collected ≤ 7 days after onset of symptoms (Fig 3.23). IgM antibody testing for Zika and dengue should be performed in NAAT-negative serum specimens and serum collected >7 after onset of symptoms. For individuals traveling to or living in areas not experiencing a Zika virus outbreak, refer to testing guidance for dengue.

Zika Laboratory Testing in Pregnant People. Current recommendations from the Centers for Disease Control and Prevention (CDC; www.cdc.gov/zika/hc-providers/testing-guidance.html) take into account the decreasing prevalence of Zika virus

FIG 3.23. DENGUE AND ZIKA VIRUS TESTING RECOMMENDATIONS FOR NONPREGNANT PERSONS WITH A CLINICALLY COMPATIBLE ILLNESS AND RISK FOR INFECTION WITH BOTH VIRUSES^a

IgM indicates immunoglobulin M; NAAT, nucleic acid amplification test; PRNT, plaque-reduction neutralization test.

^a*Specimen and test selection:* Dengue and Zika virus NAATs, IgM antibody testing, and PRNTs should be performed on serum. Some NAATs also can be performed on plasma, whole blood, cerebrospinal fluid, or urine, and some antibody tests can be performed on plasma, whole blood, or cerebrospinal fluid. Laboratories might choose to perform dengue and Zika virus NAATs and IgM antibody testing simultaneously rather than sequentially, or to perform dengue virus nonstructural protein-1 testing instead of dengue virus NAAT.

Indications to repeat assay(s): If the patient's illness has epidemiologic or clinical significance (eg, first case of local transmission in area, new transmission mode, or unusual clinical syndrome), repeat a positive NAAT on newly extracted RNA from the same specimen. For indeterminate IgM antibody test results, repeat IgM antibody testing or perform PRNT on the same specimen. In areas where PRNTs are not performed, report the indeterminate results and request a second serum specimen for IgM antibody testing.

Interpretation of results: Dengue and Zika virus IgM antibodies can be detected in serum for months following infection. The specific timing of infection cannot be determined. Data on the epidemiology of viruses known to be circulating at the location of exposure and clinical findings should be considered when interpreting the results of serologic diagnostic testing. Figure illustrates dengue and Zika virus testing recommendations for nonpregnant persons with a clinically compatible illness and risk for infection with both viruses. Diagnostic testing recommendations include immunoglobulin M assays, nucleic acid amplification tests, and plaque reduction neutralization tests.

From: Sharp TM, Fischer M, Muñoz-Jordán JL, et al. Dengue and Zika virus diagnostic testing for patients with a clinically compatible illness and risk for infection with both viruses. *MMWR Recomm Rep*. 2019;68(1):1-10.

disease cases globally, current dengue outbreaks in many areas of the world, and current knowledge of diagnostic limitations.^{1,2} For asymptomatic pregnant people with recent travel to areas with risk of Zika (wwwnc.cdc.gov/travel/page/zika-travel-information), Zika virus testing is not routinely recommended because of its inability to differentiate between recent and remote infections and risk of false-positive results. Testing recommendations for symptomatic pregnant people who had recent travel to areas with active dengue transmission and risk of Zika virus transmission can be found at www.cdc.gov/zika/hc-providers/testing-guidance.html.

Zika Laboratory Testing for Congenital Infection. Zika virus testing is recommended for infants with clinical findings consistent with congenital Zika syndrome and possible in utero Zika virus exposure, regardless of the birthing parent's testing results, and for infants without clinical findings consistent with congenital Zika syndrome who are born to persons with laboratory evidence of possible infection during pregnancy. Recommended laboratory testing for possible congenital Zika virus infection includes evaluation for Zika virus RNA in infant serum, urine and CSF, if available. Zika virus IgM antibodies testing should be performed in serum and CSF, if available.

Laboratory testing of infants should be performed as soon as possible after birth (within the first few days of life), although testing specimens within the first few weeks to months after birth might still be useful. Diagnosis of congenital Zika virus infection is confirmed by a positive Zika virus NAAT or by a positive Zika virus IgM and neutralizing antibody result. If neither Zika virus RNA nor Zika IgM antibodies are detected on the appropriate specimens obtained within the first few days after birth, congenital Zika virus infection is unlikely (Table 3.91).

If the infant's initial sample is IgM nonnegative (nonnegative serologic terminology varies by assay and might include "positive," "equivocal," "presumptive positive," or "possible positive") and the NAAT result is negative, and PRNT was not performed on the birthing parent's sample, PRNTs for Zika and dengue viruses should be performed on the infant's initial sample. If the Zika virus PRNT result is negative, this suggests that the infant's Zika virus IgM test result is a false positive. For infants with clinical findings consistent with congenital Zika syndrome or evidence in the birthing parent of possible Zika virus infection during pregnancy but with no testing near the time of delivery, a PRNT at age ≥ 18 months (after transplacentally acquired antibodies have dissipated from the infant's system) might help confirm or rule out congenital Zika virus infection.

Fig 3.24 (p 969) outlines the current recommended evaluation of infants with possible congenital Zika virus from exposure during pregnancy.³

TREATMENT: No specific antiviral treatment currently is available for Zika virus disease. Supportive care is indicated, including rest, fluids, and symptomatic treatment

Table 3.91. Interpretation of Results of Laboratory Testing of Infant’s Blood, Urine, and/or Cerebrospinal Fluid for Evidence of Congenital Zika Virus Infection^a

Infant Test Result ^b		Interpretation	Comments
NAAT	IgM		
Positive	Any result	Confirmed congenital Zika virus infection	Distinguishing between congenital and postnatal infection is difficult in infants who live in areas where there is ongoing transmission of Zika virus and who are not tested soon after birth. If the timing of infection cannot be determined, infants should be evaluated as if they had congenital Zika virus infection.
Negative	Nonnegative ^c	Probable congenital Zika virus infection ^d	If Zika virus PRNT result is negative, this suggests that the infant’s Zika virus IgM test is a false positive.
Negative	Negative	Congenital Zika virus infection unlikely ^d	Congenital Zika virus infection is unlikely if specimens are collected within the first few days after birth and the clinical evaluation is normal; however, health care providers should remain alert for any new findings of congenital Zika virus infection.

NAAT indicates nucleic acid amplification test; IgM, immunoglobulin M, PRNT, plaque-reduction neutralization test.
^aAdapted from: Adebajo T, Godfred-Cato S, Viens L, et al. Update: interim guidance for the diagnosis, evaluation, and management of infants with possible congenital Zika virus infection—United States, October 2017. *MMWR Morb Mortal Wkly Rep.* 2017;66(41):1089–1099.
^bInfant serum, urine, or cerebrospinal fluid.
^cNonnegative serologic terminology varies by assay and might include “positive,” “equivocal,” “presumptive positive,” or “possible positive.”
^dLaboratory results should be interpreted in the context of timing of infection during pregnancy; serology results in birthing parent, clinical findings consistent with congenital Zika syndrome, and any confirmatory testing with PRNT.

(acetaminophen to relieve fever and antihistamines to treat pruritus). Aspirin and non-steroidal anti-inflammatory drugs (NSAIDs) should be avoided until dengue can be ruled out to reduce the risk of hemorrhagic complications.

Clinical Management of Infants With Clinical Findings Consistent With Congenital Zika Infection. Zika virus testing is recommended (see Zika Laboratory Testing for Congenital Infection, p 967), ultrasonography of the head should be performed, and a comprehensive ophthalmologic examination should be performed by age 1 month by an ophthalmologist experienced in assessment of infants. Referrals to a developmental specialist and early intervention are recommended. Additional consultation should be considered by infectious diseases (for evaluation of other congenital infections and assistance with Zika virus diagnosis and testing), clinical genetics (for evaluation for other causes of microcephaly or congenital anomalies), and neurology by age 1 month (for comprehensive neurologic examination and consideration for other evaluations, such as advanced neuroimaging and electroencephalography [EEG]). Infants should be referred for automated brainstem response (ABR) testing by age 1 month

FIG 3.24. RECOMMENDATIONS FOR THE EVALUATION OF INFANTS WITH POSSIBLE CONGENITAL ZIKA VIRUS INFECTION BASED ON INFANT CLINICAL FINDINGS,^{a,b} TEST RESULTS IN BIRTHING PARENT,^{c,d} AND INFANT TEST RESULTS^{e,f}

ABR indicates auditory brainstem response; CSF, cerebrospinal fluid; CZS, congenital Zika syndrome; IgM, immunoglobulin M; NAAT, nucleic acid amplification test; PRNT, plaque-reduction neutralization test.

Adapted from Adebanjo T, Godfred-Cato S, Viens L, et al. Update: interim guidance for the diagnosis, evaluation, and management of infants with possible congenital Zika virus infection—United States, October 2017. *MMWR Morb Mortal Wkly Rep.* 2017;66(41):1089–1099

FIG 3.24. RECOMMENDATIONS FOR THE EVALUATION OF INFANTS WITH POSSIBLE CONGENITAL ZIKA VIRUS INFECTION BASED ON INFANT CLINICAL FINDINGS,^{a,b} TEST RESULTS IN BIRTHING PARENT,^{c,d} AND INFANT TEST RESULTS,^{e,f} CONTINUED

^aAll infants should receive a standard evaluation at birth and at each subsequent well-child visit by their health care providers, including (1) comprehensive physical examination, including growth parameters; and 2) age-appropriate vision screening and developmental monitoring and screening using validated tools. Infants should receive a standard newborn hearing screen at birth, preferably using auditory brainstem response (ABR).

^bAutomated ABR by age 1 month if newborn hearing screen passed but performed with otoacoustic emission methodology.

^cLaboratory evidence of possible Zika virus infection during pregnancy is defined as 1) Zika virus infection detected by a Zika virus RNA NAT on any maternal, placental, or fetal specimen (referred to as NAAT-confirmed), or 2) diagnosis of Zika virus infection, timing of infection cannot be determined or unspecified flavivirus infection, timing of infection cannot be determined by serologic tests on a maternal specimen (ie, positive/equivocal Zika virus IgM and Zika virus PRNT titer ≥ 10 , regardless of dengue virus PRNT value; or negative Zika virus IgM, and positive or equivocal dengue virus IgM, and Zika virus PRNT titer ≥ 10 , regardless of dengue virus PRNT titer). The use of PRNT for confirmation of Zika virus infection, including in pregnant people, is not routinely recommended in Puerto Rico (www.cdc.gov/zika/laboratories/lab-guidance.html).

^dThis group includes people who were never tested during pregnancy as well as those whose test result was negative because of issues related to timing or sensitivity and specificity of the test. Because the latter issues are not easily discerned, all birthing parents with possible exposure to Zika virus during pregnancy who do not have laboratory evidence of possible Zika virus infection, including those who tested negative with currently available technology, should be considered in this group.

^eLaboratory testing of infants for Zika virus should be performed as early as possible, preferably within the first few days after birth, and includes concurrent Zika virus NAAT in infant serum and urine, and Zika virus IgM testing in serum. If CSF is obtained for other purposes, Zika virus NAAT and Zika virus IgM testing should be performed on CSF.

^fLaboratory evidence of congenital Zika virus infection includes a positive Zika virus NAAT or a nonnegative Zika virus IgM with confirmatory neutralizing antibody testing, if PRNT confirmation is performed.

if the newborn hearing screen was passed using only otoacoustic emission (OAE) methodology.

Clinical Management of Infants Without Clinical Findings Consistent With Congenital Zika Infection but Laboratory Evidence of Possible Zika Virus Infection of the Birthing Parent During Pregnancy. Zika virus testing is recommended (see Zika Laboratory Testing for Congenital Infection, p 967), and ultrasonography of the head should be performed by age 1 month to detect subclinical brain findings. All infants should have a comprehensive ophthalmologic examination by age 1 month to detect subclinical eye findings. Infants should be referred for automated ABR testing by 1 month of age if newborn screen was passed using only OAE methodology. Infants should be monitored for findings consistent with congenital Zika syndrome that could develop over time (eg, impaired visual acuity/function, hearing problems, developmental delay, delay in head growth).

Clinical Management of Infants Without Clinical Findings Consistent With Congenital Zika Infection Whose Birthing Parent Had Possible Zika Virus Infection During Pregnancy but Without Laboratory Evidence of Zika Virus During Pregnancy. Zika virus testing is not routinely recommended, and specialized clinical evaluation or follow-up is not routinely indicated. Health care providers can consider additional evaluation in consultation with families. If findings suggestive of congenital Zika virus disease are identified at any time, referrals to the appropriate specialists should be made.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended. People infected with Zika virus should be protected from further mosquito exposure, especially during the first week of illness, to reduce the risk of local transmission to others.

CONTROL MEASURES: No vaccines or preventive drugs are available, but a number of candidate vaccines are under evaluation in clinical trials. Prevention and control measures rely on personal prevention measures to avoid mosquito bites and community-level programs to reduce vector densities in areas with endemic infection. Personal measures include using insect repellent; wearing long pants, socks, and long-sleeved shirts while outdoors; and staying in air-conditioned buildings or buildings with window and door screens. Permethrin-treated clothing and gear can repel mosquitoes. Travelers returning to the United States from an area with risk of Zika, even if asymptomatic, should take steps to prevent mosquito bites for 3 weeks to minimize spread to local mosquito populations (www.cdc.gov/zika/prevention/prevent-mosquito-bites.html).

Insect repellents registered by the US Environmental Protection Agency (EPA) can be used according to directions on the product labels. Products containing N,N-diethyl-meta-toluamide (DEET), picaridin, oil of lemon eucalyptus, IR3535, para-menthane-diol (PMD), and 2-undecanone provide protection from mosquito bites (see Prevention of Mosquito-borne and Tick-borne Infections, p 207). More information about these ingredients can be found at www.epa.gov/insect-repellents/skin-applied-repellent-ingredients. All travelers should take precautions to avoid mosquito bites to prevent Zika virus infection and other mosquito-borne diseases.

Sexual Transmission. Zika virus can be transmitted sexually. Couples in which the man or woman has had possible Zika virus exposure who want to maximally reduce their risk for sexually transmitting Zika virus to the uninfected partner should use condoms or abstain from sex for at least 3 months for men or 2 months for women after symptom onset (if symptomatic) or last possible Zika virus exposure (if asymptomatic) (www.cdc.gov/zika/prevention/sexual-transmission-prevention.html).¹ Sperm should not be donated for at least 3 months from infection or last exposure.

People Who Are Pregnant or Seeking to Become Pregnant. Pregnant people should not travel to areas with ongoing Zika outbreaks (wwwnc.cdc.gov/travel/page/zika-travel-information). Before traveling to areas with current or past transmission of Zika, pregnant people should discuss their travel plans with their health care provider. In deciding whether to travel, pregnant people should consider the destination, reasons for traveling, and ability to prevent mosquito bites. There is no restriction on the use of insect repellents by pregnant women if used in accordance with the instructions on the product label. Male partners of pregnant people who have traveled to areas with local transmission of Zika virus should abstain from sex or use condoms for the duration of the pregnancy to avoid sexual transmission to their pregnant partners (www.cdc.gov/zika/prevention/sexual-transmission-prevention.html).

For couples who have possible Zika virus exposure and who are considering pregnancy, the CDC recommends postponing pregnancy for 3 months following potential exposure or diagnosis of Zika infection (www.cdc.gov/zika/prevention/sexual-transmission-prevention.html).

¹ The terms man, men, male, woman, and women refer to sex assigned at birth.

Blood and Tissue Donation. Following the decrease in incidence of Zika virus in the United States and its territories, the US Food and Drug Administration (FDA) removed the requirement for routine Zika virus NAAT screening of blood donations. However, it is recommended that individuals who were infected with Zika virus infection defer blood donations for 120 days following symptom resolution or their last positive test, whichever is longer, to reduce the risk for transfusion-associated transmission of Zika virus. It is also recommended that individuals should be ineligible to donate human cells, tissues, and cellular and tissue-based products if they had a diagnosis of Zika virus infection within the past 6 months. Individuals suspected of having Zika virus infection at any point during a pregnancy should not be eligible to donate umbilical cord blood, placenta tissue, or other gestational tissues.

Breastfeeding. The World Health Organization and Centers for Disease Control and Prevention (CDC) recommend infants born to a person with suspected, probable, or confirmed Zika virus infection, or to a person who lives in or has traveled to areas with Zika virus, should be fed according to local infant feeding guidelines. Breastfeeding is encouraged even in areas where Zika virus is found because of the benefits of breastfeeding.

Public Health Reporting. Health care professionals should report suspected Zika virus infection to their state or local health departments to facilitate diagnosis and mitigate the risk of local transmission. Zika virus disease and congenital infections were added to the list of nationally notifiable diseases in 2016. State health departments should then report cases to the CDC through ArboNET, the national surveillance system for arboviral diseases.

Antimicrobial Agents and Related Therapy

..... INTRODUCTION

Initial studies evaluating the efficacy and safety of new antimicrobial agents are usually conducted in adults, with pediatric studies occurring later. The product label (package insert) approved by the US Food and Drug Administration (FDA) for a given antimicrobial drug provides information on indications based on clinical trial data reviewed by the FDA. Virtually all current antimicrobial product labels are available at <https://dailymed.nlm.nih.gov/dailymed/>. The FDA also maintains a website (www.accessdata.fda.gov/scripts/cder/daf/) of approved drug products with therapeutic equivalence evaluations, an online repository of labels for approved drugs (<https://labels.fda.gov/>), and information about drug shortages (www.accessdata.fda.gov/scripts/drugshortages/default.cfm). Additional information from the American Society of Health System Pharmacists on current drug shortages in the United States can be found at www.asph.org/shortages.

An FDA-approved indication usually means that adequate and well-controlled studies were conducted, presented to, and reviewed by the FDA for use in the populations in which the drug was investigated. However, accepted medical practice often includes use of drugs that are not reflected in approved indications found in the drug label (“off-label” use). These additional clinical uses of antimicrobial agents may become apparent and investigated years after initial approval of an agent. Oftentimes, because of high cost, additional trials are not performed or presented to the FDA to allow for a change in the package label. For this reason, lack of FDA approval may not necessarily mean lack of effectiveness. Unapproved use also does not imply improper use, provided that reasonable supporting medical evidence exists and that use of the drug is deemed to be in the best interest of the patient. The decision to prescribe a drug is the responsibility of the medical provider, who must weigh the risks and benefits of using the drug for a specific situation.

Some antimicrobial agents with proven therapeutic benefit in adults are not approved by the FDA for use in pediatric patients or, rarely, are considered contraindicated in children because of possible toxicity. The following information delineates general principles for use of fluoroquinolones, tetracyclines, and other approved agents.

Fluoroquinolones

Fluoroquinolones (eg, ciprofloxacin, levofloxacin, moxifloxacin, delafloxacin) should not be used routinely as first-line agents in children younger than 18 years except when specific indications exist or in specific conditions for which there are no alternative agents (including oral agents) and the drug is known to be effective for the specific situation. Use of fluoroquinolones in adults and children is a driver of fluoroquinolone resistance and, therefore, using fluoroquinolones judiciously is an important strategy

to combat antibiotic resistance as well as to improve patient safety. Information on the safety of fluoroquinolones for children was reviewed and published by the American Academy of Pediatrics.¹

Rare risks related to fluoroquinolones are summarized as follows:

- *Clostridioides difficile* (formerly called *Clostridium difficile*) disease: Fluoroquinolones are among the most common antimicrobials to be associated with *C difficile* disease.
- Tendinopathy: Fluoroquinolones are associated in adults with an increased risk of tendon rupture (with a predilection for the Achilles tendon) and tendonitis, with further increased risk in people older than 60 years; in those who have received renal, heart, kidney, or lung transplants; and in those with concurrent use of corticosteroids. To date, there have been no reports of Achilles tendon rupture in children in association with fluoroquinolone use.
- QT interval prolongation: Certain fluoroquinolones (moxifloxacin, levofloxacin, ciprofloxacin) can prolong the QT interval and should be avoided, if possible, in patients with long QT syndrome, those with hypokalemia or hypomagnesemia, those with organic heart disease including congestive heart failure, those receiving an antiarrhythmic agent from class Ia (particularly quinidine) or class III (see www.ncbi.nlm.nih.gov/books/NBK482322/), those who are receiving a concurrent drug that prolongs the QTc interval independently, and those with hepatic insufficiency-related metabolic derangements that may promote QT prolongation.
- Central nervous system toxicity: Neurologic complications associated with fluoroquinolone use, although very uncommon in children, include peripheral neuropathy, seizures, lightheadedness, sleep disorders, hallucinations, dizziness, headaches, disturbances in attention, disorientation, agitation, nervousness, memory impairment, delirium, and pseudotumor cerebri.
- Myasthenia gravis: Fluoroquinolones may unmask or worsen muscle weakness in people with myasthenia gravis.
- Arthralgia: Transient arthralgia has been reported in patients treated with fluoroquinolones. However, arthralgia has not been confirmed by clinical examination and controlled trials have not yet proven direct causal effect of fluoroquinolones. Some pediatric studies have observed an increased incidence of reversible adverse events involving joints or surrounding tissues with fluoroquinolones compared with other agents. For some fluoroquinolones, cartilage damage in some animal models occurs at doses that approximate therapeutic doses in humans. The mechanism of damage remains speculative, but there are emerging in vitro data to suggest direct collagen effects. Long-term safety data have been reported for both levofloxacin and moxifloxacin. To date, there is no compelling evidence of long-term sequelae related to fluoroquinolone bone or joint toxicity in children.
- Thrombocytopenia, immune-mediated hemolytic anemia, hepatic dysfunction, renal dysfunctions (interstitial nephritis and crystal nephropathy), hyperglycemia/hypoglycemia, hypersensitivity, and photosensitivity reactions have also been reported.

The FDA has issued a Drug Safety Communication for the fluoroquinolone class, advising that health care providers should not prescribe systemic fluoroquinolones to patients who have other treatment options for acute bacterial sinusitis, acute bacterial

¹Jackson MA, Schutze GE; American Academy of Pediatrics, Committee on Infectious Diseases. The use of systemic and topical fluoroquinolones. *Pediatrics*. 2016;138(5):e20162706

exacerbation of chronic bronchitis, and uncomplicated urinary tract infections, because the risks outweigh the benefits in these patients.¹ Although ciprofloxacin is approved for use in children 1 year and older with complicated urinary tract infection or pyelonephritis, it should not be a first-line agent, and other agents should be used preferentially if the pathogens are suspected or documented to be susceptible to other agents with a more favorable safety profile. The significant exceptions in which ciprofloxacin may be used as a first-line agent in children are for postexposure prophylaxis for inhalation anthrax (ciprofloxacin primarily, with levofloxacin and moxifloxacin considered equivalent alternatives; see Anthrax, p 232) and treatment of plague (ciprofloxacin, levofloxacin, or moxifloxacin; see Plague, p 671).

Circumstances in which use of systemic fluoroquinolones may be justified in children include the following: (1) parenteral therapy is not practical, and no other safe and effective oral agent is available (eg, tularemia); and (2) infection is caused by a multidrug-resistant pathogen for which there is no other effective intravenous or oral agent available. Clinical situations for the use of systemic or topical fluoroquinolones may include the following:

- Urinary tract, bone, or other invasive infections, including chronic suppurative otitis media or malignant otitis externa caused by *Pseudomonas aeruginosa* or other multidrug-resistant, gram-negative bacteria resistant to beta-lactams and other classes of antimicrobial agents.
- Multidrug-resistant (beta-lactam, carbapenem, macrolide, and trimethoprim-sulfamethoxazole resistant) pneumococcal infections.
- Gastrointestinal tract infection or bacteremia caused by suspected or documented multidrug-resistant *Shigella* species, *Salmonella* species, *Vibrio cholerae*, *Campylobacter jejuni*, or *Campylobacter coli* or *Enterobacteriales*.
- Mycobacterial infections that are multidrug resistant for which no other oral drug is available or appropriate.
- Serious infections attributable to fluoroquinolone-susceptible pathogen(s) in children with severe allergy to alternative agents.
- Otorrhea associated with tympanic membrane perforation as well as tympanostomy tube otorrhea, for which topical fluoroquinolone-containing agents are considered as safer alternatives to aminoglycoside-containing agents.

Tetracyclines

Use of tetracyclines as a class of drugs in pediatric patients historically has been limited because of reports that this class could cause permanent dental discoloration in children younger than 8 years, because their degradation products are incorporated in tooth enamel. The period of odontogenesis to completion of formation of enamel in permanent teeth appears to be the critical time for effects of these drugs, and it is now known that the calcification stage of tooth development starts at the sixth week of development in utero and is usually completed at 3 to 4 months of life. The degree of teeth staining from tetracyclines appears to depend on dosage, duration of therapy, and which drug in the tetracycline class is used.

¹ US Food and Drug Administration. FDA Drug Safety Communication: FDA advises restricting fluoroquinolone antibiotic use for certain uncomplicated infections; warns about disabling side effects that can occur together. Available at: www.fda.gov/Drugs/DrugSafety/ucm500143.htm

Doxycycline binds less readily to calcium compared with other members of the tetracycline class. The use of doxycycline was previously limited largely to patients 8 years and older due to historical concern for a drug class effect with tetracyclines. However, data from the United States and Europe suggest that doxycycline is not likely to cause visible teeth staining or enamel hypoplasia in children younger than 8 years. These reassuring data support the current recommendation by the American Academy of Pediatrics that doxycycline can be administered without regard to the patient's age or the duration of therapy. When used, patients of all skin tones and colors should be careful to avoid excess sun exposure because of photosensitivity associated with doxycycline.

Antimicrobial Agents Approved for Use in Adults but Not Children

Antimicrobial agents in a variety of classes have been studied and approved by the FDA for use in adults for certain indications, particularly for infections caused by methicillin-resistant *Staphylococcus aureus* and multidrug-resistant gram-negative bacilli but still are under investigation for pharmacokinetics and safety in children. For some agents that the pharmaceutical sponsor wishes to market for children, additional investigation for clinical and microbiologic efficacy in children are required to obtain FDA approval. These agents include but are not limited to oritavancin, telavancin, imipenem/relebactam, meropenem/vaborbactam, lefamulin, plazomicin, and for older children, tetracycline-class agents eravacycline and omadacycline. These drugs should be used in children only when no other safe and effective agents that are FDA approved for use in children are available and when benefits are expected to exceed risks for that patient. For these agents with relatively undefined or emerging safety and efficacy in pediatrics, consultation with an expert in pediatric infectious diseases should be considered.

..... BETA-LACTAM AND MONOBACTAM ALLERGIES^{1,2}

Although true penicillin allergy (immunoglobulin [Ig] E mediated) occurs in only 1% of the population, a full 10% of patients are labeled as penicillin allergic. Penicillin allergy is often unconfirmed and reported by patients and families because of a history of rash (urticarial or nonurticarial), other adverse events (eg, diarrhea), or even family history. Labeling a patient as penicillin allergic complicates treatment of many infections (eg, acute otitis media, sinusitis, and skin and soft tissue infections), leading to alternative antibiotic therapies that often are more broad spectrum, increase antibiotic resistance, and are less efficacious. To reduce antibiotic allergy overlabeling, investigation of the type of reaction and timing of the penicillin allergy should be undertaken. For patients who do not report potential IgE-mediated reactions (eg, anaphylaxis,

¹ Joint Task Force on Practice Parameters representing the American Academy of Allergy, Asthma and Immunology; American College of Allergy, Asthma and Immunology; Joint Council of Allergy, Asthma and Immunology: Drug allergy: an updated practice parameter. *Ann Allergy Asthma Immunol.* 2010;105(4):259-273

² Kahn DA, Banerji A, Blumenthal KG, et al. Drug allergy: a 2022 practice parameter update. *J Allergy Clin Immunol.* 2022;150(6):1333-1393

wheezing, lightheadedness, bronchospasm, angioedema/swelling, flushing/redness) or more severe reactions (eg, Stevens-Johnson syndrome), penicillin allergy delabeling should be considered.

Most (80%) patients with a history of true IgE-mediated penicillin allergy lose their sensitivity after 10 years. Therefore, in patients with a remote history of allergy (>10 years ago) or a history of benign reactions (eg, nonspecific rash or delayed urticarial rash), oral challenge testing should be undertaken to remove the penicillin allergy label without the need for skin testing. In patients with a recent history of a

^aThis matrix describes the risk of cross-reactivity between 2 beta-lactam antibiotics. Boxes with a symbol indicate either a similar (light gray) or an identical (dark gray) side chain and, therefore, higher risk for an allergic reaction. Empty boxes indicate a lack of side-chain similarity and decreased risk of allergic reaction.

Reproduced with permission from Blumenthal KG, Shenoy ES, Wolfson AR, et al. Addressing inpatient beta-lactam allergies: a multi-hospital implementation. *J Allergy Clin Immunol Pract.* 2017;5(3):616-625.

suspected IgE-mediated reaction (eg, immediate urticaria), skin testing should be performed prior to oral challenge testing. In patients who report other adverse events from penicillin (eg, headache, abdominal pain) or a family history of penicillin allergy, de-labeling procedures are not necessary; the penicillin allergy label may be removed and penicillin antibiotics may be used as needed.

Studies have shown that the risk of beta-lactam cross-reactivity with cephalosporins is lower than previously reported and is believed to be related to beta-lactam ring R group side chains (see Fig 4.1). Patients with unconfirmed nonanaphylactic penicillin allergy can safely receive any cephalosporin without any testing or precautions. Patients with a history of penicillin anaphylaxis may receive a non-cross-reactive cephalosporin (eg, cefazolin) without prior testing.

Patients with cephalosporin allergy should be categorized by severity of reaction and whether the reaction is confirmed or not. In patients with nonanaphylactic and unconfirmed reactions to cephalosporins, penicillin antibiotic agents may be prescribed without testing or precautions. For example, amoxicillin may be safely prescribed in patients with history of urticaria to cephalexin without testing. However, patients with previous anaphylaxis to a cephalosporin should undergo penicillin skin testing prior to receipt of a penicillin agent.

Patients with a history of penicillin or cephalosporin allergy, even anaphylaxis, may receive carbapenems and/or aztreonam without prior testing or precautions (with the exception of ceftazidime because of identical R1 side chain).

A cephalosporin cross-reactivity matrix has been published (Fig 4.1) that quantifies the likelihood of cross-reactivity. This figure indicates side-chain cross-reactivity only; when considering cross-reactivity between penicillins and cephalosporins, cross-reactivity is also possible with the core beta-lactam ring.

..... ANTIMICROBIAL RESISTANCE AND ANTIMICROBIAL STEWARDSHIP: APPROPRIATE AND JUDICIOUS USE OF ANTIMICROBIAL AGENTS

Antimicrobial Resistance

The Centers for Disease Control and Prevention (CDC), World Health Organization (WHO), and other international agencies have identified antimicrobial resistance as one of the world's most pressing public health threats. In the United States, more than 2.8 million people are infected with antimicrobial-resistant bacteria, and at least 35 000 deaths occur annually as a direct result of these infections.¹ Highly resistant gram-negative pathogens (eg, carbapenemase-producing *Enterobacterales* and *Acinetobacter* species, multidrug-resistant *Pseudomonas aeruginosa*, and extended-spectrum beta-lactamase-producing *Enterobacterales*), gram-positive pathogens (eg, methicillin-resistant *Staphylococcus aureus* and *Enterococcus* species resistant to ampicillin and vancomycin),

¹ Centers for Disease Control and Prevention. Antibiotic Resistance Threats in the United States 2019.

Available at: www.cdc.gov/drugresistance/pdf/threats-report/2019-ar-threats-report-508.pdf

and drug-resistant *Candida* species are increasingly associated with invasive infections. *Clostridioides difficile* disease is the most common cause of diarrhea acquired in a health care facility and an infection that usually results from antimicrobial exposure. *C. difficile* causes approximately 223 900 infections and at least 12 800 deaths annually in the United States. The CDC has ranked the antimicrobial-resistant bacteria and fungi that have the most impact on human health in categories of urgent, serious, and concerning threats (Table 4.1).

The presence of resistant pathogens complicates patient management, increases morbidity and mortality, and increases medical expenses for patients and the health care system. Studies have estimated that antimicrobial resistance in the United States adds as much as \$20 billion in excess costs to the health care system each year, and the costs to society from lost productivity are as high as \$35 billion.

Factors Contributing to Resistance

The use of antimicrobial agents is a key driver of antimicrobial resistance. Antimicrobial agents are among the most commonly prescribed drugs used in human medicine. Many studies have measured the extent of inappropriate or unnecessary antibiotic use, which has been observed in 25% to 50% of hospitalized adults and children. The problem of inappropriate antibiotic use extends to outpatient settings, where the bulk of antibiotics are prescribed. In the United States, it is estimated that one-third of outpatient antibiotic prescriptions are inappropriate, including half of those prescribed for respiratory tract infections, millions of which are for children.

Table 4.1. Antimicrobial-Resistant Bacteria and Fungi Posing Health Threats

Urgent Threats	Serious Threats	Concerning Threats	Watch List
Carbapenem-resistant <i>Acinetobacter</i>	Drug-resistant <i>Campylobacter</i>	Erythromycin-resistant group	Azole-resistant <i>Aspergillus</i>
<i>Candida auris</i>	Drug-resistant <i>Candida</i>	A <i>Streptococcus</i>	<i>fumigatus</i>
<i>Clostridioides difficile</i>	ESBL-producing <i>Enterobacterales</i>	Clindamycin-resistant group	Drug-resistant <i>Mycoplasma genitalium</i>
Carbapenem-resistant <i>Enterobacterales</i>	Vancomycin-resistant enterococci (VRE)	B <i>Streptococcus</i>	Drug-resistant <i>Bordetella pertussis</i>
Drug-resistant <i>Neisseria gonorrhoeae</i>	Multidrug-resistant <i>Pseudomonas aeruginosa</i>		
	Drug-resistant nontyphoidal <i>Salmonella</i>		
	Drug-resistant <i>Salmonella</i> serotype Typhi		
	Drug-resistant <i>Shigella</i>		
	Methicillin-resistant <i>Staphylococcus aureus</i> (MRSA)		
	Drug-resistant <i>Streptococcus pneumoniae</i>		
	Drug-resistant tuberculosis		

Adapted from www.cdc.gov/drugresistance/biggest-threats.html.

The number of antibiotic-resistant bacteria and the diversity of molecular mechanisms of resistance continue to increase, while the development of newer, effective antimicrobial agents has dwindled. The loss of effective antimicrobial agents will hamper clinicians' efforts to treat potentially life-threatening infections. Compounding this problem, advances in medical treatment involving immunosuppression have expanded the population of immunocompromised people, who rely on the receipt of effective antimicrobial agents to prevent or control infection. When first- and second-line treatment options are rendered ineffective against antimicrobial resistant pathogens, clinicians are forced to use agents that may be more toxic, costly, and/or less effective.

The overuse of antimicrobial agents in animal agriculture also contributes substantially to the problem of antimicrobial resistance.¹ The CDC has determined that antimicrobial use in animals is linked to resistance in humans. The US Food and Drug Administration has described a pathway toward reducing inappropriate antimicrobial use in animals, and major medical and public health organizations, including the American Academy of Pediatrics (AAP), have called for stronger action.²

Actions to Prevent or Slow Antimicrobial Resistance

Antimicrobial resistance can only be addressed through concerted and collaborative efforts. The CDC's Antibiotic Resistance Solutions initiative invests in US infrastructure to detect, respond to, contain, and prevent antimicrobial resistant infections (www.cdc.gov/drugresistance/solutions-initiative/index.html). Actions to combat antimicrobial resistance include:

1. **Prevent infections and reduce the spread of resistance.** Antimicrobial-resistant infections can be prevented by immunization, infection prevention in health care settings, safe food preparation and handling, and handwashing. The CDC has also provided guidance on the containment of highly resistant pathogens of public health concern (www.cdc.gov/hai/containment/).
2. **Track antimicrobial resistant infections.** The CDC, in collaboration with health care facilities and state and local health departments, gathers data on antimicrobial-resistant infections to help inform strategies and interventions for prevention. The CDC Antibiotic Resistance Laboratory Network (www.cdc.gov/drugresistance/solutions-initiative/ar-lab-network.html) provides regional capacity to detect and characterize resistant pathogens.
3. **Improve antimicrobial use and promote antimicrobial stewardship.** It is critical to modify the way antimicrobial agents are used in humans and animals. Unnecessary and inappropriate use of antimicrobial agents is common across the continuum of care. Inappropriate use of antimicrobial agents often is a result of

¹ Katz SE, Banerjee R; American Academy of Pediatrics, Committee on Infectious Diseases, Council on Environmental Health and Climate Change. Technical report: Antimicrobial agents in animals: One Health perspectives and implications for pediatrics. *Pediatrics*. 2024; in press

² Pediatric Infectious Diseases Society. Pediatric ASP Toolkit. Advocacy Addressing Antibiotic Overuse in Animal Agriculture and the Environment. Available at: <https://pids.org/pediatric-asp-toolkit/advocacy-addressing-antibiotic-overuse-in-animal-agriculture-and-the-environment/>

errors in antimicrobial selection, dosing, or duration of therapy. Unnecessary exposure to antimicrobial agents results in adverse drug reactions, subsequent treatment challenges related to the development of antimicrobial resistance, and complications including *C difficile* disease. Every health care facility should have a formal antimicrobial stewardship program (ASP) built on the CDC's Core Elements of Antimicrobial Stewardship (see next section). Outpatient antimicrobial stewardship also is important to combat inappropriate antibiotic prescribing and antibiotic resistance.

4. **Develop drugs and improve diagnostic tests.** Discovery of new antimicrobial agents is needed to keep pace with the emergence of pathogen resistance. Unfortunately, the number of antimicrobial agents in late-phase clinical development is low. In particular, few agents are being developed with new mechanisms of action to treat resistant gram-negative infections. In addition, new diagnostic tests are needed to guide antimicrobial therapy and to track the development of resistance.

Antimicrobial Stewardship

The primary goal of antimicrobial stewardship is to optimize antimicrobial use with the aim of decreasing inappropriate use that leads to unwarranted toxicity and spread of resistant organisms. The CDC's Core Elements of Antibiotic Stewardship provides a framework for implementing stewardship across the spectrum of health care and includes guidance for hospitals, including small and critical access hospitals; nursing homes; outpatient settings; and resource-limited settings outside the United States (www.cdc.gov/antibiotic-use/core-elements/index.html). The AAP and Pediatric Infectious Diseases Society have developed a toolkit to aid in the implementation of inpatient stewardship programs (<https://pids.org/pediatric-asp-toolkit/>).

For inpatient facilities, the CDC describes 7 core elements needed for a successful ASP (www.cdc.gov/antibiotic-use/healthcare/implementation/core-elements.html):

- *Hospital leadership commitment.* Hospital administration should support and provide dedicated time to a stewardship program leader and a pharmacist co-leader as well as financial and technologic resources needed to accomplish the programmatic goals.
- *Accountability.* A program leader (often a physician) should work collaboratively with a pharmacy leader and other core members of the ASP team (infectious diseases specialists, clinical pharmacists, nurses, clinical microbiologists, hospital epidemiologists, infection prevention professionals, and information systems specialists). This leader should ensure that other core elements of a successful program are implemented.
- *Pharmacy expertise.* A pharmacy leader should work collaboratively with the physician leader to implement the key actions and other core elements.
- *Action.* Numerous actions have been described to successfully improve antibiotic use. Requiring **prior authorization** for select antimicrobials and/or prolonged durations of therapy (eg, beyond 48–72 hours) and **prospective audit with feedback** are evidence-based approaches proven to reduce unnecessary antimicrobial use,

adverse drug effects, and costs. Additional actions include development of clinical practice guidelines, clinical decision support, clinician and patient education, conversion from intravenous to oral agents, and dose optimization. Supplementation of these interventions with face-to-face interactions is recommended when possible, and stewardship of antimicrobial prescribing at the point of hospital discharge is an emerging target.

- **Tracking.** Antibiotic use data should be monitored and reported as days of therapy per 1000 patient days or days present. The CDC has developed the Antimicrobial Use and Resistance module within the National Healthcare Safety Network that provides a standardized antimicrobial administration ratio for a specific institution. The standardized antimicrobial administration ratio can be used in benchmarking with other institutions. (www.cdc.gov/nhsn/pdfs/pscmanual/11pscaurcurrent.pdf). Other data to be monitored may include hospital-onset *C difficile* disease rates, length of stay, adverse drug events, and rates of concerning antibiotic-resistant pathogens (eg, carbapenem-resistant *Enterobacterales*, methicillin-resistant *S aureus*), and hospital costs.
- **Reporting.** Regular updates on key process and outcome metrics, including antimicrobial use, resistance, adverse effects, and cost, should be given to prescribers, pharmacists, nurses, and senior administrators.
- **Education.** All health care workers should receive annual education regarding current antimicrobial stewardship practices and additional methods to improve use. Furthermore, efforts are needed to educate patients, families, and caregivers about antimicrobial stewardship and the impact of inappropriate antimicrobial use.

As part of the Choosing Wisely campaign, the AAP and the Pediatric Infectious Diseases Society (www.pids.org) have published “Five Things Physicians and Patients Should Question” about antimicrobial therapy:

- Don’t initiate empiric antibiotic therapy in a patient with suspected invasive bacterial infection without first confirming that blood, urine, or other appropriate cultures have been obtained, excluding exceptional cases.
- Don’t use a broad-spectrum antimicrobial agent for perioperative prophylaxis or continue prophylaxis after the incision is closed for uncomplicated clean and clean-contaminated procedures.
- Don’t treat uncomplicated community-acquired pneumonia in otherwise healthy, immunized, hospitalized patients with antibiotic therapy broader than ampicillin.
- Don’t use vancomycin or carbapenems empirically for neonatal intensive care patients unless an infant is known to have a specific risk for pathogens resistant to narrower-spectrum agents.
- Don’t place peripherally inserted central catheters and/or use prolonged intravenous antibiotics in otherwise healthy children with infections that can be transitioned to an appropriate oral agent.

Although inpatients are frequently exposed to broad-spectrum and potentially toxic antimicrobial agents, the vast majority of antibiotic exposure occurs in the outpatient setting. The CDC has developed the Core Elements of Outpatient Antibiotic Stewardship to help improve the use of antibiotics in this setting (www.cdc.gov/antibiotic-use/core-elements/outpatient.html). These core elements include commitment, action for policy and practice, tracking and reporting, education, and

expertise. Actions that have been successful in the outpatient setting include clinician audit and feedback with peer comparisons, commitment “nudge” posters, communications training, clinical decision support, patient education about viral and bacterial infections or adverse events associated with antibiotic use, and clinician education. Interventions that incorporate a combination of approaches tend to be most effective. In addition, pediatricians should seek understanding of parent expectations for antibiotics, which can influence clinician antibiotic prescribing.

The AAP, along with the Pediatric Infectious Diseases Society, has developed pediatric toolkits for implementing antibiotic stewardship in both inpatient and outpatient settings (<https://pids.org/pediatric-asp-toolkit/>).

Role of the Clinician

Clinicians can integrate key recommendations that focus on antibiotic prescribing for common infections in children. These include the following:

1. Confirm the diagnosis of urinary tract infection by documenting that the patient is symptomatic and has a properly obtained urinalysis and positive quantitative culture. When the infection is confirmed and susceptibility tests are completed, choose an appropriate agent with the narrowest spectrum of activity to target the isolated organism. If cultures are negative and alternative diagnoses are found, contact families to recommend discontinuing antibiotics.
2. Before treating a patient for bacterial pneumonia, ensure that there is not an alternate diagnosis. Respiratory syncytial virus infections in infants are rarely complicated by bacterial infection, but migratory atelectasis is common. For infants with bronchiolitis, antibiotics are not indicated unless a concomitant bacterial infection is present.¹
3. Standardize processes to ensure that appropriate cultures and other diagnostic tests are obtained before antimicrobial agents are administered.
4. Know how to access local antibiograms and be aware of antimicrobial resistance patterns.
5. Initiate antimicrobial therapy promptly for suspected or proven infection, and document indication, dose, timing, and anticipated duration.
6. Perform an “antibiotic timeout” in hospitalized patients to reassess response to therapy within 48 hours, considering new clinical and laboratory data. Adjust therapy to use the most appropriate agent with the narrowest spectrum and to discontinue antibiotic therapy when a treatable bacterial infection is excluded.
7. Collaborate with the local antimicrobial stewardship team and request formal infectious diseases consultation for complicated cases, such as those with immune deficiency, severe or prolonged illness, difficult to treat organisms, or uncertain diagnosis.

In addition, clear and effective communication is critical for antibiotic stewardship across settings. A study implementing an online intervention (Dialogue Around Respiratory Tract Illness Treatment) demonstrated improvement in antibiotic prescribing for respiratory tract infection when clinicians followed 4 consecutive communication steps: (1) review your findings for a viral infection with the family;

¹ Ralston SL, Lieberthal AS, Meissner HC, et al. Clinical practice guideline: the diagnosis, management, and prevention of bronchiolitis. *Pediatrics*. 2015;136(4):2015-2862

(2) provide a specific diagnosis that is nonbacterial in origin; (3) offer positive treatment recommendations like hydration and fever control; and (4) offer a contingency plan if the child does not get better. The CDC has also developed a communication training module for clinicians to improve outpatient antibiotic prescribing (www.train.org/cdctrain/course/1076989/). Additional information for health care professionals and parents on judicious use of antimicrobial agents and antimicrobial resistance is available on the CDC website (www.cdc.gov/antibiotic-use/community/materials-references/index.html and www.cdc.gov/drugresistance).

Principles of Appropriate Use of Antimicrobial Therapy for Upper Respiratory Tract Infections

More than three-quarters of outpatient antibiotic prescriptions for children are given for 5 conditions: otitis media, sinusitis, cough illness/bronchitis, pharyngitis, and nonspecific upper respiratory tract infection (the common cold). Antibiotics are often prescribed even though most of these illnesses are caused by viruses. Children treated with antibiotics for respiratory tract infections are at increased risk of becoming colonized with resistant respiratory tract flora, including *Streptococcus pneumoniae* and *Haemophilus influenzae*. These same children are more likely to experience failure of subsequent antimicrobial therapy and are likely to spread resistant bacteria to close contacts. In addition, antibiotics are the most common cause of emergency department visits for adverse drug events in children. The following principles can assist pediatricians in prescribing antibiotic agents appropriately and only when needed for these common pediatric conditions.

OTITIS MEDIA

- The decision to initiate antibiotic therapy versus observation for children diagnosed with acute otitis media (AOM) should incorporate information about illness severity, laterality of infection, age, and assurance of follow-up. **Immediate antibiotic treatment** is indicated for children <6 months of age, those with otorrhea or severe signs and symptoms (temperature $\geq 39^{\circ}\text{F}$ [102.2°F], ear pain for ≥ 48 hours, or moderate to severe ear pain), and children 6 through 23 months of age with bilateral AOM (regardless of severity). **Observation and pain management** for 48 to 72 hours with close follow-up can be offered (on the basis of shared decision making with the parent or caregiver) to children 6 through 23 months of age without severe symptoms and unilateral AOM and for children 24 months and older without severe symptoms (with unilateral or bilateral AOM).
- When antibiotics are used for AOM, a narrow-spectrum agent (eg, amoxicillin, 80–90 mg/kg per day in 2 divided doses) should be used for most children. For children younger than 24 months or those with severe symptoms at any age, a 10-day course is recommended. For children 2 through 5 years of age without severe symptoms, a 7-day course may be used. For children 6 years and older without severe symptoms, a 5- to 7-day course may be used. Microbiologic and clinical failure with high-dose amoxicillin has been associated with highly penicillin-resistant pneumococci (uncommon currently with widespread use of pneumococcal conjugate

vaccine) and with beta-lactamase-producing *Haemophilus* species and *Moraxella* species, which might be increasing as the proportion of cases of AOM caused by pneumococci decreases. Including beta-lactamase coverage by using amoxicillin-clavulanate when treating a child for AOM is indicated if the child has received amoxicillin in the last 30 days, has concurrent purulent conjunctivitis, or has a history of recurrent AOM unresponsive to amoxicillin.

- Children with underlying medical conditions, craniofacial abnormalities, chronic or recurrent otitis media, or perforation of the tympanic membrane represent a more complicated and diverse population. Initial therapy with a 10-day antibiotic course is likely to be more effective than shorter courses for many of these children.
- Persistent middle ear effusion (MEE) is common and can be detected by pneumatic otoscopy (with or without verification by tympanometry) after resolution of acute symptoms. Two weeks after successful antibiotic treatment of AOM, 60% to 70% of children have MEE, decreasing to 40% at 1 month and 10% to 25% at 3 months after successful antibiotic treatment. The presence of MEE without clinical symptoms is defined as otitis media with effusion (OME). OME must be differentiated clinically from AOM and requires infrequent additional monitoring and no antibiotic therapy.

ACUTE SINUSITIS

- Clinical practice guidelines from the AAP¹ and the Infectious Diseases Society of America² outline evidence-based criteria for the diagnosis and treatment of acute bacterial sinusitis. Existing clinical criteria are limited in their ability to differentiate bacterial from viral acute rhinosinusitis. A clinical diagnosis of acute bacterial sinusitis requires the presence of at least one of the following criteria: (1) persistent nasal discharge (of any quality) or daytime cough (which may be worse at night) without evidence of clinical improvement for ≥ 10 days; (2) a worsening course (worsening or new onset of nasal discharge, daytime cough, or fever after initial improvement); or (3) body temperature of $\geq 39^{\circ}\text{C}$ ($\geq 102.2^{\circ}\text{F}$) with either purulent nasal discharge and/or facial pain concurrently for at least 3 consecutive days in a child who appears ill. Findings on sinus imaging correlate poorly with disease and should not be used for diagnosing acute uncomplicated bacterial sinusitis or to distinguish acute bacterial sinusitis from viral upper respiratory infection. Computed tomography and/or magnetic resonance imaging of sinuses is indicated when complications (eg, orbital or central nervous system complications) are suspected.
- Antibiotic therapy is indicated for all children with severe onset or a worsening course. For children with nonsevere, persistent illness with ≥ 10 days of symptoms, either observation for an additional 3 days or antibiotic therapy is indicated.
- When antibiotic therapy is initiated, amoxicillin alone or with clavulanate is preferred. Amoxicillin may be used in standard dose (45 mg/kg/day in 2 divided doses);

¹ Wald ER, Applegate KE, Bordley C, et al; American Academy of Pediatrics. Clinical practice guideline for the diagnosis and management of acute bacterial sinusitis in children aged 1 to 18 years. *Pediatrics*. 2013;132(1):e262-e280

² Chow AW, Benninger MS, Brook I, et al; Infectious Disease Society of America. IDSA clinical practice guideline for acute bacterial rhinosinusitis in children and adults. *Clin Infect Dis*. 2012;54(8):e72-e112

in areas with high prevalence (>10%) of nonsusceptible *S pneumoniae*, a high dose (80–90 mg/kg/day in 2 divided doses) should be used. Amoxicillin-clavulanate (80–90 mg/kg/day of amoxicillin with 6.4 mg/kg/day of clavulanate [14:1 formulation] in 2 divided doses) may be indicated for children with moderate-to-severe illness, children younger than 2 years, children attending child care, or when antimicrobial resistance is likely (eg, recent treatment with amoxicillin). Five days of therapy is often sufficient.

COUGH ILLNESS/BRONCHITIS

- Nonspecific cough illness/bronchitis in children typically does not warrant antimicrobial treatment.
- Prolonged cough is most often caused by a viral pathogen, but may be caused by *Bordetella pertussis*, *Bordetella parapertussis*, *Mycoplasma pneumoniae* and other *Mycoplasma* species, or *Chlamydia pneumoniae*. When infection caused by one of these organisms is suspected clinically or is confirmed, appropriate antimicrobial therapy is indicated (see Pertussis, p 656, *Mycoplasma pneumoniae* and Other *Mycoplasma* Infections, p 616, and Chlamydial Infections, p 298).

PHARYNGITIS

(See Group A Streptococcal Infections, p 785.)

- Diagnosis of group A streptococcal pharyngitis should be made based on results of appropriate laboratory tests in conjunction with clinical and epidemiologic findings.
- Group A streptococcal testing should only be performed in patients with signs and symptoms of pharyngitis without evidence of a viral upper respiratory infection. Testing is not recommended for children younger than 3 years.
- Most cases of pharyngitis are caused by viruses. Antibiotics should not be prescribed to children with pharyngitis without positive group A streptococcal testing. Rarely, other bacteria may cause pharyngitis (eg, *Arcanobacterium haemolyticum*, *Corynebacterium diphtheriae*, *Francisella tularensis*, groups G and C hemolytic streptococci, *Neisseria gonorrhoeae*, *Fusobacterium* species), and treatment should be provided according to recommendations in disease-specific chapters in Section 3.
- Penicillin (intramuscular injection or 10 days orally) remains the treatment of choice for group A streptococcal pharyngitis. Amoxicillin suspension (once daily dosing for 10 days) may be more palatable to children than penicillin and is equally as effective.

THE COMMON COLD

- Antimicrobial agents should not be given for the common cold.
- Mucopurulent rhinitis (thick, opaque, or discolored nasal discharge that begins a few days into a viral upper respiratory tract infection) commonly accompanies the common cold and is not an indication for antibiotic treatment.
- Symptomatic therapies like ibuprofen, acetaminophen, humidified air, and honey in children older than 12 months can be recommended for symptomatic relief.

..... TABLES OF ANTIBACTERIAL DRUG DOSAGES

Recommended dosages for antibacterial agents commonly used for neonates (see Table 4.2, p 988) and for infants and children (see Table 4.3, p 993) are provided separately because of the pharmacokinetic and dosing differences between these 2 groups.

Table 4.2 is organized by variables such as gestational age (GA), postnatal age (PNA), and postmenstrual age (PMA) that best guide neonatal dosing for a given group of antimicrobial agents. Aminoglycosides and vancomycin are listed in separate tables to highlight their target serum concentration. For agents used to treat *Bacillus anthracis*, see Fluoroquinolones (p 973) and Anthrax (p 232).

Recommended dosages are not absolute and are intended only as a guide. When a dosage range is provided, the high dose generally is intended for severe infections. Clinical judgment about the disease, predicted drug concentration at the site of infection, alterations in renal or hepatic function, drug interactions, patient response, and laboratory test results may dictate modifications of these dosage recommendations in an individual patient. In some cases, monitoring of serum drug concentrations is recommended to avoid toxicity and to achieve concentrations associated with therapeutic efficacy. For vancomycin, this includes a recent consensus recommendation to utilize area under the curve (AUC)-guided therapeutic monitoring, preferably with Bayesian estimation, for all pediatric age groups based on developmental changes of vancomycin clearance documented from the newborn to the adolescent to reduce the risk of nephrotoxicity, as explained in the tables' footnotes. Trough-only monitoring is no longer recommended.

Product label information or a pediatric pharmacist should be consulted for guidance on the appropriate methods of preparation and administration, measures to be taken to avoid drug interactions, and other precautions. US Food and Drug Administration (FDA)-approved drug labels can be found online at the FDA website (<https://labels.fda.gov/>), Drugs@FDA (www.accessdata.fda.gov/scripts/cder/daf/), and DailyMed (<https://dailymed.nlm.nih.gov/dailymed/>).

For antimicrobial agents under investigation and not yet approved for use in children by the FDA, their indications under study and dosages can be found at <http://clinicaltrials.gov>.

Vancomycin^m

Begin with a 20-mg/kg loading dose followed by a maintenance dose, according to the table

GA ≤ 28 wk 6 d		GA ≥ 29 wk 0 d	
Creatinine (mg/dL)	Dosage	Creatinine (mg/dL)	Dosage
< 0.5	15 mg/kg every 12 h	< 0.7	15 mg/kg every 12 h
0.5–0.7	20 mg/kg every 24 h	0.7–0.9	20 mg/kg every 24 h
0.8–1	15 mg/kg every 24 h	1–1.2	15 mg/kg every 24 h
1.1–1.4	10 mg/kg every 24 h	1.3–1.6	10 mg/kg every 24 h
> 1.4	15 mg/kg every 48 h	> 1.6	15 mg/kg every 48 h

Table 4.2. Antibacterial Drugs for Neonates (≤ 28 Postnatal Days of Age),^a continued**Other glycopeptides**

Drug	Route	All Neonates
------	-------	--------------

Dalbavancin	IV	22.5 mg/kg, one time
-------------	----	----------------------

GA, gestational age; IM, intramuscular; IV, intravenous; PNA, postnatal age; PO, oral.

^aDosages are given as per dose and the per dose frequency.

^bHigher (double) doses than those listed may be required for meningitis, although safety and efficacy data for dosing of neonates with central nervous system (CNS) infection are lacking for these agents.

^cHigher or more frequent dosing required for systemic, non-CNS, intermediately susceptible *Enterobacterales* infections.

^dCefotaxime is available by importation from Canada. See www.fda.gov/media/152896/download for details.

^eGiven dose also appropriate for meningitis. Neonates should not receive IV ceftriaxone if they also are receiving IV calcium in any form, including parenteral nutrition. Use in hyperbilirubinemic neonates should be undertaken thoughtfully, especially for those who were born preterm. In vitro studies have shown that ceftriaxone can displace bilirubin from its binding to serum albumin.

^fMay give 30 mg/kg, every 12 h, if target pathogen minimum inhibitory concentration (MIC) is ≤ 4 mg/L, such as *E coli*.

^gAn association between orally administered erythromycin and azithromycin and infantile hypertrophic pyloric stenosis (IHPS) has been reported in infants younger than 6 weeks. Infants treated with either of these antimicrobials should be followed for signs and symptoms of IHPS. Because of antibiotic resistance, these agents are not recommended to treat congenital *Mycoplasma hominis* infections.

^h20 mg/kg, every 24 hours for 3 days, for *Ureaplasma* or *Chlamydia trachomatis* infection.

ⁱSee *Haemophilus influenzae* Infections, p 400, and Meningococcal Infections, p 585, for alternate dosing in special situations.

^kBegin with a 15-mg/kg loading dose.

^lDesired serum or plasma concentrations: 20–40 mg/L or 10 x MIC (peak), <7 mg/L (trough).

^lDesired serum or plasma concentrations: 6–12 mg/L or 10 x MIC (peak), <2 mg/L (trough).

^mThe maintenance dose should begin at the same number of hours after the loading dose as the maintenance interval. Creatinine concentrations normally fluctuate and are partly influenced by transplacental maternal creatinine in the first week of postnatal age. Cautious use of creatinine-based dosing strategy with frequent reassessment of renal function and vancomycin serum concentrations is recommended in neonates ≤ 7 days of age. The area-under-the-curve (AUC) to MIC has been identified as the most appropriate pharmacokinetic/pharmacodynamic (PK/PD) target vancomycin in adult patients with methicillin-resistant *Staphylococcus aureus* (MRSA) infections and is preferred over trough monitoring to prevent unnecessary overexposure to vancomycin. Although there are limitations in prospective outcomes data in pediatric patients with serious MRSA infections, the most recent consensus guideline from the American Society of Health-System Pharmacists, the Infectious Diseases Society of America, the Pediatric Infectious Diseases Society, and the Society of Infectious Diseases Pharmacists recommends AUC-guided therapeutic monitoring, preferably with Bayesian estimation, for all pediatric age groups receiving vancomycin.ⁿ This estimation accounts for developmental changes of vancomycin clearance from newborn to adolescent. Dosing in children should be designed to achieve an AUC of 400–600 mg-hour/L (assuming MIC of 1 mg/L) and/or trough levels <15 mg/L to minimize acute kidney injury risks. Bayesian estimation can be completed with 2 levels, with 1 level being recommended 1–2 hours after end of vancomycin infusion, and the second level being drawn 4–6 hours after end of infusion. Levels can be obtained as early as after the second dose. Software to assist with these calculations is available online and for purchase. It is recommended to avoid AUC >800 mg-hour/L and trough concentrations >15 mg/L. In situations in which AUC calculation is not feasible, a trough concentration ≥ 10 mg/L is very highly likely ($>90\%$) to achieve the AUC target in neonates and children when the MIC is 1 mg/L. Trough concentrations as low as 7 mg/L can still achieve an AUC ≥ 400 mg-hour/L in some preterm neonates because of their slower clearance. For centers where invasive MRSA infection is relatively common or where MRSA with MIC of 1 mg/L is common, an online dosing tool is available that may improve the likelihood of empirically achieving AUC ≥ 400 mg-hour/L, compared with doses given in Table 4.2 (<https://connect.insight-rx.com/neovanco>).

ⁿRybak MJ, Le J, Lodise TP, et al. Executive summary: Therapeutic monitoring of vancomycin for serious methicillin-resistant *Staphylococcus aureus* infections: a revised consensus guideline and review by the American Society of Health-System Pharmacists, the Infectious Diseases Society of America, the Pediatric Infectious Diseases Society, and the Society of Infectious Diseases Pharmacists. *J Pediatric Infect Dis Soc*. 2020;9(3):281–284

Table 4.3. Antibacterial Drugs for Pediatric Patients Beyond the Newborn Period

Drug Generic (Trade Name)	Generic Available	Route	Dosage per kg per Day Absolute Maximum Dosage Provided, If Known	Comments ^a
Aminoglycosides				Not ideal for CNS infections. See Table 4.2 footnotes for serum concentration targets.
Amikacin ^b	Y	IV, IM	15–22.5 mg, divided in 2–3 doses or once daily	Higher doses than those given are appropriate for cystic fibrosis.
Gentamicin ^b	Y	IV, IM	6–7.5 mg, divided in 3 doses, or 5–7.5 mg once daily	
Neomycin	Y	PO	100 mg, divided in 4 doses, max 12 g per day	For some enteric infections.
Tobramycin ^b	Y	IV, IM	6–7.5 mg, divided in 3–4 doses, or 5–7.5 mg once daily	Higher doses than those given are appropriate for cystic fibrosis.
		Inhaled	300 mg, inhaled every 12 h	
Aztreonam (Azactam)	Y	IV, IM	90–120 mg, divided in 3 or 4 doses, max 8 g per day	A monobactam. Can be used for CNS infections.
Carbapenems ^c				
Imipenem/cilastatin (Primaxin)	Y	IV	60–100 mg, divided in 4 doses, max 4 g per day	Caution when treating CNS infections because of increased risk of seizures. High end of dose range for <i>Pseudomonas aeruginosa</i> infections.

Table 4.3. Antibacterial Drugs for Pediatric Patients Beyond the Newborn Period, continued

Drug Generic (Trade Name)	Generic Available	Route	Dosage per kg per Day Absolute Maximum Dosage Provided, If Known	Comments ^a
Meropenem (Merrem)	Y	IV	60 mg, divided in 3 doses, max 3 g per day 120 mg, divided in 3 doses for meningitis, max 6 g per day	Extended infusion over 3 to 4 hours may be needed for susceptible infections in critically ill children.
Ertapenem (Invanz)	N	IV/IM	30 mg, divided in 2 doses, max 1 g per day ≥13 y and adults, 1 g, once daily	Poor activity against <i>Pseudomonas</i> and <i>Acinetobacter</i> . Should not be used for CNS infections.
Cephalosporins ^c				The generation of each agent is listed as a guide to antimicrobial spectrum.
Cefaclor (Ceclor)	Y	PO	20–40 mg, divided in 2 or 3 doses, max 1 g per day	Second generation.
Cefadroxil (Duricef)	Y	PO	30 mg, divided in 2 doses, max 2 g per day	First generation.
Cefazolin (Ancef)	Y	IV, IM	25–75 mg, divided in 3 doses, max 6 g per day Up to 150 mg, divided in 3–4 doses for bone/joint infections, max 12 g per day	First generation. Limited data on dosages above 100 mg/kg/day. Should not be used for CNS infections.
Cefdinir (Omnicef)	Y	PO	14 mg, divided in 1 or 2 doses, max 600 mg/day	Third generation. Inadequate activity against penicillin-resistant <i>Streptococcus pneumoniae</i> .
Cefepime (Maxipime)	Y	IV, IM	100 mg, divided in 2 doses, max 4 g per day 150 mg, divided in 3 doses for <i>Pseudomonas</i> infections or febrile neutropenia, max 6 g per day	Fourth generation. Extended infusion over 3 to 4 hours may be needed for susceptible infections in critically ill children. Can be used for CNS infections.

Table 4.3. Antibacterial Drugs for Pediatric Patients Beyond the Newborn Period, continued

Drug Generic (Trade Name)	Generic Available	Route	Dosage per kg per Day		Comments ^a
			Absolute Maximum Dosage Provided, If Known		
Cefixime (Suprax)	Y	PO	8 mg, divided in 1 or 2 doses, max 400 mg per day		Third generation. Inadequate activity against penicillin-resistant <i>Streptococcus pneumoniae</i> .
Cefotaxime (Claforan) ^d	Y	IV, IM	150–180 mg, divided in 3 doses, max 8 g per day 200–225 mg, divided in 4 doses for meningitis, max 12 g per day		Third generation. Up to 300 mg, divided in 4 or 6 doses. May be used for CNS infections.
Cefotetan (Cefotan)	Y	IV, IM	60–100 mg, divided in 2 doses, max 6 g per day		Second generation. A cephamycin, active against anaerobes. Should not be used for CNS infections.
Cefoxitin (Mefoxin)	Y	IV, IM	80–160 mg, divided in 3–4 doses, max 12 g per day		Second generation. A cephamycin, active against anaerobes. Should not be used for CNS infections.
Cefpodoxime (Vantin)	Y	PO	10 mg, divided in 2 doses, max 400 mg per day 800 mg (not per kg), divided in 2 doses for severe non-MRSA skin infections and ≥40 kg.		Third generation.
Cefprozil (Cefzil)	Y	PO	15–30 mg, divided in 2 doses, max 1 g per day		Second generation.

Table 4.3. Antibacterial Drugs for Pediatric Patients Beyond the Newborn Period, continued

Drug Generic (Trade Name)	Generic Available	Route	Dosage per kg per Day		Comments ^a
			Absolute Maximum Dosage Provided, If Known		
Ceftaroline (Teflaro)	N	IV	1 mo to <2 mo: 18 mg, divided in 3 doses		Fifth generation with anti-MRSA activity. No activity against <i>Pseudomonas</i> species. Adult dose: 400 mg/dose, every 8 h, or 600 mg/dose, every 12 h (max 1200 mg/ day).
			2 mo to <2 y: 24 mg, divided in 3 doses		Potentially useful for CNS infections, based on limited data.
			≥2 y: ≤33 kg: 36 mg, divided in 3 doses >33 kg: 1200 mg (not per kg), divided in 2–3 doses		
Ceftazidime (Fortaz)	Y	IV, IM	90–150 mg, divided in 3 doses 200–300 mg, divided in 3 doses for serious <i>Pseudomonas</i> infections		Third generation. Max 6 g per day (12 g per day for serious <i>Pseudomonas</i> infections). Can be used for CNS infections.
Ceftazidime/avibactam (Avycaz)	N	IV	<6 mo: 120 mg, divided in 3 doses 6 mo–18 y: 150 mg, divided in 3 doses, max 6 g per day		Dose based on ceftazidime component. Used for certain multidrug-resistant gram- negative bacterial infections. Can be used for CNS infections.
Ceftolozane/ tazobactam (Zerbaxa)	N	IV	90 mg, divided in 3 doses, max 4.5 g per day		Used for complicated intra-abdominal infections and complicated urinary tract infections

Table 4.3. Antibacterial Drugs for Pediatric Patients Beyond the Newborn Period, continued

Drug Generic (Trade Name)	Generic Available	Route	Dosage per kg per Day Absolute Maximum Dosage Provided, If Known	Comments ^a
Ceftriaxone (Rocephin)	Y	IV, IM	50–75 mg, once daily, max 1 g per day (for non-CNS, non-endocarditis infections) 100 mg, divided in 1 or 2 doses, max 4 g per day (for CNS or endocarditis infections) 50 mg/kg, IM, once daily for 1–3 days for AOM, max 1 g per day	Third generation.
Cefuroxime (Zinacef)	Y	IV, IM	100–150 mg, divided in 3 doses, max 6 g per day	Second-generation. Limited activity against penicillin-resistant <i>Streptococcus pneumoniae</i> . Other agents preferred for CNS infections.
Cefuroxime axetil (Ceftin)	Y	PO	20–30 mg, divided in 2 doses, max 1 g per day Up to 100 mg, divided in 3 doses for bone or joint infections, max 3 g per day	Second-generation. Limited activity against penicillin-resistant <i>Streptococcus pneumoniae</i> .
Cephalexin (Keflex)	Y	PO	25–50 mg divided in 2 doses 75–100 mg divided in 3–4 doses for bone or joint infections, max 4 g per day	First-generation.
Clindamycin (Cleocin)	Y	IM, IV	20–40 mg, divided in 3–4 doses, max 2.7 g per day	Often active against <i>Streptococcus pneumoniae</i> , <i>Streptococcus pyogenes</i> , and <i>Staphylococcus aureus</i> (including some MRSA) and many anaerobes of the respiratory tract. Penetrates into brain but not CSF.
	Y	PO	10–25 mg, divided in 3 doses 30–40 mg, divided in 3–4 doses for AOM or CA-MRSA, max 1.8 g per day	

Table 4.3. Antibacterial Drugs for Pediatric Patients Beyond the Newborn Period, continued

Drug Generic (Trade Name)	Generic Available	Route	Dosage per kg per Day Absolute Maximum Dosage Provided, If Known	Comments ^a
Daptomycin (Cubicin)	N	IV	For <i>Staphylococcus aureus</i> bacteremia: 1–6 y: 12 mg, once daily 7–11 y: 9 mg, once daily 12–17 y: 7 mg, once daily For skin and skin structure infections: 1–2 y: 10 mg, once daily 2–6 y: 9 mg, once daily 7–11 y: 7 mg, once daily 12–17 y: 5 mg, once daily	Neuromuscular toxicity in neonatal and juvenile canine model. FDA warns to avoid use in infants <12 mo. Not used for CNS infections.
Fluoroquinolones see also p 973, and Anthrax, p 232.				
Ciprofloxacin (Cipro)	Y	PO	30 mg, divided in 2 doses, max 1.0 g per day	Can be used to treat CNS infections.
		IV	20–30 mg, divided in 2 or 3 doses, max 1.2 g per day	
Levofloxacin (Levaquin)	Y	PO	<50 kg: 16 mg, divided in 2 doses, max 500 mg per day ≥50 kg: 500 mg per dose (not per kg), once daily	For empiric therapy or therapy of penicillin- resistant strains of anthrax, the benefits of fluoroquinolones for pediatric anthrax are far greater than potential toxicities.
		IV	<50 kg: 20 mg, divided in 2 doses, max 500 mg per day ≥50 kg: 500 mg per dose (not per kg), once daily	

Table 4.3. Antibacterial Drugs for Pediatric Patients Beyond the Newborn Period, continued

Drug Generic (Trade Name)	Generic Available	Route	Dosage per kg per Day Absolute Maximum Dosage Provided, If Known	Comments ^a
Macrolides				
Azithromycin (Zithromax, Zmax)	Y	PO	5–10 mg, once daily for the immediate-release products 60 mg as a single dose for the extended-release (ER) formulation <u>Respiratory tract infection dosages</u> (per kg, interval is once daily): AOM: 10 mg for 3 days; or 30 mg for 1 day; or 10 mg for 1 day then 5 mg for 4 days Pharyngitis: 12 mg for 1 day, then 6 mg for 4 days Sinusitis: 10 mg for 3 days CAP: 10 mg for 1 day, then 5 mg for 4 days	Per dose max 250 mg for 6 mg/kg, 500 mg for 10–12 mg/kg, 1.5 g for 30 mg/kg. Normal adult total course is 1.5–2 g. Total course max 2.5 g. Multiple additional indications. See relevant chapters in Section 3.
	Y	IV	10 mg, once daily, max 500 mg per day	See <i>Legionella</i> Infections, p 531. Can be used for some CNS infections.
	Clarithromycin (Biaxin)	Y	PO	15 mg, divided in 2 doses, max 1 g per day
Erythromycin (numerous)	Y	PO	40–50 mg, divided in 3–4 doses, max 4 g per day	
	N	IV	20 mg, divided in 4 doses, max 4 g per day	Administer over at least 60 minutes to potentially prevent cardiac arrhythmias. Not used for CNS infections.

Table 4.3. Antibacterial Drugs for Pediatric Patients Beyond the Newborn Period, continued

Drug Generic (Trade Name)	Generic Available	Route	Dosage per kg per Day Absolute Maximum Dosage Provided, If Known	Comments ^a
Fidaxomicin (Dificid)	N	PO	≥6 mo (per day, not per kg/day, divided twice a day): 4–<7 kg: 160 mg 7–<9 kg: 240 mg 9–<12.5 kg: 320 mg ≥12.5 kg: 400 mg	For treatment of <i>Clostridioides difficile</i> infection.
Metronidazole (Flagyl)	Y	PO	Range: 15–50 mg, divided in 3 doses, max 2.25 g per day 30 mg, divided in 3 doses for anaerobic bacterial infections including <i>Clostridioides difficile</i> (maximum 500 mg per dose) For bacterial vaginosis, see Table 4.4 (p 1007) and Table 4.5 (p 1014) For <i>Trichomonas vaginalis</i> , see Table 4.4 (p 1007) and Table 4.5 (p 1014) For Amebiasis, see Table 4.11 (p 1036)	Can be used for CNS infections.
	Y	IV	22.5–40 mg, divided in 3 or 4 doses, max 4 g per day	Can be used for CNS infections.
Nitrofurantoin (Furadantin, Macrochantin, Macrobid)	Y	PO	UTI prophylaxis: 1–2 mg, once daily Cystitis treatment: <12 y: 5–7 mg divided in 4 doses, max 200 mg per day ≥12 y: 200 mg total daily dosage (not per kg), divided in 2 doses	For treatment of cystitis; not appropriate for pyelonephritis. Macrobid form for twice daily dosing.

Table 4.3. Antibacterial Drugs for Pediatric Patients Beyond the Newborn Period, continued

Drug Generic (Trade Name)	Generic Available	Route	Dosage per kg per Day Absolute Maximum Dosage Provided, If Known	Comments ^a
Oxazolidinones				
Linezolid (Zyvox)	Y	PO, IV	≤11 y: 30 mg divided in 3 doses, max 1200 mg per day >11 y: 1200 mg total daily dose (not per kg) divided in 2 doses	Myelosuppression increases with duration of therapy over 10 days. Can be used for CNS infections (IV or PO).
Tedizolid (Sivextro)	N	PO, IV	≥ 12 y: 200 mg (not per kg) once daily	Not known if effective for CNS infections.
Penicillins ^c				
Amoxicillin (Amoxil)	Y	PO	Standard dose: 40–45 mg, divided in 3 doses High dose: 80–90 mg, divided in 2 doses, max 4 g per day Streptococcal pharyngitis: 50 mg once daily (see Group A Streptococcal Infections, p 785). <i>Bacillus anthracis</i> exposure: 75 mg, divided in 3 doses, max 3 g per day, for prophylaxis and empiric treatment (see Anthrax, p 232). See fluoroquinolones row above for empiric or therapy of penicillin-resistant strains of anthrax.	Higher doses may be needed for some penicillin-resistant <i>Streptococcus pneumoniae</i> infections (see p 810).

Table 4.3. Antibacterial Drugs for Pediatric Patients Beyond the Newborn Period, continued

Drug Generic (Trade Name)	Generic Available	Route	Dosage per kg per Day Absolute Maximum Dosage Provided, If Known	Comments ^a
Amoxicillin-clavulanic acid (Augmentin)	Y	PO	14:1 Formulation: 90 mg, divided in 2 doses 7:1 Formulation: 25–45 mg, divided in 2 doses, max 1750 mg per day 4:1 Formulation: 30 mg, divided in 2 doses for <3 months of age	Dosed on amoxicillin component. 14:1 Formulation – Augmentin ES-600 7:1 Formulation – Augmentin 400 4:1 Formulation – Augmentin 250
Ampicillin	Y	IV, IM	50–200 mg, divided in 4 doses, max 8 g per day 300–400 mg, divided in 6 doses for meningitis, endocarditis, max 12 g per day	Can be used for CNS infections.
	Y	PO	50–100 mg, divided in 4 doses, max 2 g per day	
Ampicillin-sulbactam (Unasyn)	Y	IV	100–200 mg, divided in 4 doses, max 8 g per day 400 mg, divided in 4 doses for meningitis	Dosed on ampicillin component. Can be used for CNS infections.
Dicloxacillin (Dynapen)	Y	PO	12–25 mg, divided in 4 doses, max 1 g per day 100 mg, divided in 4 doses for bone or joint infections, max 2 g per day	Oral suspension not commercially available.
Nafcillin (Nallpen)	Y	IV, IM	100–200 mg, divided in 4–6 doses, max 12 g per day	Can be used for CNS infection.
Oxacillin (Bactocill)	Y	IV, IM	100–200 mg, divided in 4–6 doses, max 12 g per day	Can be used for CNS infection.
Penicillin G, crystalline potassium or sodium	Y	IV, IM	100 000–300 000 U, divided in 4–6 doses, 300 000–400 000 U, divided in 6 doses for CNS infection	Max 24 million U per day.

Table 4.3. Antibacterial Drugs for Pediatric Patients Beyond the Newborn Period, continued

Drug Generic (Trade Name)	Generic Available	Route	Dosage per kg per Day Absolute Maximum Dosage Provided, If Known	Comments ^a
Penicillin G procaine	Y	IM	50 000 U, divided in 1–2 doses, max 1.2 million U	Not safe for IV administration. Should not be used for CNS infection. As of July 2023, no longer manufactured in the United States.
Penicillin G benzathine (Bicillin LA)	N	IM	<27 kg (60 lb): 600 000 U (not per kg), one time >27 kg (60 lb): 1.2 million U (not per kg), one time See Table 4.2 for congenital syphilis dosing	Not safe for IV administration. Main use is treatment of group A streptococcal infections (see p 785). Should not be used for acute CNS infection (see Syphilis, p 825).
Penicillin G benzathine/procaine (Bicillin CR)	N	IM	<14 kg (30 lb): 600 000 U (not per kg), one time 14–27 kg (30–60 lb): 1.2 million U (not per kg), one time ≥27 kg (60 lb): 2.4 million U (not per kg), one time	Not safe for IV administration. Main use is treatment of group A streptococcal infections (see p 785).
Penicillin V	Y	PO	25–50 mg, divided in 4 doses, max 2 g per day	50–75 mg, divided in 4 doses for group A streptococcal pneumonia.
Piperacillin-tazobactam (Zosyn)	Y	IV	240–300 mg, divided in 3–4 doses, max 16 g per day	Dosed on piperacillin component. Extended infusion may be needed for susceptible-dose dependent infections. 400–600 mg, divided in 6 doses, max 24 g per day, may be appropriate in some patients with cystic fibrosis. Other agents preferred for CNS infections.

Table 4.3. Antibacterial Drugs for Pediatric Patients Beyond the Newborn Period, continued

Drug Generic (Trade Name)	Generic Available	Route	Dosage per kg per Day Absolute Maximum Dosage Provided, If Known	Comments ^a
Polymyxins				Not ideal for CNS infections; local (intraventricular) administration required to achieve therapeutic concentrations.
Colistimethate (Colymycin M)	Y	IV, IM	2.5–5 mg base, divided in 3 doses	Up to 7 mg base/kg/day may be required. 1 mg base = 2.7 mg colistimethate.
Polymyxin B	Y	IV	2.5 mg, divided in 2 doses	>3 mg/kg/day not well studied. 1 mg = 10 000 U.
Rifamycins				
Rifampin (Rifadin)	Y	IV, PO	15–20 mg, divided in 1–2 doses, max 600 mg per day See p 902–905 for <i>Mycobacterium tuberculosis</i> dosing	Should not be used routinely as monotherapy because of rapid emergence of resistance. Many experts recommend using a daily rifampin dose of at least 20 mg/kg/day for infants and toddlers. Can be used for CNS infections (IV or PO).
Rifaximin (Xifaxan)	N	PO	20–30 mg, divided in 3 doses, max 600 mg per day	For travelers' diarrhea
Sulfonamides				
Sulfadiazine	Y	PO	120–150 mg, divided in 4 doses, max 6 g per day Rheumatic fever secondary prevention: 500 mg (not per kg), once daily in children <30 kg; 1 g, once daily in bigger children and adults	G6PD deficiency should be evaluated when using this drug.

Table 4.3. Antibacterial Drugs for Pediatric Patients Beyond the Newborn Period, continued

Drug Generic (Trade Name)	Generic Available	Route	Dosage per kg per Day Absolute Maximum Dosage Provided, If Known	Comments ^a
Trimethoprim- Sulfamethoxazole (TMP-SMX) (Bactrim, Septra)	Y	PO, IV	8–12 mg, divided in 2 doses, max 640 mg per day 2 mg, once daily for UTI prophylaxis 15–20 mg, divided in 3–4 doses for <i>Pneumocystis jirovecii</i> treatment, no max; 5 mg, divided in 2 doses 3 times/wk for prophylaxis	Dosed on TMP component. See also <i>Pneumocystis jirovecii</i> Infections (p 676). Can be used for CNS infections.
Tetracyclines see also p 975				
Doxycycline (Vibramycin)	Y	PO, IV	2.2–4.4 mg, divided in 2 doses, max 200 mg per day	Can be used for CNS infections (IV or PO). Higher doses reported (max 400 mg per day) in adults with Lyme neuroborreliosis.
Minocycline (Minocin)	Y	PO, IV	4 mg, divided in 2 doses, max 200 mg per day	Other agents preferred for CNS infections.
Tetracycline	Y	PO	25–50 mg, divided in 4 doses, max 2 g per day	Tetracycline limited to ≥8 y of age.
Vancomycin and other glycopeptides				
Vancomycin (Vancocin)	Y	IV	45–60 mg, divided in 3–4 doses 60–70 mg, divided in 4 doses, may be necessary in some patients to achieve target serum concentrations for invasive MRSA infections	Measured serum concentrations should guide ongoing therapy. ^e Can be used for CNS infections.
		PO	40 mg, divided in 4 doses, up to 500 mg per day	For treatment of <i>Clostridioides difficile</i> infection (see Table 3.3, p 317). Up to 2 g per day divided in 4 doses for severe, complicated cases.

Table 4.3. Antibacterial Drugs for Pediatric Patients Beyond the Newborn Period, continued

Drug Generic (Trade Name)	Generic Available	Route	Dosage per kg per Day		Comments ^a
			Absolute Maximum Dosage Provided, If Known		
Dalbavancin (Dalvance)	N	IV	<6 y: 22.5 mg, one time ≥6 y: 18 mg, one time, max 1500 mg (not per kg)		Should not be used for CNS infections.

AOM indicates acute otitis media; CAP, community-acquired pneumonia; CA-MRSA, community associated methicillin-resistant *Staphylococcus aureus*; CDI, *Clostridioides difficile* infection; CNS, central nervous system; eGFR, estimated glomerular filtration rate; ER, extended-release; FDA, US Food and Drug Administration; G6PD, glucose-6-phosphate dehydrogenase; IBD, inflammatory bowel disease; IM, intramuscular; IV, intravenous; MRSA, methicillin-resistant *Staphylococcus aureus*; PO, oral; SBBO, small bowel bacterial overgrowth; SSTI, skin and soft tissue infection; UTI, urinary tract infection.

^aComments regarding CNS infections are based on FDA-approved indication or evidence from clinical studies in children or adults and apply to administration by the intravenous route unless otherwise specified.

^bExtended interval (“once daily”) dosing may provide equal efficacy with reduced toxicity.

^cChildren with a history of an IgE-mediated, immediate hypersensitivity reaction to penicillins (urticaria, angioedema, bronchospasm, anaphylaxis) who require treatment with an alternate beta-lactam should be considered for skin testing (if available) to confirm the allergy, and/or undergo supervised graded clinical challenge or desensitization with the alternate beta-lactam agent under the supervision of an expert in drug allergy and desensitization. See Beta-lactam and Monobactam Allergies (p 976) and Fig 4.1 (p 979).

^dCefotaxime is available by importation from Canada. See www.fda.gov/media/152896/download for details.

^eThe area-under-the-curve to minimum inhibitory concentration (AUC/MIC) has been identified as the most appropriate pharmacokinetic/pharmacodynamic (PK/PD) target vancomycin in adult patients with methicillin-resistant *Staphylococcus aureus* (MRSA). Although there are limitations in prospective outcomes data in pediatric patients with serious MRSA infections, the most recent consensus guideline from the American Society of Health-System Pharmacists, the Infectious Diseases Society of America, the Pediatric Infectious Diseases Society, and the Society of Infectious Diseases Pharmacists recommends AUC-guided therapeutic monitoring, preferably with Bayesian estimation, for all pediatric age groups receiving vancomycin.^f This estimation accounts for developmental changes of vancomycin clearance from newborn to adolescent, and is preferred over trough monitoring to prevent unnecessary overexposure to vancomycin. Dosing in children should be designed to achieve an AUC of 400–600 mg-hour/L (assuming MIC of 1 mg/L) and/or trough levels <15 mg/L to minimize acute kidney injury risks. Bayesian estimation can be completed with 2 levels, with 1 level being recommended 1–2 hours after end of vancomycin infusion, and the second level being drawn 4–6 hours after end of infusion. Levels can be obtained as early as after the second dose. Software to assist with these calculations is available online and for purchase. It is recommended to avoid AUC >800 mg-hour/L and troughs >15 mg/L. Most children younger than 12 years will require higher doses to achieve optimal AUC/MIC compared with older children.

^fRybak MJ, Le J, Lodise TP, et al. Executive summary: Therapeutic monitoring of vancomycin for serious methicillin-resistant *Staphylococcus aureus* infections: a revised consensus guideline and review by the American Society of Health-System Pharmacists, the Infectious Diseases Society of America, the Pediatric Infectious Diseases Society, and the Society of Infectious Diseases Pharmacists. *J Pediatric Infect Dis Soc.* 2020;9(3):281-284

SEXUALLY TRANSMITTED INFECTIONS

Table 4.4. Guidelines for Treatment of Sexually Transmitted Infections in Children ≥45 kg, Adolescents, and Young Adults According to Syndrome

For further information concerning other acceptable regimens and diseases not included, see recommendations in disease-specific chapters in Section 3. In addition, recommendations on treatment of sexually transmitted infections have been issued by the Centers for Disease Control and Prevention at www.cdc.gov/std/treatment.^a

		Treatment of Children Weighing ≥45 kg, Adolescents, and Young Adults ^a
Organisms/ Diagnoses		
Urethritis and Cervicitis: Inflammation of urethra and/or cervix with erythema and/or mucoid, mucopurulent, or purulent discharge	<i>Neisseria gonorrhoeae</i>	45–150 kg: Ceftriaxone, 500 mg, IM, in a single dose ^b >150 kg: Ceftriaxone, 1 g, IM, in a single dose ^b If chlamydial infection has not been excluded, also treat for <i>Chlamydia trachomatis</i> (see next row)
	<i>Chlamydia trachomatis</i>	Recommended: Doxycycline, 100 mg, orally, 2 times daily for 7 days Alternative: Azithromycin, 1 g, orally, in a single dose OR Levofloxacin, 500 mg, orally, once daily for 7 days
	Nongonoccal urethritis ^c or cervicitis	Recommended: Doxycycline, 100 mg, orally, 2 times daily day for 7 days Alternative: Azithromycin, 1 g, orally, in a single dose OR Azithromycin, 500 mg, orally, as a single dose, followed by 250 mg, orally once daily for 4 additional days

Table 4.4. Guidelines for Treatment of Sexually Transmitted Infections in Children ≥45 kg, Adolescents, and Young Adults According to Syndrome, continued

	Organisms/ Diagnoses	Treatment of Children Weighing ≥45 kg, Adolescents, and Young Adults ^a
Persistent and Recurrent Nongonococcal Urethritis: Persistent symptoms after treatment with objective signs of urethral inflammation	The most common cause of persistent or recurrent NGU is <i>Mycoplasma genitalium</i> , especially following doxycycline therapy	<i>M genitalium</i> treatment If macrolide sensitive: Doxycycline, 100 mg, orally, 2 times daily for 7 days, followed by azithromycin, 1 g, orally, initial dose, followed by 500 mg, orally, once daily for 3 additional days (2.5 g total) If macrolide resistant or no resistance testing available: Doxycycline, 100 mg, orally, 2 times daily for 7 days, followed by moxifloxacin, 400 mg, orally, once daily for 7 days
	<i>Trichomonas vaginalis</i> (in males who only have sex with females ^d)	Recommended: Metronidazole, 2 g, orally, in a single dose ^e Alternative: Tinidazole, 2 g, orally, in a single dose ^e
Vulvovaginitis	<i>T vaginalis</i>	Recommended: Metronidazole, 500 mg, orally, 2 times daily for 7 days Alternative: Tinidazole, 2 g, orally, in a single dose ^f
	Bacterial vaginosis	Recommended: Metronidazole, 500 mg, orally, 2 times daily for 7 days OR Metronidazole gel, 0.75%, 1 full applicator (5 g), intravaginally, once daily for 5 days OR Clindamycin cream 2%, 1 full applicator (5 g), intravaginally at bedtime, for 7 days ^g Alternative: Clindamycin, 300 mg, orally, 2 times daily for 7 days ^g OR Clindamycin ovules, 100 mg, intravaginally, once at bedtime for 3 days ^g OR Secnidazole, 2-g oral granule in a single dose ^h

Table 4.4. Guidelines for Treatment of Sexually Transmitted Infections in Children ≥45 kg, Adolescents, and Young Adults According to Syndrome, continued

Organisms/ Diagnoses		Treatment of Children Weighing ≥45 kg, Adolescents, and Young Adults ^a
Pelvic inflammatory disease (PID) ⁱ	Bacterial vaginosis	OR Tinidazole, 2 g, orally, once daily for 2 days ^f OR Tinidazole, 1 g, orally, once daily for 5 days ^f
	<i>Candida albicans</i> (and occasionally other <i>Candida</i> species or yeasts)	See Table 4.6, Recommended Regimens for Vulvovaginal Candidiasis (p 1016)
		Recommended Parenteral Regimens:
		Ceftriaxone, 1 g, IV, every 24 h PLUS Doxycycline, 100 mg, orally or IV, every 12 h PLUS Metronidazole, 500 mg, orally or IV, every 12 h
		OR
		Cefotetan, 2 g, IV, every 12 h OR Cefoxitin, 2 g, IV, every 6 h PLUS Doxycycline, 100 mg, orally or IV, every 12 h
		Alternative Parenteral Regimens:
		Ampicillin-sulbactam, 3 g, IV, every 6 h PLUS Doxycycline, 100 mg, orally or IV, every 12 h
		OR
		Clindamycin, 900 mg, IV, every 8 h PLUS Gentamicin loading dose, IV or IM (2 mg/kg body weight), followed by a maintenance dose (1.5 mg/kg body weight) every 8 h; single daily dosing (3–5 mg/kg body weight) can be substituted

Table 4.4. Guidelines for Treatment of Sexually Transmitted Infections in Children ≥45 kg, Adolescents, and Young Adults According to Syndrome, continued

Organisms/ Diagnoses		Treatment of Children Weighing ≥45 kg, Adolescents, and Young Adults ^a
		Recommended Intramuscular/ Oral Regimens^{j,k}: One of the following: Ceftriaxone, 500 mg, IM, once OR Cefoxitin, 2 g, IM, and Probenecid, 1 g, orally, in a single dose concurrently OR Other parenteral third-generation Cephalosporin (eg, Cefizoxime, Cefotaxime) PLUS Doxycycline, 100 mg, orally, 2 times daily for 14 days PLUS Metronidazole, 500 mg, orally, 2 times daily for 14 days Alternative Intramuscular/ Oral Regimens: Levofloxacin, 500 mg, orally, once daily for 14 days OR Moxifloxacin, 400 mg, orally, once daily for 14 days PLUS Metronidazole, 500 mg, orally, 2 times daily for 14 days ^l OR Azithromycin, 500 mg, IV, daily for 1–2 doses, followed by 250 mg, orally, daily PLUS Metronidazole, 500 mg, 3 times daily for 12–14 days ^l Benzathine penicillin G, 2.4 million U, IM, in a single dose
Genital ulcer disease	<i>Treponema pallidum</i> (primary or secondary syphilis)	

Table 4.4. Guidelines for Treatment of Sexually Transmitted Infections in Children ≥ 45 kg, Adolescents, and Young Adults According to Syndrome, continued

Organisms/ Diagnoses	Treatment of Children Weighing ≥ 45 kg, Adolescents, and Young Adults ^a
Genital herpes simplex virus (HSV)—1 st clinical episode ^{mm}	Acyclovir, 400 mg, orally, 3 times daily for 7–10 days OR Valacyclovir, 1 g, orally, twice daily for 7–10 days OR Famciclovir, 250 mg, orally, 3 times daily for 7–10 days
Genital HSV—episodic treatment of recurrences	Acyclovir, 800 mg, orally, 2 times daily for 5 days OR Acyclovir, 800 mg, orally, 3 times daily for 2 days OR Famciclovir, 1 g, orally, 2 times daily for 1 day OR Famciclovir, 500 mg, orally, once, followed by 250 mg, orally, 2 times daily for 2 days OR Famciclovir, 125 mg, orally, 2 times daily for 5 days OR Valacyclovir, 500 mg, orally 2 times daily for 3 days OR Valacyclovir, 1 g, orally, once daily for 5 days
Genital HSV—suppressive therapy	Acyclovir, 400 mg, orally, 2 times daily OR Valacyclovir, 500 mg, orally, once daily ⁿ OR Valacyclovir, 1 g, orally, once daily OR Famciclovir, 250 mg, orally, 2 times daily
<i>Haemophilus ducreyi</i> (chancroid)	Azithromycin, 1 g, orally, in a single dose OR Ceftriaxone, 250 mg, IM, in a single dose OR Ciprofloxacin, 500 mg, orally, 2 times daily for 3 days ^o OR Erythromycin base, 500 mg, orally, 3 times daily for 7 days

Table 4.4. Guidelines for Treatment of Sexually Transmitted Infections in Children ≥45 kg, Adolescents, and Young Adults According to Syndrome, continued

	Organisms/ Diagnoses	Treatment of Children Weighing ≥45 kg, Adolescents, and Young Adults ^a
	<i>Klebsiella granulomatis</i> (granuloma inguinale [Donovanosis])	Recommended: Azithromycin, 1 g, orally, once/wk, or 500 mg, orally, daily, for at least 3 weeks ^P Alternatives Doxycycline, 100 mg, orally, 2 times daily for at least 3 weeks ^P OR Erythromycin base, 500 mg, orally, 4 times daily for at least 3 weeks ^P OR Trimethoprim-sulfamethoxazole, 1 double- strength (160 mg/800 mg) tablet, orally, 2 times daily for >3 weeks ^P
	<i>C trachomatis</i> serovars L1, L2, or L3 (Lymphogranuloma venereum [LGV])	Recommended: Doxycycline, 100 mg, orally, 2 times daily for 21 days Alternative: Azithromycin, 1 g, orally, once weekly for 3 weeks ^Q OR Erythromycin base, 500 mg, orally 4 times daily for 21 days
	Epididymitis	<i>C trachomatis</i> , <i>N</i> <i>gonorrhoeae</i> Ceftriaxone, 500 mg, IM, in a single dose If >150 kg: Ceftriaxone, 1 g, IM in a single dose PLUS Doxycycline, 100 mg, orally, 2 times daily for 10 days
	Enteric organisms (eg, <i>Escherichia coli</i>), <i>C trachomatis</i> , <i>N</i> <i>gonorrhoeae</i> among males who practice insertive anal sex	Ceftriaxone, 500 mg, IM, in a single dose If >150 kg: Ceftriaxone, 1 g, IM in a single dose PLUS Levofloxacin, 500 mg, orally, once daily for 10 days
	Proctitis	<i>C trachomatis</i> , <i>N</i> <i>gonorrhoeae</i> , HSV Ceftriaxone, 500 mg, IM, in a single dose If >150 kg: Ceftriaxone, 1 g, IM in a single dose

Table 4.4. Guidelines for Treatment of Sexually Transmitted Infections in Children ≥ 45 kg, Adolescents, and Young Adults According to Syndrome, continued

	Organisms/ Diagnoses	Treatment of Children Weighing ≥ 45 kg, Adolescents, and Young Adults ^a
External anogenital warts (ie, penis, groin, scrotum, vulva, perineum, external anus, and perianus)	Human papillomavirus	PLUS Doxycycline, 100 mg, orally, 2 times daily for 7 days; extend to 21 days for presence of bloody discharge, perianal or mucosal ulcers, or tenesmus and a positive rectal <i>C trachomatis</i> test PLUS in the presence of rectal ulcers, one of the following: Valacyclovir, 1 g, orally, 2 times daily OR Acyclovir, 400 mg, orally, 3 times daily OR Famciclovir, 250 mg, orally, 3 times daily for 7–10 days <i>Patient-applied:</i> Imiquimod 3.75% or 5% cream^{a,f} OR Podofilox 0.5% solution or gel^o OR Sinecatechins 15% ointment^o <i>Provider-administered:</i> Cryotherapy with liquid nitrogen or cryoprobe OR Surgical removal either by tangential scissor excision, tangential shave excision, curettage, laser, or electrosurgery OR Trichloroacetic acid or bichloroacetic acid 80%–90% solution

IM indicates intramuscularly; STI, sexually transmitted infection.

^aFor additional information and recommendations, see Centers for Disease Control and Prevention. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(RR-4):1-187. Available at: www.cdc.gov/std/treatment-guidelines/toc.htm

^bIf ceftriaxone is not available or feasible, may substitute cefixime, 800 mg, orally, in a single dose.

^cNongonococcal urethritis (NGU) is diagnosed when microscopy indicates inflammation without evidence of diplococci by Gram, methylene blue, or gentian violet staining on microscopy. If microscopy is unavailable, urine testing for leukocyte esterase can be performed on first-void urine, and microscopic examination of sediment from a spun first-void urine demonstrating ≥ 10 white blood cells/high-powered field has a high negative predictive value.

^dThe terms male and female refer to sex assigned at birth.

^eIn areas where *T vaginalis* is prevalent, males who have sex with females and have persistent or recurrent urethritis should be presumptively treated for *T vaginalis*.

^fBreastfeeding should be deferred for 72 hours after lactating person has received a 2-g dose of tinidazole.

Table 4.4. Guidelines for Treatment of Sexually Transmitted Infections in Children ≥45 kg, Adolescents, and Young Adults According to Syndrome, continued

- ^gIntravaginal clindamycin might weaken latex or rubber products (eg, condoms and diaphragms), and their use within 72 hours after intravaginal clindamycin treatment is not recommended.
- ^hOral granules should be sprinkled onto unsweetened applesauce, yogurt, or pudding before ingestion. A glass of water can be taken after administration to aid in swallowing.
- ⁱHospitalization and parenteral treatment is recommended if patient has severe illness such as tubo-ovarian abscess, is pregnant, or is unable to tolerate or follow ambulatory regimens.
- ^jPatients with inadequate response to outpatient therapy after 72 hours should be reevaluated for possible misdiagnosis and may require parenteral therapy.
- ^kThe recommended third-generation cephalosporins are limited in the coverage of anaerobes. Therefore, the addition of metronidazole to treatment regimens with third-generation cephalosporins should be considered.
- ^lCan consider if the patient has cephalosporin allergy, gonorrhea community prevalence and individual risk are low, and follow-up is likely.
- ^mTreatment can be extended if healing is incomplete after 10 days of therapy.
- ⁿValacyclovir, 500 mg, once a day, might be less effective than other valacyclovir or acyclovir dosing regimens for persons with frequent recurrences (ie, ≥10 episodes/year).
- ^oAvoid in pregnancy or while breastfeeding.
- ^pTreat for at least 3 weeks and until all lesions have completely healed.
- ^qBecause this regimen has not been validated, a test of cure with a *C trachomatis* nucleic acid amplification test 4 weeks after completion of treatment can be considered.
- ^rWash treatment area with soap and water 6–10 hours after application.

Adapted from Centers for Disease Control and Prevention. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(RR-4):1-187. Available at: www.cdc.gov/std/treatment-guidelines/toc.htm

Table 4.5. Guidelines for Treatment of Sexually Transmitted Infections in Infants and Children <45 kg According to Syndrome

Preferred regimens are listed. For further information concerning other acceptable regimens and diseases not included, see recommendations in disease-specific chapters in Section 3. In addition, recommendations on treatment of sexually transmitted infections have been issued by the Centers for Disease Control and Prevention in 2021^a (www.cdc.gov/std/treatment-guidelines/toc.htm).

Syndrome	Organisms/ Diagnoses	Treatment of Infants and Children <45 kg ^{a,b}
Urethritis: Inflammation of urethra with erythema and/or mucoid, mucopurulent, or purulent discharge	<i>Neisseria gonorrhoeae</i> , <i>Chlamydia trachomatis</i> Other causes include <i>Mycoplasma genitalium</i> , possibly <i>Ureaplasma urealyticum</i> , and sometimes <i>Trichomonas vaginalis</i> and herpes simplex virus (HSV)	Ceftriaxone, 25–50 mg/kg, IV or IM, in a single dose, not to exceed 250 mg, IM ^c PLUS Erythromycin base or ethylsuccinate, 50 mg/kg per day, orally, in 4 divided doses for 14 days
Note: Cervicitis occurs rarely in prepubertal children		

Table 4.5. Guidelines for Treatment of Sexually Transmitted Infections in Infants and Children <45 kg According to Syndrome, continued

Syndrome	Organisms/ Diagnoses	Treatment of Infants and Children <45 kg ^{a,b}
Prepubertal vaginitis (STI related):	<i>N gonorrhoeae</i>	Ceftriaxone, 25–50 mg/kg, IV or IM, in a single dose, not to exceed 250 mg, IM ^c
	<i>C trachomatis</i>	Erythromycin base or ethylsuccinate, 50 mg/kg per day, orally, in 4 divided doses for 14 days
	<i>T vaginalis</i>	Metronidazole, 45 mg/kg per day, orally, in 3 divided doses (max 2 g/day) for 7 days
	Bacterial vaginosis	Metronidazole, 15–25 mg/kg per day, orally, in 3 divided doses (max 2 g/day) for 7 days
Genital ulcer disease	<i>Treponema pallidum</i> (primary syphilis) ^d	Benzathine penicillin G, 50 000 U/kg, IM, up to the adult dose of 2.4 million U in a single dose
	HSV—1 st clinical episode	Acyclovir, 80 mg/kg per day, orally, in 4 divided doses (max 3.2 g/day) for 7–10 days OR Valacyclovir, 40 mg/kg per day (max 2 g/day), orally, in 2 divided doses for 7–10 days
	<i>Haemophilus ducreyi</i> (chancroid)	Ceftriaxone, 50 mg/kg, IM, in a single dose (max 250 mg) OR Azithromycin, 20 mg/kg, orally, in a single dose (max 1 g)
Anogenital warts	Human papillomavirus	Same as for adolescents. See Table 4.4.

IM indicates intramuscularly; STI, sexually transmitted infection.

^aFor additional information and recommendations, see Centers for Disease Control and Prevention. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(RR-4):1-187. Available at: www.cdc.gov/std/treatment-guidelines/toc.htm.

^bInfants and children aged ≥1 month with a sexually transmitted infection should be evaluated for sexual abuse (eg, through consultation with child-protection services). See Table 2.5, p 183.

^cProviders treating patients with a severe cephalosporin allergy should consult an infectious disease specialist (see also Beta-lactam and Monobactam Allergies, p 976).

^dInfants and children >1 mo of age who receive a diagnosis of syphilis should have medical records from their birthing parent and delivery reviewed to assess whether they have congenital or acquired syphilis. Infants and children ≥1 mo of age with primary syphilis should be managed by a pediatric infectious disease specialist.

Table 4.6. Recommended Treatment Regimens for Vulvovaginal Candidiasis^a**Over-the-Counter Intravaginal Agents^b**

Clotrimazole 1% cream, 5 g, intravaginally, for 7–14 days

OR

Clotrimazole 2% cream, 5 g, intravaginally, for 3 days

OR

Miconazole 2% cream, 5 g, intravaginally, for 7 days

OR

Miconazole 4% cream, 5 g, intravaginally, for 3 days

OR

Miconazole, 100-mg vaginal suppository, 1 suppository for 7 days

OR

Miconazole, 200-mg vaginal suppository, 1 suppository for 3 days

OR

Miconazole, 1200-mg vaginal suppository, 1 suppository for 1 day

OR

Tioconazole, 6.5% ointment, 5 g, intravaginally, in a single application

Prescription Intravaginal Agents^b

Butoconazole 2% cream (single-dose bioadhesive product), 5 g, intravaginally, in a single application

OR

Terconazole 0.4% cream, 5 g, intravaginally, daily for 7 days

OR

Terconazole 0.8% cream, 5 g, intravaginally, for 3 days

OR

Terconazole, 80-mg vaginal suppository, 1 suppository for 3 days

Prescription Oral Agent

Fluconazole, 150-mg oral tablet, 1 tablet in single dose

^aAdapted from Centers for Disease Control and Prevention. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(RR-4):1-187. Available at: www.cdc.gov/std/treatment-guidelines/candidiasis.htm.

^bThese creams and suppositories are oil-based and might weaken latex condoms and diaphragms.

ANTIFUNGAL DRUGS FOR SYSTEMIC FUNGAL INFECTIONS

Table 4.7 (p 1021) provides data on the relative in vitro susceptibilities of specific fungal species with amphotericin B, azoles, echinocandins, and flucytosine.

Polyenes

Amphotericin B is a fungicidal agent that is effective against a broad array of fungal species. Amphotericin B, especially the “conventional” deoxycholate formulation, is associated with multiple adverse reactions, particularly acute and chronic renal toxicity, so its use is limited to certain patients, primarily neonates. Lipid-associated formulations of amphotericin B, especially liposomal amphotericin B, limit renal toxicity but also are associated with multiple other adverse effects and do not achieve optimal concentrations in some sites of infection (eg, kidneys).

Amphotericin B deoxycholate is the preferred formulation for treatment of neonates with systemic candidiasis because of better penetration into the central nervous system, urinary tract, and eye, which often are involved in neonatal *Candida* infections; lipid-associated formulations do not penetrate as well into many of these body sites. Amphotericin B deoxycholate is generally administered intravenously in a single daily dose of 1 mg/kg in 5% dextrose in water at a concentration of 0.1 mg/mL and delivered through a central or peripheral venous catheter. Infusion times of 1 to 2 hours have been shown to be well tolerated in adults and older children and theoretically increase the blood-to-tissue gradient, thereby improving drug delivery. Total duration of therapy depends on the type and extent of the specific fungal infection.

Amphotericin B deoxycholate is eliminated by a renal mechanism for approximately 2 weeks after therapy is discontinued. No adjustment in dose is required for neonates or for children with impaired renal function, because serum concentrations are not increased significantly in these patients. Because of concentration-dependent killing, if renal toxicity occurs, it is recommended to maintain the dose but switch to alternate-day dosing. Neither hemodialysis nor peritoneal dialysis significantly decreases serum concentrations of the drug.

Infusion-related reactions to amphotericin B deoxycholate include fever, chills, and sometimes nausea, vomiting, headache, generalized malaise, hypotension, and arrhythmias; these reactions are rare in neonates. Onset usually is within 1 to 3 hours after starting the infusion; duration typically is less than an hour. Hypotension and arrhythmias are idiosyncratic reactions that are unlikely to occur if not observed after the initial dose but also can occur in association with rapid infusion. Multiple regimens have been used to prevent infusion-related reactions, but few have been studied in controlled clinical trials. Pretreatment with acetaminophen, alone or combined with diphenhydramine, may alleviate febrile reactions; these reactions appear to be less common in children than in adults. Hydrocortisone (25–50 mg in adults

and older children) also can be added to the infusion to decrease febrile and other systemic reactions. Tolerance to febrile reactions develops with time, allowing tapering and eventual discontinuation of the hydrocortisone and often diphenhydramine and antipyretic agents. Meperidine and ibuprofen have been effective in preventing or treating fever and chills in some patients who are refractory to the conventional premedication regimen.

Toxicity from amphotericin B deoxycholate can include nephrotoxicity, hepatotoxicity, anemia, or neurotoxicity. Nephrotoxicity is caused by decreased renal blood flow and can be prevented or ameliorated by hydration, saline solution loading (0.9% saline solution over 30 minutes) before infusion of amphotericin B, and avoidance of diuretic drugs. Hypokalemia is common and can be exacerbated by sodium loading. Renal tubular acidosis can occur but usually is mild. Permanent nephrotoxicity is related to cumulative dose. Nephrotoxicity is increased by concomitant administration of amphotericin B and aminoglycosides, cyclosporine, tacrolimus, cisplatin, nitrogen mustard compounds, or acetazolamide. Anemia is secondary to inhibition of erythropoietin production. Neurotoxicity occurs rarely and can manifest as confusion, delirium, obtundation, psychotic behavior, seizures, blurred vision, or hearing loss.

Lipid preparations of amphotericin B, such as amphotericin B lipid complex (ABLC [Abelcet]) and liposomal amphotericin B (L-AmB [AmBisome]), are the preferred formulation in all patient populations except neonates. Lipid formulations of amphotericin B achieved higher central nervous system concentrations than other formulations of amphotericin B in a rabbit model. Acute infusion-related reactions occur with both formulations but are less frequent with AmBisome. Nephrotoxicity is less common with lipid-associated products than with amphotericin B deoxycholate. Liver toxicity, which generally is not associated with amphotericin B deoxycholate, has been reported with the lipid formulations.

Pyrimidines

Among pyrimidine antifungal agents, only flucytosine (5-fluorocytosine) is approved by the US Food and Drug Administration (FDA) for use in children. Flucytosine has a limited spectrum of activity against fungi (*Cryptococcus* and *Candida* species) and has potential for toxicity and should be avoided in the setting of renal dysfunction. When flucytosine is used as a single agent, resistance often emerges rapidly. Flucytosine should be used in combination with amphotericin B for cryptococcal meningitis. It is important to monitor complete blood cell counts and serum concentrations of flucytosine to avoid bone marrow toxicity, reported to frequently occur with flucytosine serum trough concentrations ≥ 100 $\mu\text{g/mL}$. Flucytosine is only available in oral formulation in the United States.

Azoles

Six oral azoles are available in the United States: ketoconazole, fluconazole, itraconazole, voriconazole, posaconazole, and isavuconazonium sulfate (the prodrug for

isavuconazole). All have relatively broad activity against common fungi but differ in their in vitro activity (see Table 4.7, p 1021), bioavailability, adverse effects, and potential for drug interactions. Fewer data are available regarding safety and efficacy of azoles in pediatric than in adult patients. Azoles are easy to administer and have little toxicity, but their use can be limited by the frequency of their interactions with coadministered drugs. These drug interactions can result in decreased serum concentrations of the azole potentially leading to therapeutic failure or unexpected toxicity from the coadministered drug (caused by increased serum concentrations of the coadministered drug). When considering use of azoles, the patient's concurrent medications should be reviewed to avoid potential adverse clinical outcomes. The FDA reaffirmed in 2016 that it strongly discourages use of systemic ketoconazole for uncomplicated skin and nail infections because of significant risks of liver toxicity, adrenal insufficiency, and interactions with multiple medications that have resulted in at least 1 fatality.

Another potential limitation of azoles is emergence of resistant fungi, especially *Candida* species resistant to fluconazole and *Aspergillus fumigatus* resistant to itraconazole, posaconazole, and voriconazole. *Candida krusei* are intrinsically resistant to fluconazole, and strains of *Candida glabrata* and *Candida parapsilosis* increasingly are resistant to fluconazole. Itraconazole is approved by the FDA for treatment of blastomycosis and histoplasmosis (nonmeningeal) and for empiric therapy of febrile neutropenic patients with suspected fungal infection. Efficacy and safety have not been established in pediatric patients. Itraconazole does not cross the blood-brain barrier and should not be used for infections of the central nervous system. Itraconazole formulations are not interchangeable; when taken on an empty stomach, the oral solution has greater bioavailability and is preferred over the capsule formulation. A super bioavailable (SUBA) itraconazole formulation was approved by the FDA in 2018 for individuals ≥ 18 years of age for the treatment of aspergillosis, blastomycosis, and histoplasmosis in individuals intolerant of amphotericin. Voriconazole has been approved by the FDA for individuals 2 years and older for primary treatment of invasive *Aspergillus* species, for candidemia in nonneutropenic patients, for esophageal candidiasis, and for refractory infection with *Fusarium* species and some *Scedosporium* species, such as *Scedosporium apiospermum*. Intravenous and oral formulations are available. Posaconazole is approved for use in adults (all formulations), children ≥ 13 years of age (delayed-release tablets and oral suspension), and children ≥ 2 years of age and weighing ≤ 40 kg (powder for delayed-release oral suspension) for prophylaxis of invasive aspergillosis and candidiasis in patients who are high risk of developing these infections. In addition, the oral suspension is approved for treatment of oropharyngeal candidiasis. Strategies to enhance absorption are necessary (eg, administration with high-fat meal, avoidance of proton pump inhibitors) when using the oral suspension. Isavuconazole, available in oral and intravenous forms, has been approved by the FDA for patients 18 years or older for invasive aspergillosis and invasive mucormycosis. Dose adjustments for most azoles are required in patients with renal and/or hepatic insufficiency. Posaconazole renal clearance is negligible; therefore, in patients with renal impairment as well as in patients on intermittent hemodialysis, no dose adjustment is required. Therapeutic

monitoring of azole drugs, especially itraconazole, voriconazole, and posaconazole, with measurement of serum trough concentrations is critical in patients with invasive fungal infections (see Table 4.7, p 1021). Drugs with a narrow therapeutic window that are P-glycoprotein substrates, such as digoxin, may require dose adjustment when administered concomitantly with isavuconazole.

Echinocandins

Caspofungin, micafungin, and anidulafungin are the only echinocandins approved by the FDA. Caspofungin is approved for treatment of pediatric patients 3 months of age and older with invasive candidiasis and esophageal candidiasis; for empiric therapy for presumed fungal infections in febrile neutropenic patients; and for treatment of aspergillosis in patients who are refractory to or intolerant of other antifungal drugs. Clinical trials have demonstrated safety and efficacy in pediatric patients as young as 3 months of age. Although efficacy and safety of caspofungin has not specifically been evaluated in neonates, in retrospective studies of immunocompromised pediatric patients that included neonates, the safety and tolerability of caspofungin was favorable. Micafungin is approved by the FDA for intravenous treatment of pediatric patients 4 months and older with candidemia without meningoencephalitis, acute disseminated candidiasis, *Candida* peritonitis and abscesses, and esophageal candidiasis and for prophylaxis of invasive *Candida* infections in patients undergoing hematopoietic cell transplantation. Although micafungin is not FDA approved for aspergillosis, data are available to support its use in the treatment of refractory disease, preferably in combination with another antifungal agent.¹ Anidulafungin is not approved by the FDA for use in children but is FDA approved for the treatment of candidemia, *Candida* infections, and esophageal candidiasis in adults.

Triterpenoids

Ibrexafungerp was approved for adults with vulvovaginal candidiasis following 2 phase 3 studies and is the first new class of antifungals approved since 2001. Similar to the echinocandins, ibrexafungerp noncompetitively inhibits beta-1,3-glucan synthase and is also fungicidal against *Candida* species and *Aspergillus* species. Ibrexafungerp is the first orally available glucan synthase inhibitor and has a long half-life, suggesting once daily dosing for clinical use. Similar to the echinocandins, initial studies show limited to no distribution to the central nervous system and variable distribution to the eye. Dose adjustment is required when used concomitantly with strong CYP3A inhibitors or inducers to avoid systemic toxicity or therapeutic failure. In a phase 2 study for invasive candidiasis, ibrexafungerp as step-down therapy following initial echinocandin therapy was well-tolerated and achieved a favorable global response similar to the standard of care. It currently is not approved for use in children.

Therapeutic drug monitoring (treatment)	No	No	Obtain trough after at least 10 days of therapy. Therapeutic trough 1–2 µg/mL (when measured by high-pressure liquid chromatography, both itraconazole and its bioactive hydroxy-itraconazole metabolite are reported, the sum of which should be considered in assessing drug levels). The itraconazole oral solution formulation is preferred over the capsule formulation because of improved absorption, and should be taken on an empty stomach.	Obtain trough after at least 3 days of therapy. Therapeutic trough 2–6 µg/mL. It is important to individualize dosing in patients following initiation of voriconazole therapy, because there is high interpatient variability in metabolism.	IV and PO tablets: Obtain trough after at least 3 days of therapy. Therapeutic trough 1–4 µg/mL, with a target of 1.25 µg/mL. PO suspension: Obtain trough after at least 10 days of therapy. Therapeutic trough 1–4 µg/mL, with a target of 1.25 µg/mL.	Unknown.	Obtain 2 h post-peak levels after 3–5 doses. Peak 40–80 µg/mL.	No

Fungal Species	Amphotericin B Formulations	Fluconazole	Itraconazole	Voriconazole	Posaconazole	Isavuconazole	Flucytosine	Echinocandins ^a
Common adverse reactions	Infusion reaction, nephrotoxicity (watch potassium, magnesium); liposomal: hepatotoxicity	Hepatotoxicity, increased QTc, headache, gastrointestinal tract effects	Hepatotoxicity, increased QTc; negative inotrope (avoid in congestive heart failure).	Hepatotoxicity, increased QTc, central nervous system effects, vision changes, phototoxicity.	Hepatotoxicity, increased QTc, headache, gastrointestinal tract effects.	Headache, hypokalemia, abdominal pain, nausea, diarrhea, conjunctivitis, flu-like illness, hepatotoxicity, cough.	Neutropenia, hepatotoxicity (avoid in decreased renal function), gastrointestinal.	Usually well tolerated; gastrointestinal tract effects, headache, hepatotoxicity.

CSF indicates cerebrospinal fluid; IV, intravenous; PO, oral.

NOTE: ++, more active, scenario dependent; +, usually active; +/-, variably active; -, usually not active.

^aCaspofungin, anidulafungin, and micafungin.

^bMold.

^cEndemic fungi where mold/yeast phase is temperature dependent.

RECOMMENDED DOSES OF PARENTERAL AND ORAL ANTIFUNGAL DRUGS

Table 4.8. Recommended Doses of Parenteral and Oral Antifungal Drugs

Drug	Route	Dose (per day)	Adverse Reactions ^{a,b}
Amphotericin B deoxycholate (see Antifungal Drugs for Systemic Fungal Infections, p 1017, for detailed information)	IV	0.8 mg/kg/day to 1.0 mg/kg per day (or 1.5 mg/kg every other day) (max 1.5 mg/kg/day); infuse as a single dose over 2–4 h.	Fever, chills, phlebitis, gastrointestinal tract symptoms, headache, hypotension, renal dysfunction, hypokalemia, anemia, cardiac arrhythmias, neurotoxicity, anaphylaxis.
	IT	0.01–0.025 mg, slow increase to 0.5 mg, twice/wk.	Headache, gastrointestinal tract symptoms, arachnoiditis/radiculitis.
Amphotericin B lipid complex (Abelcet) ^c	IV	3–5 mg/kg per day, infused over 2 h.	Fever, chills, other reactions associated with amphotericin B deoxycholate, but less nephrotoxicity; hypokalemia, hepatotoxicity has been reported with lipid complex.
Liposomal amphotericin B (AmBisome) ^c	IV	3–5 mg/kg, infused over 1–2 h. IFI prophylaxis ^d : 1 mg/kg/dose every other day or 2.5 mg/kg/dose twice/wk. Doses up to 10 mg/kg have been used in patients with mucormycosis or central nervous system infection.	Fever, chills, fewer infusion reactions and less nephrotoxicity than associated with amphotericin B deoxycholate; hypokalemia, hepatotoxicity has been reported.

Table 4.8. Recommended Doses of Parenteral and Oral Antifungal Drugs, continued

Drug	Route	Dose (per day)	Adverse Reactions ^{a,b}
Anidulafungin ^{c,e}	IV	For adults and adolescents 12 y and older: Candidemia and other forms of <i>Candida</i> infections: 200 mg on day 1, followed by 100-mg daily dose thereafter for at least 14 days after the last positive culture. Esophageal candidiasis: 100 mg on day 1, followed by 50-mg daily dose thereafter for a minimum of 14 days and for at least 7 days following resolution of symptoms. Dosage in pediatric patients (2 y through 11 y): Candidemia and other forms of <i>Candida</i> infections: 3-mg/kg loading dose on day 1, followed by 1.5 mg/kg once daily thereafter. Maximum loading dose 200 mg and daily dose 100 mg. Esophageal candidiasis: 1.5-mg/kg loading dose on day 1, followed by 0.75 mg/kg once daily thereafter.	Fever, headache, nausea, vomiting, diarrhea, leukopenia, hypokalemia, hepatitis, hepatic enzyme elevations, hypersensitivity, and phlebitis. Because of high alcohol content of solution, the rate of infusion should not exceed 1.1 mg/minute.
Caspofungin ^c	IV	Dosage in adults (18 y and older): 70-mg loading dose on day 1, followed by 50 mg once daily for all indications except esophageal candidiasis. For esophageal candidiasis, use 50 mg once daily with no loading dose. Dosage in pediatric patients (3 mo through 17 y of age): For all indications, 70-mg/m² loading dose on day 1, followed by 50 mg/m² once daily thereafter. Maximum dose should not exceed 70 mg, regardless of the patient's weight and calculated dose. Dosage in neonates: 25 mg/m² daily.	Adults: Diarrhea, pyrexia, hepatic enzymes elevations, and hypokalemia. Pediatric: diarrhea, rash, hepatic enzymes elevations, hypokalemia, infusion-related reactions. Isolated cases of hepatic dysfunction, hepatitis, or hepatic failure have been reported.

Table 4.8. Recommended Doses of Parenteral and Oral Antifungal Drugs, continued

Drug	Route	Dose (per day)	Adverse Reactions ^{a,b}
Clotrimazole	PO	Oropharyngeal candidiasis: 10-mg lozenge, 5 times per day for 14 consecutive days (dissolved slowly in mouth).	Gastrointestinal tract symptoms, unpleasant mouth sensations, hepatotoxicity.
Fluconazole	IV, PO	Neonatal candidiasis^f: 25 mg/kg on day 1, followed by 12 mg/kg/dose once daily Oropharyngeal and esophageal candidiasis: 6 mg/kg (adult dose: 200 mg) on the first day, followed by 3–6 mg/kg (adult dose: 100 mg) once daily. Doses up to 12 mg/kg/day have been used based on clinical judgment. Systemic <i>Candida</i> infections: 12 mg/kg/day. Prophylaxis in children (when indicated)^d: 6 mg/kg once daily (max 400 mg/day). Cryptococcal meningitis (children)^g: Following induction therapy with amphotericin B plus flucytosine for at least 2 weeks, fluconazole 10–12 mg/kg/day (max 800 mg per day) in 2 divided doses for at least 8 weeks; for suppression of relapse in children with AIDS, use 6 mg/kg (max 200 mg per day) once daily.	Rash, gastrointestinal tract symptoms, hepatotoxicity, Stevens-Johnson syndrome, anaphylaxis. Requires dose adjustment for renal impairment

Table 4.8. Recommended Doses of Parenteral and Oral Antifungal Drugs, continued

Drug	Route	Dose (per day)	Adverse Reactions ^{a,b}
Flucytosine	PO	Cryptococcal meningitis (adults) [§] : Following induction therapy with amphotericin B plus flucytosine for at least 2 weeks, fluconazole 12 mg/kg/day (max 800 mg per day) in 2 divided doses for at least 8 weeks; 200 mg once daily is used for suppression of relapse of cryptococcal meningitis in patients with AIDS.	
		Coccidioidomycosis (adults): 400 mg once daily, can use up to 800 mg once daily in non-meningitis, and up to 1200 mg once daily in meningitis.	
		100 mg/kg/day, divided dosing every 6 h (adjust dose for renal dysfunction and neonatal age); follow 2-h post peak levels closely (therapeutic range $\leq 100 \mu\text{g/mL}$).	Bone marrow suppression, hepatotoxicity, renal dysfunction, gastrointestinal tract symptoms, rash, neuropathy, confusion, hallucinations. Cytosine arabinoside, a cytostatic agent, has been reported to inactivate the antifungal activity of flucytosine by competitive inhibition; drugs that impair glomerular filtration may prolong the biological half-life of flucytosine. The hematologic parameters and liver and kidney function should be monitored during therapy. Flucytosine should be used in combination with amphotericin B for the treatment of cryptococcosis because of the emergence of resistance to flucytosine.

Table 4.8. Recommended Doses of Parenteral and Oral Antifungal Drugs, continued

Drug	Route	Dose (per day)	Adverse Reactions ^{a,b}
Griseofulvin	PO	Ultramicrosize: 10–15 mg/kg, once daily; maximum dose per day, 750 mg. Microsize: 20–25 mg/kg per day divided in 2 doses; maximum dose per day, 1000 mg.	Rash, paresthesias, leukopenia, gastrointestinal tract symptoms, proteinuria, hepatotoxicity, mental confusion, headache.
Ibrexafungerp	PO	300 mg (2 tablets of 150 mg) twice a day for 1 day, for a total treatment dosage of 600 mg; not currently approved for use in children	The most frequent adverse reactions ($\geq 2\%$) reported in clinical trials of vulvovaginal candidiasis treatment were diarrhea, nausea, abdominal pain, dizziness, and vomiting
Isavuconazole (prodrug is isavuconazonium sulfate) ^h	IV, PO	Adults: Approved in individuals ≥ 18 y of age. 200 mg, every 8 h for 6 doses, then 200 mg, once daily (corresponding to 372 mg of the sulfate compound every 8 h for 6 doses, then 372 mg daily), starting 12 to 24 h after the last loading dose. No target therapeutic concentration has been defined for isavuconazole. Pediatrics: Very limited pharmacokinetic and safety data available in children ≤ 17 y of age: Loading dose of 10 mg of isavuconazonium sulfate/kg/dose every 8 h for 6 doses (max 372 mg of isavuconazonium sulfate/dose), followed 12–24 h after last loading dose by maintenance dose of 10 mg of isavuconazonium sulfate/kg/dose IV every 24 h (max 372 mg of isavuconazonium sulfate/dose).	Most frequent adverse reactions are nausea, vomiting, diarrhea, headache, elevated aminotransferases, hypokalemia, constipation, dyspnea, cough, peripheral edema, and back pain. CYP3A4 inhibitors or inducers may alter the plasma concentrations of isavuconazole. Appropriate therapeutic drug monitoring and dose adjustment of immunosuppressants (ie, tacrolimus, sirolimus, and cyclosporine) may be necessary when coadministered with isavuconazole. Drugs with a narrow therapeutic window that are P-gp substrates, such as digoxin, may require dose adjustment coadministered concomitantly with isavuconazole.

Table 4.8. Recommended Doses of Parenteral and Oral Antifungal Drugs, continued

Drug	Route	Dose (per day)	Adverse Reactions ^{a,b}
Itraconazole ^c	PO	Children: 10 mg/kg per day divided into 2 doses; for endemic mycoses 2–5 mg/kg/dose three times a day for 3 days, then 2–5 mg/kg/dose twice daily (max of 200 mg/dose); acidic pH for better absorption; oral solution supplies more reliable bioavailability; serum trough concentrations of itraconazole should be 1 to 2 µg/mL. A trough level should be checked 10 days or later following initiation to ensure adequate drug exposure; when measured by high-pressure liquid chromatography, both itraconazole and its bioactive hydroxyitraconazole metabolite are reported, the sum of which should be considered in assessing the trough concentration; the itraconazole oral solution formulation is preferred over the capsule formulation because of improved absorption, and should be taken on an empty stomach; IFI prophylaxis^d: 2.5 mg/kg twice a day, with minimum therapeutic level of 0.5 µg/mL. Adults: 200–400 mg/day once or twice a day for treatment of aspergillosis; 200 mg 3 times daily for 3 days and then 200 mg once or twice daily for treatment of endemic mycoses; 100–200 mg once daily for oropharyngeal and esophageal candidiasis. A super bioavailable (SUBA) itraconazole is now approved by the Food and Drug Administration for the treatment of pulmonary and extrapulmonary blastomycosis in individuals 18 years or older, with pharmacokinetic studies of this formulation demonstrating less variable absorption than conventional itraconazole capsules and a similar side effect profile; data in children are lacking.	Gastrointestinal tract symptoms, rash, edema, headache, hypokalemia, hepatotoxicity, tremor, thrombocytopenia, leukopenia; strong P450 CYP3A4 inhibitor; serious cardiovascular events, including QT prolongation, torsades de pointes, ventricular tachycardia, cardiac arrest, and/or sudden death have occurred in patients using cisapride, pimozide, levacetylmethadol (levomethadyl), methadone, or quinidine concomitantly with itraconazole and/or other CYP3A4 inhibitors, should not be used in patients with congestive heart failure.

Table 4.8. Recommended Doses of Parenteral and Oral Antifungal Drugs, continued

Drug	Route	Dose (per day)	Adverse Reactions ^{a,b}
Micafungin ⁱ	IV	Adults: 100 mg daily for treatment of candidemia, acute disseminated candidiasis, <i>Candida</i> peritonitis and abscesses; 150 mg daily for esophageal candidiasis; and 50 mg daily for prophylaxis of candida infections in hematopoietic cell transplant recipients. Pediatric: 2 mg/kg/day (max 100 mg daily) for candidemia and acute disseminated candidiasis, <i>Candida</i> peritonitis and abscesses; Doses up to 7 mg/kg/day have been used for disseminated candidiasis. 1 mg/kg/day (max 50 mg daily) for prophylaxis of <i>Candida</i> infections; for treatment of esophageal candidiasis, 3 mg/kg/day is used for children ≤30 kg and 2.5 mg/kg/day with a max 150 mg daily is used for children ≥30 kg; neonatal dosing is 10 mg/kg/day.	Fever, headache, nausea, vomiting, diarrhea, rash, thrombocytopenia, hepatic enzyme elevations, histamine-mediated symptoms including rash, pruritus, facial swelling, and vasodilatation can occur during infusion.
Nystatin	PO	Infants: 200 000 U, 4 times a day, after meals. Children and adults: 400 000–600 000 U, 3 times a day, after meals.	Gastrointestinal tract symptoms, rash.
Posaconazole ^c	PO, IV ^j	Adults and adolescents ^k : for prophylaxis of invasive <i>Aspergillus</i> and <i>Candida</i> infections ^d . IV formulation is approved only for use in patients 2 y or older, however there are no weight-based dosing recommendations. 300 mg, IV, twice a day on first day, followed by 300 mg, IV, once daily starting on second day.	Diarrhea, nausea, fever, vomiting, headache, coughing, hypokalemia, rash, edema, headache, anemia, neutropenia, thrombocytopenia, fatigue, thrombophlebitis, arthralgia, myalgia, fever; interactions with P450 CYP3A4 substrate drugs and can potentiate QT prolongation; posaconazole injection should be avoided in patients with moderate or severe renal impairment (creatinine clearance <50 mL/min).

Table 4.8. Recommended Doses of Parenteral and Oral Antifungal Drugs, continued

Drug	Route	Dose (per day)	Adverse Reactions ^{a,b}
		Delayed-release tablets can be used in children >2 y of age and weighing >40 kg; delayed-release oral suspension can be used in children ≥2 y and weighing ≤40 kg; Immediate release oral suspension can be used in children 13 y and older; 300 mg delayed-release tablets twice a day on the first day followed by 300 mg once daily, starting on second day; or delayed-release oral suspension, dosing based on weight and loading dose on first day, then maintenance dosing starting on second day [10 to <12 kg: 90 mg twice daily on first day, then 90 mg once daily; ≥12 to <17 kg: 120 mg twice daily on first day, then 120 mg once daily; ≥17 kg to <21 kg: 150 mg twice daily on first day, then 150 mg once daily; ≥21 kg to <26 kg: 180 mg twice daily on first day, then 180 mg once daily; ≥26 kg to <36 kg: 210 mg twice daily on first day, then 210 mg once daily; or ≥36 kg to 40 kg: 240 mg twice daily on first day, then 240 mg once daily]; 200 mg (5-mL) immediate release oral solution 3 times a day; duration of therapy for both IV and oral is based on recovery from neutropenia or immunosuppression; tablet and liquid forms are not interchangeable given bioavailability and dosing differences; give oral formulations with food. Delayed release tablet is better absorbed. For oropharyngeal candidiasis: oral suspension 100 mg (2.5 mL) twice a day on first day followed by 100 mg once daily for 13 days. For oropharyngeal candidiasis refractory to itraconazole and/ or fluconazole: oral suspension 400 mg (10 mL) twice a day; duration of therapy is based on the severity of the patient's underlying disease and clinical response.	

Table 4.8. Recommended Doses of Parenteral and Oral Antifungal Drugs, continued

Drug	Route	Dose (per day)	Adverse Reactions ^{a,b}
		Serum trough concentrations of posaconazole should be 1 to 4 µg/mL, with a target of 1.25 µg/mL. For intravenous and oral tablet formulations, a trough level should be checked 3 days or later following initiation to ensure adequate drug exposure. For oral liquid formulation, a trough level should be checked 10 days or later following initiation to ensure adequate drug exposure.	
Terbinafine	PO	Children: once daily dosing Onychomycosis: 10–20 kg: 62.5 mg/day; 21–40 kg: 125 mg/day; >40 kg: 250 mg/day; treatment course of 12 wk for toenails, 6 wk for fingernails. Tinea capitis: <25 kg: 125 mg/day, 25–35 kg: 187.5 mg/day; >35 kg: 250 mg once daily; treatment course of 6 wk. Adults: 250 mg, once daily.	Common adverse events include headache, diarrhea, rash, dyspepsia, liver enzyme abnormalities, pruritus, taste disturbance, nausea, abdominal pain, and flatulence; liver failure, sometimes leading to liver transplant or death, has been reported with the use of oral terbinafine. Obtain pretreatment serum aminotransferases. Terbinafine is an inhibitor of CYP450 2D6 isozyme and has an effect on metabolism of desipramine. Drug interactions with cimetidine, fluconazole, cyclosporine, rifampin, and caffeine have also been reported.

Table 4.8. Recommended Doses of Parenteral and Oral Antifungal Drugs, continued

Drug	Route	Dose (per day)	Adverse Reactions ^{a,b}
Voriconazole ^c	IV, PO	Treatment or IFI prophylaxis^d: • if 2–<12 y of age or 12–14 y of age and weight <50 kg: 9 mg/kg, IV, twice daily on day 1 of treatment; thereafter 8 mg/kg, IV, twice daily or 9 mg/kg, PO, twice daily; • if ≥15 y of age or 12–14 y of age and weight ≥50 kg: 6 mg/kg, IV, twice daily on day 1 of treatment; thereafter 4 mg/kg, IV, twice daily or 200 mg, PO, twice daily; • Trough levels should be obtained after 5 days of therapy; therapeutic trough levels are 2–6 µg/mL. Esophageal candidiasis: • If 2–<12 y of age or 12–14 y of age and weight <50 kg: 4 mg/kg IV every 12 h; PO 9 mg/kg every 12 h (max of 350 mg/dose PO every 12 h) • Not evaluated in ≥15 y of age or 12–14 y of age and weight ≥50 kg; adult dosing regimen is applied with max dosing of 200 mg, PO, every 12 h.	Concentration- or dose-related toxicities: hepatic toxicity, arrhythmias/QT prolongation, dermatologic reactions, visual disturbance, hallucinations, increased liver enzymes and bilirubin, encephalopathy; phototoxicity, rash; central nervous system-related toxicities are more associated with trough levels above 6 µg/mL. Close monitoring of voriconazole serum trough concentrations is critical for both efficacy and safety. Most experts agree that voriconazole trough concentrations should be measured on day 3 or later after initiating treatment and for children, therapeutic trough concentrations are 2–6 µg/mL. It is important to individualize dosing in patients following initiation of voriconazole therapy, because there is high interpatient variability in metabolism.

Table 4.8. Recommended Doses of Parenteral and Oral Antifungal Drugs, continued

Drug	Route	Dose (per day)	Adverse Reactions ^{a,b}
		A simpler proposed oral regimen for IFI prophylaxis ^d : 200 mg, PO, twice daily if weight is ≥ 40 kg and 100 mg, PO, twice daily if weight is < 40 kg; if IV needed, then 4 mg/kg every 12 h is administered.	

CYP indicates cytochrome P; GVDH, graft versus host disease; IFI, Invasive fungal infection; IT, intrathecal; IV, intravenous; PO, oral.

^aSee package insert or listing in current edition of the *Physicians' Desk Reference* or www.pdr.net (for registered users only).

^bInteractions with other drugs are common. Consult www.fda.gov/drugs/development-resources/drug-interactions-labeling and the Physicians' Desk Reference (a drug interaction reference or database) or a pharmacist before prescribing these medications.

^cLimited efficacy and safety data in pediatric patients are available.

^dInvasive fungal infection prophylaxis in at-risk pediatric patients with immunosuppression attributable to cancer or hematopoietic cell transplant.

^eSafety and effectiveness of anidulafungin in patients ≤ 16 years of age has not been established.

^fExperience with fluconazole in neonates is limited to pharmacokinetic studies in preterm newborn infants. Based on the prolonged half-life seen in preterm newborn infants (gestational age 26 to 29 weeks), these children, in the first 2 weeks of life, should receive the same dosage (mg/kg) as in older children, but administered every 72 hours. After the first 2 weeks, these children should be dosed once daily.

^gPerfect JR, Dismukes WE, Dromer F, et al. clinical practice guidelines for the management of cryptococcal disease: 2010 update by the Infectious Diseases Society of America. *Clin Infect Dis*. 2010;50(3):291–322.

^hSafety and effectiveness of isavuconazole in patients younger than 18 years have not been established.

ⁱLimited efficacy and safety data in pediatric patients younger than 4 months are available.

^jIV formulation of posaconazole is recommended only for 18 years or older. For systemic *Candida* infections including candidemia, disseminated candidiasis, and pneumonia, optimal therapeutic dosage and duration of therapy have not been established. In open, noncomparative studies of small numbers of patients, doses of up to 400 mg daily have been used.

^kSafety and effectiveness of posaconazole have been established in the age groups 13 years and older.

.....
**TOPICAL DRUGS FOR SUPERFICIAL
 FUNGAL INFECTIONS**

Table 4.9. Topical Drugs for Superficial Fungal Infections

Drug	Strength	Formulation	Trade Name Examples	Application(s) per Day	Adverse Reactions/Notes
Basic fuchsin, phenol, resorcinol, and acetone (Rx and OTC)		S	Castellani Paint Modified	1	Excellent for intertriginous areas. Stains skin and clothing. Also available as a colorless solution with alcohol and without basic fuchsin. This is an alternative if the patient cannot tolerate other topical antifungals. Not FDA approved. Must be compounded.
Butenafine HCl (Rx and OTC)	1%	C	Mentax; Lotrimin Ultra	1–2, typically for 2 wk; Lotrimin Ultra may be used 2/day for 1 wk or 1/day for 4 wk	Safety and efficacy in patients younger than 12 y of age have not been established. Do not occlude. ^a Sensitivity to allylamines. Not to be used on scalp or nails.
Ciclopirox olamine (Rx)	0.77%; Nail lacquer 8%	C, L, S, Sh, P, G, NL	Loprox; Penlac nail lacquer; Ciclodan	2 for up to 4 wk; can be longer duration if applied to nails	Irritant dermatitis, hair discoloration; shake lotion vigorously before application; safety and efficacy in children younger than 10 y of age have not been established. Precautions: diabetes mellitus; immune compromise; seizures. Do not occlude. ^a
Clotrimazole (Rx and OTC)	1%	C, O, S, Com; check with pharmacist	Topical solution (more than 10 preparations); Lotrimin, Desenex, Microtrin/ Mycozyl AC, FungiCURE, Gyne-Lotrimin, Alevazol	1 (Rx) 2 (OTC) for 2–4 wk	Irritant dermatitis. Avoid topical steroid combinations. ^b Vaginal products contain excipients (eg, benzyl alcohol) not for use in other topical locations

Table 4.9. Topical Drugs for Superficial Fungal Infections, continued

Drug	Strength	Formulation	Trade Name Examples	Application(s) per Day	Adverse Reactions/Notes
Clotrimazole and betamethasone dipropionate (Rx)	1%/0.05%	C, L	Lotriderm, Lotrisone	2 ^b for up to 2 wk for tinea corporis/cruris, 4 wk for pedis	Significant drug interactions exist, even with topical formulations; use caution Irritant dermatitis: Not FDA approved for patients younger than 17 y and not recommended for diaper dermatitis. In 2 studies in pediatric subjects, 39.5% of tinea pedis patients and 47.1% of tinea cruris patients demonstrated adrenal suppression as determined by cosyntropin testing. If used in the groin area, patients should use medication for 2 wk only and use sparingly. Do not occlude. ^a Safety and efficacy not established in children. Contraindication: avoid steroid in varicella.
Econazole nitrate (Rx)	1%	C, F	Zolpak, Ecoza	1 (dermatophyte) 2 (candidiasis) up to 4 wk	Irritant dermatitis; foam approved for tinea pedis in children 12 y and older. Concomitant administration of econazole and warfarin has resulted in enhancement of anticoagulation effect.
Efinaconazole (Rx)	10%	S	Jublia	1, for 48 wk applied to nails (<i>Trichophyton rubrum</i> and <i>Trichophyton mentagrophytes</i>)	Application site dermatitis; application site vesicles; application site pain. Safety and effectiveness in pediatric patients younger than 6 y have not been established.

Table 4.9. Topical Drugs for Superficial Fungal Infections, continued

Drug	Strength	Formulation	Trade Name Examples	Application(s) per Day	Adverse Reactions/Notes
Iodoquinol and 2% hydrocortisone acetate (Rx)	1%	G, C	Dermazene, Vytone	3–4	Burning/itching sensation. Local allergic reaction. Can stain skin and clothes. Can interfere with results of thyroid function tests. Not to be used under occlusion in the diaper area. Not intended for use on infants. Not FDA approved. Safety and efficacy in children have not been established. Most formulations contain benzyl alcohol derivatives
Ketoconazole (Rx and OTC)	1%, 2%	C, Sh, G, F	Nizoral, Nizoral AD, Sebizol, Xolegel, Extina, Ketodan, Ketoderm	1 (tinea dermatophyte) for 2–6 wk 2 (candidiasis) Once to treat (Rx S) Every 3–4 days (OTC S)	Potential sulfite reaction with anaphylactic or asthmatic reaction; shampoo can cause dry or oily hair and increase hair loss; irritant dermatitis. May interfere with permanent waving or changes in hair texture. Cream formulation only intended for patients 12 y and older; safety and efficacy not established for younger than 12 y. Foam must not be applied directly to hands, but onto a cool surface and applied using fingertips. OTC shampoo may be used for up to 8 wk to treat, and then used as needed to control dandruff.
Luliconazole (Rx)	1%	C	Luzu	1 (x 2 wk for tinea pedis; x 1 wk for tinea cruris and tinea corporis)	Application site reactions in <1% during Phase 3 clinical trials. Contact dermatitis and cellulitis have been reported during postmarketing surveillance. Safety and efficacy have been established in children 12 to <18 y with tinea pedis and tinea cruris and for children 2 to <18 y with tinea corporis.

Table 4.9. Topical Drugs for Superficial Fungal Infections, continued

Drug	Strength	Formulation	Trade Name Examples	Application(s) per Day	Adverse Reactions/Notes
Miconazole nitrate (Rx and OTC)	2%	O, C, P, S, Sp, SpP; check with pharmacist ^c	More than 10 preparations; Lotrimin, Cruex, Podactin, Desenex, Zeasorb AF, Micatrin	2 (seborrhea), apply 2–3 times/day for several months 2 (C, L) 2 (P, L) 1 (pityriasis versicolor)	Irritant and allergic contact dermatitis. Not recommended for children younger than 2 y. Also available as vaginal suppository intended only for patients 12 y and older.
Miconazole nitrate and 15% Zinc oxide (Rx)	0.25%	O	Vusion	Every diaper change for 1 wk	Skin irritation. Can be used in children 4 wk and older. Do not routinely use for more than 7 days. Do not use in infants or children who do not have a normal immune system.
Naftifine HCl (Rx)	1%, 2% gel	C, G	Naftin	1 (C) 1–2 (Gel) for 2 wk	Burning/stinging, irritant dermatitis. Safety and efficacy of gel formulation in children have not been established. Do not occlude. ^a
Nystatin (Rx and OTC)	100 000 U/mL or 100 000 U/g	C, P, O, Com	Nystatin, Nystop powder, Nyamyc	2–4 (C) 2–3 (P)	Nontoxic except with topical steroid combinations. ^d

Table 4.9. Topical Drugs for Superficial Fungal Infections, continued

Drug	Strength	Formulation	Trade Name Examples	Application(s) per Day	Adverse Reactions/Notes
Nystatin and triamcinolone acetonide (Rx)	100 000 USP nystatin and 1 mg triamcinolone acetonide (0.1%)	C, O	Mycolog-II,	2 ^b	Pediatric patients may demonstrate greater susceptibility to topical corticosteroid-induced hypothalamic-pituitary-adrenal (HPA) axis suppression and Cushing syndrome than mature patients because of a larger ratio of skin surface area to body weight. Contraindications: Hypersensitivity to component drug. Avoid steroid use in varicella or vaccinia. Do not occlude. ^a Use lowest effective dose. Do not routinely use for more than 2 wk.
Oxiconazole (Rx)	1%	C, L	Oxistat	1–2 (tinea dermatophyte), 2–4 wk depending on site; 1 (tinea (pityriasis) versicolor) for 2 wk	Pruritus, burning, irritant dermatitis. Do not occlude. Intended for patients 12 y and older; safety and efficacy not established for younger than 12 y
Sertaconazole nitrate (Rx)	2%	C	Ertaczo	2 for 4 wk (pedis), 2 wk for corporis or candida	Dry skin, skin tenderness, contact dermatitis, local hypersensitivity. Safety and efficacy in children younger than 2 y have not been established.
Sulconazole (Rx)	1%	C, S	Exelderm	1–2 (pityriasis versicolor) for 3 wk 2 (tinea pedis) for 4 wk	Irritant dermatitis. Safety and efficacy in children have not been established.

Table 4.9. Topical Drugs for Superficial Fungal Infections, continued

Drug	Strength	Formulation	Trade Name Examples	Application(s) per Day	Adverse Reactions/Notes
Tavaborole (Rx)	5%	S	Kerydin	1, for 48 wk applied to nails (<i>Trichophyton rubrum</i> and <i>Trichophyton mentagrophytes</i>)	Application site exfoliation; application site erythema; application site dermatitis. Safety and efficacy have been established in children 6 y and older.
Terbinafine (Rx and OTC)	1%	C, Sp	Lamisil, Lamisil AT	1–2, tinea pedis can use up to 2 wk	Irritant dermatitis. Avoid use of occlusive clothing or dressings. Do not apply spray to face. Safety and efficacy in children younger than 12 y have not been established.
Tolnaftate (OTC)	1%	C, P, S, SpP, SpL; check with pharmacist ^c	>10 preparations; Tinactin, Podactin, Tinaspore	2	Irritant and allergic contact dermatitis. Not recommended if younger than 2 y.
Undecylenic acid and derivatives (OTC)	8%–25%	NL, O, S, SpP, P, (check with pharmacist for formulations and applications ^c)	BioRx Sponix, Elon Dual Defense, Gordochoom, Hongo Cura, Myco Nail A	2 for 4 wk applied to nails	Irritant dermatitis. Not recommended for children younger than 2 y.

Table 4.9. Topical Drugs for Superficial Fungal Infections, continued

Drug	Strength	Formulation	Trade Name Examples	Application(s) per Day	Adverse Reactions/Notes
Other Remedies					
Gentian violet (OTC)	1%	S	...	1–3 for 3 days	Staining. Oral mucosal ulceration reported in young children in as little as 4 days, only use as a last resort. Keep out of the reach of children. Safety and efficacy in children not established. OTC monograph not final.
Selenium sulfide (Rx and OTC)	1%, 2.3%, 2.5%	Sh, L	SelRx 2.3%	Use twice weekly for 2 wk (Sh) 1 for 7 days (L)	Irritant dermatitis and ulceration. For tinea capitis, to decrease spore formation and to decrease the potential spread of the dermatophyte. Hair loss, discoloration of hair, oiliness or dryness of scalp. Safety and efficacy in children not established. May damage jewelry. Not to be used when inflammation or exudation is present.
	1%	Sh, L	Head & Shoulders, Selsun Blue	Use twice weekly for at least 2 wk	For tinea capitis, to decrease spore formation and to decrease the potential spread of the dermatophyte.

C indicates cream; Com, combinations; F, foam; FDA, US Food and Drug Administration; G, gel; L, lotion; NL, nail lacquer; O, ointment; OTC, over the counter; P, powder; PKU, phenylketonuria; Rx, prescription; S, solution; Sh, shampoo; Sp, spray; SpL, spray lotion; SpP, spray powder.

^aIndicates direct or indirect covering of skin with impermeable barrier (ie, petroleum, wound dressings).

^bTopical steroids must be used with caution in young children and in areas of thin skin (eg, diaper area). In these circumstances, high systemic exposure may occur, resulting in endogenous synthesis suppression with the potential for serious adverse effects. Potential adverse effects include irritant dermatitis, folliculitis, hypertrichosis, acneiform eruptions, hypopigmentation, perioral dermatitis, allergic contact dermatitis, maceration, secondary infection, skin atrophy, striae, and miliaria. Topical steroids may worsen superficial fungal infections and cause tinea incognito and/or Majocchi granuloma.

^cPharmacists are an excellent resource to verify formulations that are available and new (they use *Facts and Comparisons* reference products).

^dAny topical preparation has the potential to irritate the skin and cause itching, burning, stinging, erythema, edema, vesicles, and blister formation. For more information on individual drugs, see *Physician's Desk Reference* or www.pdr.net (for registered users only).

NON-HIV ANTIVIRAL DRUGS

Table 4.10. Non-HIV Antiviral Drugs^a

Generic (Trade Name)	Indication	Route	Age	Usually Recommended Dosage
Acyclovir ^{b,c,d,e} (Zovirax)	Neonatal herpes simplex virus (HSV) infection	IV	Birth to ≤4 mo	Treatment dosing: 60 mg/kg per day, in 3 divided doses for 14 days (SEM disease) or 21 days (CNS or Disseminated disease) (durations >21 days are necessary if CSF PCR remains positive near end of treatment course)
		Oral	2 wk to 8 mo	Oral suppressive dosing following completion of IV treatment; dosing: 300 mg/m ² , 3 times per day for 6 mo
	HSV encephalitis	IV	>4 mo to 12 y	30–45 mg/kg per day, in 3 divided doses for 14–21 days; FDA-approved dose of 60 mg/kg per day for this age range and indication is not recommended, as risk of acute kidney injury may increase at incremental doses exceeding 500 mg/m ² or 15 mg/kg; dosing per m ² causes excessive weight-based dosing in younger children ^f ; neurotoxicity (agitation, myoclonus, delirium, altered consciousness, etc) can occur with accumulated high acyclovir levels, often a result of renal dysfunction and unadjusted dosage
		IV	≥12 y	30 mg/kg per day, in 3 divided doses for 14–21 days ^g
		Oral	≥2 y	≤40 kg: 80 mg/kg per day, in 4 divided doses for 5 days; maximum daily dose of 3200 mg/day (800 mg/dose) >40 kg: 3200 mg, in 4 divided doses for 5 days (800 mg/dose) (Adult dose: 4000 g per day, in 5 divided doses for 5–7 days)
	Varicella in immunocompetent host ^h	IV	≥2 y	30 mg/kg per day, in 3 divided doses for 7–10 days; or 1500 mg/m ² per day, in 3 divided doses for 7–10 days ^g

Table 4.10. Non-HIV Antiviral Drugs,^a continued

Generic (Trade Name)	Indication	Route	Age	Usually Recommended Dosage
	Varicella in immunocompromised host	IV	<2 y	30 mg/kg per day, in 3 divided doses for 7–10 days
		IV	≥2 y	1500 mg/m ² per day, in 3 divided doses for 7–10 days [§] ; some experts recommend the 30 mg/kg per day, in 3 divided doses for 7–10 days
Zoster in immunocompetent host		IV (if requiring hospitalization)	All ages	Same as for varicella in immunocompetent host requiring hospitalization
		Oral	≥12 y	4000 mg/day (800 mg/dose), in 5 divided doses for 5–7 days
Zoster in immunocompromised host		IV	All ages	30 mg/kg per day, in 3 divided doses, for 7–10 days; or 1500 mg/m ² per day in 3 divided doses for 7–10 days
HSV infection in immunocompromised host (localized, progressive, or disseminated)		IV	All ages	30 mg/kg per day, in 3 divided doses for 7–14 days
		Oral	≥2 y	1000 mg/day, in 3–5 divided doses for 7–14 days
Prophylaxis of HSV, varicella, and zoster in immunocompromised hosts		Oral	≥2 y	80 mg/kg/day, in 2–3 divided doses (max dose: 800 mg) during period of risk; or 600–1000 mg/day, in 3–5 divided doses during period of risk Some experts recommend 500 mg/m ² per day, in 2–3 divided doses
		IV	All ages	15 mg/kg, in 3 divided doses during period of risk

Table 4.10. Non-HIV Antiviral Drugs,^a continued

Generic (Trade Name)	Indication	Route	Age	Usually Recommended Dosage
Adefovir ^{b,i} (Hepsera)	Genital HSV infection: first episode	Oral	≥12 y	1200 mg/day, in 3 divided doses for 7–10 days. Oral pediatric dose: 40–80 mg/kg per day, divided in 3–4 doses (max 1000 mg/day)
		IV	≥12 y	15 mg/kg per day, in 3 divided doses for 5–7 days
	Genital HSV infection: recurrence	Oral	≥12 y	1600 mg in 2 divided doses for 5 days, or 2400 mg in 3 divided doses for 2 days
	Chronic suppressive therapy for recurrent genital and cutaneous (ocular) HSV episodes	Oral	≥12 y	800 mg/day, in 2 divided doses for as long as 12 continuous mo; decisions to continue suppressive therapy should be revisited annually
	Recurrent herpes labialis	Oral	All ages	80 mg/kg per day, in 4 divided doses, for 5 to 7 days (max 3200 mg/day)
	Chronic hepatitis B	Oral	≥12 y	10 mg, once daily, in patients with CrCL ≥50 mL/min (adult data suggest the following dosage adjustment: every 48 hours for CrCL = 30–49 mL/min; every 72 for CrCL = 10–29 mL/min) Test for HIV before treatment initiation Severe acute exacerbations of hepatitis have been reported in patients who have discontinued anti-hepatitis B therapy Nonpreferred regimen; Refer to AASLD 2018 hepatitis B guidance for preferred and nonpreferred treatment regimens and duration recommendations

Table 4.10. Non-HIV Antiviral Drugs,^a continued

Generic (Trade Name)	Indication	Route	Age	Usually Recommended Dosage
		Oral	2–12 y	≥7 y–12 y: 0.25 mg/kg, 2 y–<7 y: 0.3 mg/kg once daily (both to a max of 10 mg) gives similar systemic exposure as in adults Test for HIV before treatment initiation Severe acute exacerbations of hepatitis have been reported in patients who have discontinued anti-hepatitis B therapy Nonpreferred regimen; Refer to AASLD 2018 hepatitis B guidance for preferred and nonpreferred treatment regimens and duration recommendations
Baloxavir (Xofluza)	Influenza A and B treatment or prophylaxis	Oral	≥5 y	≥80 kg: 80 mg as single dose 20–79 kg: 40 mg as single dose <20 kg: 2 mg/kg as a single dose Longer treatment duration may be needed for severely ill patients Avoid concomitant antacids, dairy products, calcium-fortified beverages, polyvalent cation-containing laxatives, or oral supplements including iron, magnesium, selenium, or zinc
Brincidofovir (Tembexa)	Smallpox Mpox (through an emergency use investigational new drug request to FDA) (see Mpox, p 606)	Oral	Adult and children, including neonates	≥48 kg: 200 mg (two 100-mg tablets or 20-mL oral suspension for patients who cannot swallow tablets), once weekly for 2 doses 10–<48 kg: 4 mg/kg oral suspension, once weekly, for 2 doses <10 kg: 6 mg/kg oral suspension, once weekly, for 2 doses

Table 4.10. Non-HIV Antiviral Drugs,^a continued

Generic (Trade Name)	Indication	Route	Age	Usually Recommended Dosage
Cidofovir (Vistide)	Cytomegalovirus (CMV) retinitis	IV	Adult dose ^j and adolescents	Induction: 5 mg/kg, once weekly, × 2 doses with probenecid 25–40 mg/kg (max 2 g) and appropriate hydration mandatory with each dose; seek alternative therapy if CrCL <55 mL/min or if ≥2+ proteinuria Maintenance: 3–5 mg/kg, once every 2 wk, with probenecid and hydration with each dose; duration dependent on CD4+ T-lymphocyte response to antiretroviral (ARV) therapy and regular ophthalmologic monitoring
Elbasvir and Grazoprevir (Zepatier)	Chronic hepatitis C (genotype 1 and 4)	Oral	≥12 y or weighing ≥30 kg	50 mg elbasvir and 100 mg grazoprevir, once daily, for 12–16 wk, with or without ribavirin Need for ribavirin is based on HCV genotype, baseline NS5A polymorphisms, and prior treatment status Test for HBV coinfection before treatment initiation Contraindicated in patients with moderate or severe hepatic impairment (Child-Pugh B or C) or those with any history of prior hepatic decompensation Hepatitis C therapy recommendations change rapidly, refer to most current AASLD/IDSA recommendations for appropriate treatment regimen

Table 4.10. Non-HIV Antiviral Drugs,^a continued

Generic (Trade Name)	Indication	Route	Age	Usually Recommended Dosage
Entecavir ^b (Baraclude)	Chronic hepatitis B	Oral	≥16 y	0.5 mg, once daily, in nucleoside-therapy-naïve patients; 1 mg once daily in patients who were previously treated with a nucleoside (not first choice in this setting); adult recommendations for renal dosage adjustment: For CrCL = 30–49 mL/min administer 50% of the usual dose or usual dose every 48 hours; For CrCL = 10–29 mL/min administer 30% of the usual dose or usual dose every 72 hours Test for HIV before treatment initiation Severe acute exacerbations of hepatitis B have been reported in patients who discontinue anti-hepatitis B therapy Refer to AASLD 2018 hepatitis B guidance for information on monitoring, toxicity, and duration of therapy
		Oral	2 to <16 y, naïve to treatment (normal renal function)	10–11 kg: 0.15-mg oral solution, once daily >11–14 kg: 0.2-mg oral solution, once daily >14–17 kg: 0.25-mg oral solution, once daily >17–20 kg: 0.3-mg oral solution, once daily >20–23 kg: 0.35-mg oral solution, once daily >23–26 kg: 0.4-mg oral solution, once daily >26–30 kg: 0.45-mg oral solution, once daily >30 kg: 0.5-mg oral solution or tablet, once daily

Table 4.10. Non-HIV Antiviral Drugs,^a continued

Generic (Trade Name)	Indication	Route	Age	Usually Recommended Dosage
Famciclovir ^b	Genital HSV infection, recurrent episodes	Oral	Lamivudine- treated/- refractory OR with known lamivudine or telbivudine resistance mutations	Double the dosage in each above weight bracket, up to 1 mg daily for ≥16 y Test for HIV before treatment initiation Severe acute exacerbations of hepatitis B have been reported in patients who discontinue anti-hepatitis B therapy Refer to AASLD 2018 hepatitis B guidance for monitoring information, toxicity, and duration of therapy
			Adult dose, ^j adolescents	Immunocompetent: 2000 mg/day, in 2 divided doses for 1 day; CDC regimens featuring smaller incremental doses and greater number of treatment days are available. People with HIV: 1000 mg, in 2 divided doses for 7 days (CDC and NIH guidelines provide range of 5–14 days)
	Daily suppressive therapy	Oral	Adult dose, ^j adolescents and children	Immunocompetent: 500 mg/day, in 2 divided doses for 1 y, then reassess for recurrence of HSV infection; HIV: 1000 mg/day, in 2 divided doses for minimum of 1 y; same dosage for children and adolescents old enough to receive adult doses
	Recurrent herpes labialis	Oral	Adult dose, ^j adolescents	Immunocompetent: 1500 mg as a single dose People with HIV: 1000 mg/day, in 2 divided doses for 7 days (CDC and NIH guidelines provide range of 5–10 days); comparatively slower resolution seen in adolescent patients

Table 4.10. Non-HIV Antiviral Drugs,^a continued

Generic (Trade Name)	Indication	Route	Age	Usually Recommended Dosage
Foscarnet ^b (Foscavir)	Herpes zoster	Oral	Adult dose, ^{h,j} adolescents	1500 mg/day, in 3 divided doses for 7 days (7–10 days in HIV patients with localized lesions, longer if lesions resolving slowly, or to complete 10–14 days total course with initial IV acyclovir if more severe skin or visceral infection)
	CMV retinitis in HIV infected patients (drug of choice in ganciclovir-resistant disease)	IV	Adult dose ^j and infants, children, and adolescents	180 mg/kg per day, in 2–3 divided doses for 14–21 days, then 90–120 mg/kg once a day for maintenance therapy and for secondary prophylaxis; may be added to ganciclovir as induction therapy, or as follow-up to failed ganciclovir monotherapy; if sight-threatening disease; IV infused no faster than 1 mg/kg/min
	HSV infection resistant to acyclovir in immunocompromised host	IV	Adult dose ^j and adolescents	80–120 mg/kg per day, in 2–3 divided doses for 3 wk or until infection resolves
	VZV infection resistant to acyclovir	IV	Adult dose ^j and adolescents Infants and children	Patients with HIV: 120–180 mg/kg per day, in 2 divided doses 120–180 mg/kg per day in 3 divided doses for 7–10 days or until no new lesions have appeared for 48 h

Table 4.10. Non-HIV Antiviral Drugs,^a continued

Generic (Trade Name)	Indication	Route	Age	Usually Recommended Dosage
Ganciclovir ^b (Cytovene)	Symptomatic congenital CMV disease	IV	Birth through 2 mo	12 mg/kg per day, divided every 12 h; duration of treatment is 6 mo, but most or all of the treatment should be accomplished with oral valganciclovir, as detailed below (there is no benefit to using ganciclovir instead of valganciclovir) for improved long-term developmental and hearing outcomes; dosage adjustment if neutropenia develops
	Acquired CMV retinitis in immunocompromised host ^k	IV	Adult dose ^j	Treatment: 10 mg/kg per day, in 2 divided doses for 14–21 days; long-term suppression 5 mg/kg per day for 7 days/wk or 6 mg/kg per day for 5 days/wk; HIV: duration of maintenance treatment is for at least 3–6 mo, with no active lesions, and with CD4+ T-lymphocyte count >100 cells/mm ³ for 3 to 6 mo in response to ART
	Disseminated CMV and retinitis	IV	Infants, children, and adolescents	10 mg/kg per day, in 2 divided doses for 14–21 days; increase to 15 mg/kg/day in 2 divided doses if needed, then 5 mg/kg body weight once daily for 5–7 days per wk for chronic suppression; discontinuation after 6 mo may be considered in children 1–5 y if CD4+ T-lymphocyte count >500/m ³ (or CD4+ T-lymphocyte percentage ≥15%); stated doses presume CrCL >50 mL/min/1.73 m ² ; may add foscarnet (180 mg/kg per day divided into 2 or 3 doses) if vision at risk, or ganciclovir intravitreal injection or implant in children 9–12 y and adolescents

Table 4.10. Non-HIV Antiviral Drugs,^a continued

Generic (Trade Name)	Indication	Route	Age	Usually Recommended Dosage
	Prophylaxis of CMV in high-risk host (eg, post-transplant)	IV	All ages	10 mg/kg per day, in 2 divided doses for 5–7 days, then 5 mg/kg once daily for 100–120 days, or 6 mg/kg per day for 5 days/wk for 100 days
	Preemptive therapy of CMV in high-risk host (eg, <100 days post HCT)	IV	All ages	10 mg/kg per day, in 2 divided doses for 7–14 days, then 5 mg/kg once daily until CMV is not detectable (antigenemia, DNA PCR, or mRNA detection methods)
	>100 days post-HCT, OR receiving steroids for GVHD, OR if positive antigenemia or viremia/PCR x 2			10 mg/kg per day in 2 divided doses for 1–2 wk or until CMV undetectable
Glecaprevir/ Pibrentasvir (Mavyret)	Chronic hepatitis C (genotypes 1–6)	Oral	≥12 y, or weighing ≥45 kg	3 tablets (glecaprevir 100 mg/pibrentasvir 40 mg per tablet) (total daily dose: glecaprevir 300 mg/pibrentasvir 120 mg) once daily with food Duration: 8, 12, or 16 wk dependent on Rx-naïve vs Rx-experienced, genotype, prior vs concurrent therapy with NS3/4A protease inhibitor vs NS5A inhibitor, or other anti-hepatitis C drugs, and no cirrhosis vs compensated cirrhosis; refer to package insert for table of recommended lengths of treatment; numerous drug interactions complicates management

Table 4.10. Non-HIV Antiviral Drugs,^a continued

Generic (Trade Name)	Indication	Route	Age	Usually Recommended Dosage
				Test for HBV coinfection before treatment initiation Contraindicated in patients with moderate or severe hepatic impairment (Child-Pugh B or C) or those with any history of prior hepatic decompensation Hepatitis C therapy recommendations change rapidly, refer to most current AASLD/IDSA recommendations for appropriate treatment regimen
		Oral	3–11 y	The oral pellet formulation is recommended for children weighing less than 45 kg. Each packet contains glecaprevir 50 mg and pibrentasvir 20 mg. <20 kg: 3 packets (total daily dose: glecaprevir 150 mg and pibrentasvir 60 mg) once daily 20–<30 kg: 4 packets (total daily dose: glecaprevir 200 mg and pibrentasvir 80 mg) once daily 30–< 45kg: 5 packets (total daily dose: glecaprevir 250 mg and pibrentasvir 100 mg) once daily Test for HBV coinfection before treatment initiation Contraindicated in patients with moderate or severe hepatic impairment (Child-Pugh B or C) or those with any history of prior hepatic decompensation Hepatitis C therapy recommendations change rapidly, refer to most current AASLD/IDSA recommendations for appropriate treatment regimen

Table 4.10. Non-HIV Antiviral Drugs,^a continued

Generic (Trade Name)	Indication	Route	Age	Usually Recommended Dosage
Lamivudine ^{b,i} (Epivir-HBV)	Chronic hepatitis B	Oral	Infants and children (HIV/ HBV coinfectd)	Children coinfectd with HIV and hepatitis B should use the approved dose for HIV Dosing is weight based Refer to the package insert for details Tablets (150-mg scored tablets) are the preferred formulation 14 to <20 kg: 75 mg BID ≥20 to <25 kg: 75 mg AM dose + 150 mg PM dose ≥25 kg: 150 mg BID Oral solution dosing: 5 mg/kg/dose (max 150 mg/dose) twice daily; standard dosing for patients with CrCL >50 mL/min/1.73 m²; monitor for lamivudine-resistance Nonpreferred regimen. Refer to AASLD 2018 hepatitis B guidance for preferred and nonpreferred treatment regimens and duration of therapy
		Oral	Adolescents (HIV/ HBV coinfectd)	Children coinfectd with HIV and hepatitis B should use the approved dose for HIV 300 mg, once daily, or 150 mg, twice daily; standard dosing for patients with CrCL >50 mL/min Nonpreferred regimen; Refer to AASLD 2018 hepatitis B guidance for preferred and nonpreferred treatment regimens and duration of therapy

Table 4.10. Non-HIV Antiviral Drugs,^a continued

Generic (Trade Name)	Indication	Route	Age	Usually Recommended Dosage
Ledipasvir (Harvoni as combination with sofosbuvir)	Chronic hepatitis C (genotypes 1, 4, 5, 6)	Oral	Infants and children (HIV negative)	3 mg/kg/dose, once daily (max of 100 mg per day); use oral solution for doses <100 mg Nonpreferred regimen; Refer to AASLD 2018 hepatitis B guidance for preferred and nonpreferred treatment regimens and duration of therapy
		Oral	Adolescents (HIV negative)	100 mg, once daily Nonpreferred regimen. Refer to AASLD 2018 Hepatitis B Guidance for preferred and nonpreferred treatment regimens and duration of therapy
		Oral	Children ≥3 y and adults	Harvoni dosing: <17 kg: 33.75 mg ledipasvir/150 mg sofosbuvir 17 kg to less than 35 kg: 45 mg ledipasvir/200 mg sofosbuvir ≥35 kg: 90 mg ledipasvir/400 mg sofosbuvir (adult dose: 90 mg ledipasvir/400 mg sofosbuvir) Ribavirin also may be added, based on genotype, cirrhosis, and liver transplant status; when used, ribavirin dosing is as follows (only available in 200-mg capsule in the US): Children: <47 kg: 15 mg/kg/day, in 2 divided doses 47–59 kg: 400 mg BID 60–73 kg: 400 mg in AM and 600 mg PM >73 kg: 600 mg BID

Table 4.10. Non-HIV Antiviral Drugs,^a continued

Generic (Trade Name)	Indication	Route	Age	Usually Recommended Dosage
				Adults: <75 kg: 400 mg in AM and 600 mg in PM ≥75 kg: 600 mg in AM and PM Dosage modification of ribavirin based on treatment-emergent anemia (after interferon adjustment) and severe renal impairment; discontinue if severe blood dyscrasias or creatinine >2 g/dL Duration 12–24 wk dependent on genotype and prior treatment experience Test for HBV coinfection before treatment initiation Hepatitis C therapy recommendations change rapidly, refer to most current AASLD/IDSA recommendations for appropriate treatment regimen
Letermovir (Prevymis)	CMV prophylaxis in seropositive patients after HCT	IV, Oral	Adults	480 mg daily, IV or oral (240 mg per day in patients taking cyclosporine), starting 0–28 between days post-transplantation and continued through day 100 post-transplantation
Maribavir (Livtency)	Treatment of refractory post-transplant CMV infection/disease	Oral	≥12 y and weighing ≥35 kg	400 mg twice daily
Nirmatrelvir plus ritonavir (Paxlovid)	Mild-to-moderate COVID-19 disease	Oral	≥12 y and weighing ≥40 kg	300 mg nirmatrelvir with 100 mg ritonavir, PO, twice daily for 5 days Available under emergency use authorization Has numerous drug-drug interactions; Consult listing on FDA or Pfizer websites prior to prescribing

Table 4.10. Non-HIV Antiviral Drugs,^a continued

Generic (Trade Name)	Indication	Route	Age	Usually Recommended Dosage
Oseltamivir ^{b,1} (Tamiflu)	Influenza A and B: treatment (see Influenza, p 511)	Oral (suspension)	Birth to <9 mo ^m	3 mg/kg twice daily for 5 days ^m ; longer treatment can be considered for patients still severely ill after 5 treatment days
		Oral (suspension)	9–11 mo	3.5 mg/kg twice daily for 5 days; longer treatment can be considered for patients still severely ill after 5 treatment days
		Oral (suspension and tablets)	1–12 y	≤15 kg: 30 mg, twice daily; 15.1–23 kg: 45 mg, twice daily; 23.1–40 kg: 60 mg, twice daily; >40 kg: 75 mg, twice daily Treatment duration is for 5 days; longer treatment can be considered for patients still severely ill after 5 treatment days; half-dose given after dialysis session
		Oral (tablets)	≥13 y	75 mg, twice daily for 5 days; longer treatment can be considered for patients still severely ill after 5 treatment days; 30 mg given after dialysis session
	Influenza A and B: prophylaxis	Oral	3 mo–12 y	Same as the above treatment doses for patients 3 mo–12 y of age, except dose given once rather than twice daily, and given for 10 days rather than 5 (following known household exposure; 7 days for others) or for up to 6 wk (pre-exposure during community outbreak); not routinely recommended for infants <3 mo given lack of efficacy data
		Oral	≥13 y	75 mg, once daily for 10 days (following known household exposure; 7 days for others) or for up to 6 wk (pre-exposure during community outbreak); dosage adjustments for moderate to severe renal insufficiency in adults

Table 4.10. Non-HIV Antiviral Drugs,^a continued

Generic (Trade Name)	Indication	Route	Age	Usually Recommended Dosage
Peramivir ^b (Rapivab)	Influenza A and B	IV	≥6 mo	6 mo to <13 y: 12 mg/kg, once (max dose: 600 mg) ≥13 y: 600 mg, once; full dose for CrCL of ≥50 mL/min/1.73 m ² Renal dosing required for CrCl <50 mL/min
Remdesivir (Veklury)	SARS-CoV-2 infection requiring hospitalization, or not hospitalized but with mild-to-moderate COVID-19 and are at high risk for progression to severe COVID-19	IV	≥28 days and weighing ≥3 kg	Adults and pediatric patients weighing ≥40 kg: Single IV loading dose of 200 mg on day 1, followed by maintenance IV doses of 100 mg QD on and after day 2 Pediatric patients ≥28 days weighing 3.0 kg through <40 kg: Single IV loading dose of 5.0 mg/kg on day 1, followed by maintenance IV doses of 2.5 mg/kg QD on and after day 2 Treatment duration 10 days if requiring mechanical ventilation and/or ECMO, or 5 days if hospitalized but not requiring mechanical ventilation or ECMO, or 3 days if nonhospitalized with mild-to-moderate COVID-19 and at high risk for progression to severe COVID-19
Sofosbuvir (Sovaldi)	Chronic hepatitis C (genotype 1, 2, 3, 4, depending on adult (all four genotypes) or pediatric (genotypes 2 or 3)	Oral	Children ≥3 y and Adults	Sofosbuvir dosing: <17 kg: 150 mg 17 kg to less than 35 kg: 200 mg ≥35 kg: 400 mg (adult dose: 400 mg) Take once daily with or without food, as a component of combination therapy with other direct-acting antivirals (eg, daclatasvir), ribavirin, or with ribavirin plus pegylated interferon; length of treatment depending on HCV genotype and concomitant therapy used

Table 4.10. Non-HIV Antiviral Drugs,^a continued

Generic (Trade Name)	Indication	Route	Age	Usually Recommended Dosage
				Ribavirin dosing (limited availability, 200-mg capsules only in US): Children: <47 kg: 15 mg/kg/day, in 2 divided doses 47–59 kg: 400 mg BID 60–73 kg: 400 mg in AM and 600 mg in PM >73 kg: 600 mg BID Adults: <75 kg: 400 mg in AM and 600 mg in PM ≥75 kg: 600 mg in AM and PM Dosage modification of ribavirin based on treatment-emergent anemia (after interferon adjustment) and severe renal impairment; discontinue if severe blood dyscrasias or creatinine >2 g/dL Sofosbuvir available in a fixed-dose combination tablet with 90 mg ledipasvir (marketed as Harvoni) for use in children ≥3 y and adults Sofosyubir available in a fixed-dose combination tablet with 100 mg velpatasvir (marketed as Epclusa) for use in adults (includes ribavirin when decompensated cirrhosis present) Sofosbuvir has potential for reduced efficacy when combined with to P-glycoprotein inducers Test for HBV coinfection before treatment initiation Hepatitis C therapy recommendations change rapidly; refer to most current AASLD/IDSA recommendations for appropriate treatment regimen

Table 4.10. Non-HIV Antiviral Drugs,^a continued

Generic (Trade Name)	Indication	Route	Age	Usually Recommended Dosage
Tecovirimat (TPOXX)	Smallpox	Oral, IV	Children ≥3 kg and adults	Intravenous: 3 kg to <35kg: 6 mg/kg IV, every 12 hours for 14 days 35 kg to <120 kg: 200 mg IV, every 12 hours for 14 days ≥120 kg: 300 mg IV, every 12 hours for 14 days Oral: 13 kg to <25 kg: 200 mg PO, 2 times daily for 14 days 25 kg to <40 kg: 400 mg PO, 2 times daily for 14 days 40 kg to <120 kg: 600 mg PO, 2 times daily for 14 days ≥120 kg: 600 mg PO, 3 times daily for 14 days
	Mpox (through expanded access Investigational New Drug protocol held by CDC) (see Mpox, p 606)			Pediatric patients weighing 13 kg or more should be switched to oral dosing to complete the 14-day treatment course as soon as oral therapy can be tolerated
Tenofovir ^b disoproxil fumarate (Viread)	Chronic hepatitis B	Oral	Adolescents ≥12 y and weighing ≥35 kg, with or without HIV coinfection, adults	300 mg, once daily; adjustment of dosing interval recommended for CrCL <50 mL/min); monitor liver function and bone density
			≥2 y and at least 10 kg, with or without HIV coinfection	General dosing: 8 mg/kg/dose once daily; weight band dosing of reduced strength tablets and oral powder formulations. Test for HIV before treatment initiation Severe acute exacerbations of hepatitis B have been reported in patients who discontinue anti-hepatitis B therapy Refer to AASLD 2018 hepatitis B guidance for information on monitoring, toxicity, and duration of therapy

Table 4.10. Non-HIV Antiviral Drugs,^a continued

Generic (Trade Name)	Indication	Route	Age	Usually Recommended Dosage
Tenofovir alafenamide fumarate (Vemlidy)	Chronic hepatitis B	Oral	Adult or ≥12 y	25 mg once daily with food; no need for renal dose adjustment but not recommended for CrCL<15 mL/min) Test for HIV before treatment initiation Severe acute exacerbations of hepatitis B have been reported in patients who discontinue anti-hepatitis B therapy Refer to AASLD 2018 hepatitis B guidance for information on monitoring, toxicity, and duration of therapy
Valacyclovir ^b (Valtrex)	Varicella	Oral	2 to <18 y	20 mg/kg, 3 times daily for 5 days, not to exceed 1 g per dose, longer if lesions unresolved; same dose for up to 6 wk after initial IV acyclovir treatment of acute retinal necrosis; HIV: same dose for 4–6 wk
	Genital HSV infection, first episode	Oral	Adult and adolescent dose	2 g/day, in 2 divided doses for 10 days (5–14 days in people with HIV); longer duration if lesions incompletely healed
			Children	<45 kg: 40 mg/kg/day in 2 divided doses ≥45 kg: 2 g/day, in 2 divided doses 7–10 days of treatment
	Episodic recurrent genital HSV infection	Oral	Adult	1 g/day, in 2 divided doses for 3 days, or 1 g/day, once daily, for 5 days; people with HIV should receive 2 g/day for 5–14 days
		Oral	Adolescent and children	>50 kg: 1000 mg once daily for 5 days <50 kg: 40 mg/kg/day in 2 divided doses

Table 4.10. Non-HIV Antiviral Drugs,^a continued

Generic (Trade Name)	Indication	Route	Age	Usually Recommended Dosage
Valganciclovir ^b (Valcyte)	Daily suppressive therapy for recurrent genital HSV infection	Oral	Adult dose ^j	Immunocompetent patients: 1000 mg, once daily for 1 y starting within 24 hours of symptom onset or assess history of recurrences (eg, 500 mg, once daily, in patients with ≤9 recurrences per y to reduce transmission) People with HIV (CD4+ T-lymphocyte count ≥100 cells/ mm ³): 500 mg, twice daily for at least 6 mo
			Adolescent and children	20 mg/kg/dose once daily (max daily dose: 500 mg or 1 g; the lower dose is less effective if frequent recurrences [eg, ≥10/y]) HIV: 500 mg, twice daily for indefinite duration; acyclovir for young children
	Recurrent herpes labialis	Oral	≥12 y	4 g/day, in 2 divided doses for 1 day HIV: 2 g/day in 2 divided doses for 5–10 days
	Herpes zoster	Oral	Adult and adolescent dose ^j	3 g/day, in 3 divided doses for 7 days
Valganciclovir ^b (Valcyte)	Congenital CMV disease	Oral	Birth through 6 mo	32 mg/kg per day, in 2 divided doses, started within the first 13 wk following birth and continued for a total of 6 mo of treatment if moderate-severe symptomatic disease, or for a total of 6 wk of treatment if isolated sensorineural hearing loss; dosage adjustment if neutropenia or renal impairment develops; mildly symptomatic or asymptomatic patients should not receive antiviral therapy; see Table 3.4, p 349

Table 4.10. Non-HIV Antiviral Drugs,^a continued

Generic (Trade Name)	Indication	Route	Age	Usually Recommended Dosage
	Acquired CMV retinitis in immunocompromised host	Oral	Adult and adolescent dose ^j	Induction treatment: 900 mg, twice daily for 2–3 wk Long-term suppression: 900 mg, once daily HIV: duration of maintenance treatment is for at least 3–6 mo, with lesions inactive, and with CD4+ T-lymphocyte count >100 cells/mm ³ for 3 mo to 6 mo in response to ART
	Prevention of CMV disease in kidney, liver, or heart transplant patients	Oral	4 mo–16 y	Dose once a day within 10 days of transplantation according to dosage algorithm based on body surface area and creatinine clearance: Dose (mg) = 7 x body surface area x CrCL (calculated using the Schwartz equation with max value set at 150 mL/ min/1.73 m ² ; see drug package insert; max 900 mg/day); round dose to the nearest 10-mg increment with solution; duration depends on type of transplant and risk status: 200 days after renal transplant, 100 days after heart or liver transplant Some experts recommend: 10 mg/kg/day, in 1 to 2 divided doses per day (max 900 mg/day), round dose to the nearest 10-mg increment with solution; duration depends on type of transplant and risk status: 200 days after renal transplant, 100 days after heart or liver transplant
		Oral	Adolescents ≥17 y	900 mg, once daily, for post-transplant patients; duration in children depends on type of transplant and risk status: 200 days after renal transplant, 100 days after heart or liver transplant

Table 4.10. Non-HIV Antiviral Drugs,^a continued

Generic (Trade Name)	Indication	Route	Age	Usually Recommended Dosage
	Prevention of CMV disease in people with HIV (CMV-seropositive children ≥6 y with CD4+ T-lymphocyte counts <50 cells/mm ³ or <6 y who are CMV-seropositive and have a CD4+ T-lymphocyte percentage <5%)	Oral	4 mo–16 y	Same calculated dose regimen as above; duration: stopping primary prophylaxis can be considered when the CD4+ T-lymphocyte count is >100 cells/mm ³ for children ≥6 y, or CD4+ T-lymphocyte percentage is >10% in children <6 y
Velpatasvir (Epclusa as combination with sofosbuvir)	Chronic hepatitis C (genotypes 1–6)	Oral	Children ≥3 y and adults	<17 kg: 37.5 mg with 150 mg sofosbuvir once daily 17 kg to less than 30 kg: 50 mg with 200 mg sofosbuvir once daily ≥30 kg: 100 mg with 400 mg sofosbuvir once daily Duration 12–24 wk dependent on prior treatment experience, concurrent ribavirin use Test for HBV coinfection before treatment initiation Hepatitis C therapy recommendations change rapidly; refer to most current AASLD/IDSA recommendations for appropriate treatment regimen

Table 4.10. Non-HIV Antiviral Drugs,^a continued

Generic (Trade Name)	Indication	Route	Age	Usually Recommended Dosage
Voxilaprevir (Vosevi as combination with sofosbuvir and velpatasvir)	Chronic hepatitis C (genotypes 1–6)	Oral	Adults	100 mg combined with 400 mg sofosbuvir and 100 mg, velpatasvir once daily; taken with food; duration: 12 wk for all genotypes and treatment-experienced patient regimens Test for HBV coinfection before treatment initiation Hepatitis C therapy recommendations change rapidly, refer to most current AASLD/IDSA recommendations for appropriate treatment regimen
Zanamivir (Relenza)	Influenza A and B: treatment (see Influenza, p 511)	Inhalation	≥7 y (treatment)	10 mg (2 inhalations, one 5-mg powder blister per inhalation), twice daily for 5 days; first 2 doses can be separated by as little as 2 hours; only use Diskhaler device; longer treatment can be considered for patients still severely ill after 5 treatment days
	Influenza A and B: prophylaxis	Inhalation	≥5 y (prophylaxis)	10 mg (2 inhalations, one 5-mg powder blister per inhalation), once daily for 10 days; CDC recommends continuing chemoprophylaxis for 7 days after last known exposure

ART indicates combination antiretroviral therapy; BID, twice a day; CDC, Centers for Disease Control and Prevention; CrCL, creatinine clearance; CNS, central nervous system; CSF, cerebrospinal fluid; FDA, US Food and Drug Administration; GVHD, graft-versus-host disease; HBeAg, hepatitis B envelope antigen; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HCT, hematopoietic cell transplant; HSV, herpes simplex virus; IM, intramuscular; IV, intravenous; NIH, National Institutes of Health; PCR, polymerase chain reaction; QD, once a day; SC, subcutaneous; SEM, skin, eyes, and/or mouth; VZV, varicella-zoster virus.

^aDrugs for human immunodeficiency virus infection are not included. See <https://hivinfo.nih.gov/home-page> for current information on HIV drugs and treatment recommendations.

^bDose should be decreased in patients with impaired renal function.

^cOral dosage of acyclovir in children should not exceed 80 mg/kg per day (3200 mg/day).

^dAcyclovir doses listed in this table are based on clinical trials and clinical experience and may not be identical to doses approved by the FDA.

Table 4.10. Non-HIV Antiviral Drugs,^a continued

Generic (Trade Name)	Indication	Route	Age	Usually Recommended Dosage
-------------------------	------------	-------	-----	----------------------------

^eIn times of shortage of intravenous acyclovir, the American Academy of Pediatrics Committee on Infectious Diseases recommends that existing supplies of intravenous acyclovir be conserved to improve availability for neonatal HSV infections, herpes simplex encephalitis, or HSV and varicella-zoster virus infections in immunocompromised patients, including more ill pregnant women with visceral dissemination of either virus. If acyclovir is not available, intravenous ganciclovir should be substituted. Alternative regimens to the use of intravenous acyclovir and other options for priority and nonpriority conditions are outlined in an exclusive *Red Book Online* Intravenous Acyclovir Shortage Table (<https://publications.aap.org/redbook/resources/15648/Intravenous-Acyclovir-Shortage-Recommendations-for?searchresult=1>).

^fMonitor for nephrotoxicity and neurologic irritation. Consider involving an infectious diseases or pharmacology specialist if weight-based dosing exceeds 800 mg per dose or if being administered with other nephrotoxic medications.

^gUse estimate of ideal body weight in children and adolescents with severe obesity.

^hSelective indications; see Varicella-Zoster Infections (p 938).

ⁱ“Nonpreferred” for treatment of chronic hepatitis B in the American Association for the Study of Liver Diseases 2018 hepatitis B guidance document (https://journals.lww.com/hep/Fulltext/2018/04000/Update_on_prevention_diagnosis_and_treatment_of.34.aspx).

^jThere are not sufficient clinical data to identify the appropriate dose for use in children.

^kSome experts use ganciclovir in immunocompromised hosts with CMV gastrointestinal tract disease and CMV pneumonitis (with or without CMV immune globulin intravenous).

^lSee Influenza (p 511) and www.cdc.gov/flu/professionals/antivirals/index.htm for specific recommendations, which may vary on the basis of most recent influenza virus susceptibility patterns.

^mPreterm, <38 weeks’ postmenstrual age, oseltamivir, 1.0 mg/kg/dose, orally, twice daily; preterm, 38 through 40 weeks’ postmenstrual age, 1.5 mg/kg/dose, orally, twice daily; preterm >40 weeks’ postmenstrual age through 8 months’ chronologic age, 3.0 mg/kg/dose, orally, twice daily.

For more information on individual drugs, refer to FDA package inserts (www.accessdata.fda.gov/scripts/cder/daf/index.cfm).

..... DRUGS FOR PARASITIC INFECTIONS

Table 4.11. Drugs for Parasitic Infections¹

Disease	Drug	Adult Dosage	Pediatric Dosage	Links to CDC Website ² and professional society guidelines
Ascariasis (<i>Ascaris lumbricoides</i> ; intestinal roundworm)	Albendazole ³	400 mg, orally, once (take with food)		www.cdc.gov/parasites/ascariasis/health_professionals/index.html
	OR			
	Mebendazole ⁴	100 mg, orally, twice daily for 3 days OR 500 mg, orally, once		
	OR			
	Ivermectin ⁵	150–200 µg/kg, orally, once (take on an empty stomach with water)		
	OR			
	Pyrantel pamoate ⁶	11 mg/kg (up to a maximum of 1 g/dose), orally, daily for 3 days (may be given as a single dose for adults)		
	OR			
	Nitazoxanide ⁷	500 mg, orally, twice daily for 3 days (take with food)	Age 1–3 y: 100 mg, orally, twice daily for 3 days Age 4–11 y: 200 mg, orally, twice daily for 3 days Age ≥12 y: 500 mg, orally, twice daily for 3 days (take with food)

	Nifurtimox ⁶⁸	8–10 mg/kg/day, orally, in 3 divided doses for 60 days; doses for ages over 17 years are off-label	Age birth to <18 years of age and 2.5 kg to less than 41 kg: 10–20 mg/kg/day, orally, in 3 divided doses for 60 days Age birth to <18 years of age and greater than or equal to 41 kg: 8–10 mg/kg/day, orally, in 3 divided doses for 60 days	
Trypanosomiasis, human African (HAT) (sleeping sickness; <i>Trypanosoma brucei rhodesiense</i> and <i>Trypanosoma brucei gambiense</i> infection)	Please see CDC guidance or WHO interim guidance for treatment of <i>gambiense</i> HAT; consultation with infectious disease or subject matter experts recommended when treating patients with HAT			www.cdc.gov/parasites/sleepingsickness/health_professionals/index.html CDC Drug Service: www.cdc.gov/laboratory/drugservice/formulary.html https://apps.who.int/iris/bitstream/handle/10665/326178/9789241550567-eng.pdf

CDC indicates Centers for Disease Control and Prevention; CNS, central nervous system; FDA, US Food and Drug Administration; IM, intramuscular; IV, intravenous.

¹ The contents of this table are provided to assist in decision making for patient management but are not a substitute for clinical judgment or expert consultation. The table may not address drug toxicities, drug-drug interactions, and issues pertinent to some special populations (eg, patients with HIV/AIDS). Recommendations in the table may not represent all potential treatment or dosage options.

² See CDC website for additional information on each disease and the treatment thereof. Not all recommended therapies and dosages included in this table match the recommendations on the pathogen-specific CDC web pages. Inclusion of the links to the CDC website does not suggest endorsement of the content of this table by the CDC.

Table 4.11. Drugs for Parasitic Infections,¹ continued

- ³ Safety of albendazole in children younger than 6 years is not certain. Studies of the use of albendazole in children as young as 1 year suggest that its use is safe. Albendazole should be taken with food when systemic absorption is desired. Some anthelmintics are very costly in the United States. The FDA website BeSafeRx (www.fda.gov/drugs/buying-using-medicine-safely/quick-tips-buying-medicines-over-internet) provides information for providers and patients who are considering online pharmacies that may provide drugs at lower cost.
- ⁴ Mebendazole is approved for some specific indications in children ages 2 and older. Safety has not been established in children; data are limited in children younger than 2 year. Some anthelmintics are very costly in the United States. The FDA website BeSafeRx (www.fda.gov/drugs/buying-using-medicine-safely/quick-tips-buying-medicines-over-internet) provides information for providers and patients who are considering online pharmacies that may provide drugs at lower cost.
- ⁵ Safety of ivermectin in treating pregnant people and children who weigh less than 15 kg has not been established. Ivermectin should be taken on an empty stomach with water.
- ⁶ Safety of pyrantel pamoate in children has not been established. According to WHO guidance on preventive chemotherapy, pyrantel may be used in children 1 year and older during mass treatment programs without diagnosis.
- ⁷ Not approved by the FDA for this indication.
- ⁸ The combination of clindamycin plus quinine, or the combination of IV azithromycin plus oral atovaquone, are options for treatment of babesiosis in patients who are severely ill.
- ⁹ Cases of cholestatic hepatitis, elevated liver enzymes, and fatal liver failure have been reported in patients treated with atovaquone.
- ¹⁰ Some immunocompromised adults with babesiosis have been treated with doses of azithromycin in the range of 600–1000 mg/day, in combination with atovaquone (750 mg twice per day).
- ¹¹ Quinine treatment is associated with thrombocytopenia, QT prolongation, ventricular arrhythmias, hypoglycemia, and serious hypersensitivity reactions. Neuromuscular blocking agents should be avoided in patients receiving quinine sulfate. Use with caution in patients with atrial fibrillation or atrial flutter.
- ¹² Tetracycline should be taken 1 hour before or 2 hours after meals containing dairy, and at least 1–2 hours before or 4 hours after an antacid. Tetracycline is not indicated for use in children younger than 8 years.
- ¹³ Iodoquinol should be taken after meals. Iodoquinol tablets currently are not available in the United States.
- ¹⁴ In cases in which suspicion of exposure is high, immediate treatment with albendazole (25–50 mg/kg/day, orally, for 10–20 days) may be appropriate. Treatment is successful when administered soon after exposure to abort the migration of larvae and should be initiated as soon as possible after ingestion of infectious material, ideally within 3 days. When given in this setting, take albendazole on an empty stomach. For clinical baylisascariasis, treatment with albendazole (take with food) with concurrent corticosteroids to help reduce the inflammatory reaction is indicated to attempt to control the disease.
- ¹⁵ Clinical significance of *Blasotocystis* species is controversial.
- ¹⁶ Praziquantel is not approved for treatment of children younger than 4 years. Take with water during meals.
- ¹⁷ There are no drug regimens with proven efficacy for the treatment of cryptosporidiosis in immunosuppressed patients.
- ¹⁸ HIV-infected patients may need longer courses of therapy for cyclosporiasis.
- ¹⁹ Expert consultation for treatment of cystoisosporiasis is recommended if the patient is immunosuppressed.
- ²⁰ Niclosamide is not available for human use in the United States. Chew thoroughly or crush and mix with a small amount of water.
- ²¹ Asymptomatic infections generally do not require treatment; when *D. fragilis* is the sole organism found in a patient with abdominal pain or diarrhea for a week or more treatment is appropriate.
- ²² Tetracycline or doxycycline also have been used for treatment.
- ²³ See text in Other Tapeworm Infections (Including Hydatid Disease), p 845. Management depends on type and location of cysts, may involve surgery, and collaboration with specialists with experience treating this infection is advised. Albendazole is not appropriate for all forms of infection.
- ²⁴ Diloxanide furoate is not commercially available in the United States.
- ²⁵ Triclabendazole is approved by the FDA for treatment of fascioliasis in children 6 years and older. Safety and effectiveness of triclabendazole in children younger than 6 years have not been established.
- ²⁶ Alternative treatments for giardiasis include albendazole, mebendazole, paromomycin, quinacrine, and furazolidone.

Table 4.11. Drugs for Parasitic Infections,¹ continued

- ²⁷ Questions about treatment of leishmaniasis should be directed to Parasitic Diseases Inquiries (404-718-4745; e-mail parasites@cdc.gov). Only selected antileishmanial agents and regimens are listed in the table. Sodium stibogluconate is not currently being manufactured. Expert consultation about these and other potential treatment options for leishmaniasis is encouraged. For some cases of cutaneous leishmaniasis, no therapy may be needed or local (vs systemic) therapy may suffice or other systemic treatments may be considered. Miltefosine (IMPAVIDO) was approved in March 2014 by the FDA—for treatment of visceral leishmaniasis caused by *L. donovani*; mucosal leishmaniasis caused by *L. (Viannia) braziliensis*; and cutaneous leishmaniasis caused by *L. (V) braziliensis*, *L. (V) guyanensis*, and *L. (V) panamensis* (ie, some New World cutaneous leishmaniasis species but no Old World cutaneous leishmaniasis species)—for patients who are at least 12 years of age, weigh at least 30 kg, and are not pregnant or breastfeeding during or for 5 months after the treatment course.
- ²⁸ Pentam 300 contains 300 mg of pentamidine isethionate salt per vial.
- ²⁹ Pediculicides should not be used for infestations of the eyelashes. Such infestations are treated with petrolatum ointment applied 2 to 4 times/day for 10 days. For pubic lice, treat with 1% permethrin, pyrethrins with piperonyl butoxide, or ivermectin.
- ³⁰ Permethrin and pyrethrin are pediculicidal; retreatment in 9–10 days is needed to eradicate the infestation. Some lice are resistant to pyrethrins and permethrin. Pyrethrins with piperonyl butoxide are recommended for use in children ≥2 years of age; permethrin for children ≥2 months of age.
- ³¹ Ivermectin is not ovicidal, but lice that hatch from treated eggs die within 48 hours after hatching. Recommended for use in children ≥6 months of age.
- ³² Spinosad causes neuronal excitation in insects leading to paralysis and death. The formulation also includes benzyl alcohol, which is pediculicidal. Two applications 7 days apart are needed. Recommended for children ≥6 months of age.
- ³³ Benzyl alcohol prevents lice from closing their respiratory spiracles, and the lotion vehicle then obstructs their airway, causing them to asphyxiate. It is not ovicidal. Two applications 9–10 days apart are needed. Recommended for use in children ≥6 months of age. Resistance, which is a problem with other drugs, is unlikely to develop.
- ³⁴ Malathion is both ovicidal and pediculicidal; 2 applications 7–9 days apart are generally necessary to kill all lice and nits. Recommended for children ≥6 years of age and contraindicated in children <24 months of age. Malathion is flammable. Do not smoke or use electrical heat sources (ie, hair dryer, curling iron, flat iron) when applying and while the hair is wet.
- ³⁵ Abametapir is ovicidal. Contains benzyl alcohol. Use is not recommended in pediatric patients younger than 6 months because of the potential for increased systemic absorption. Not available in the United States as of March 23, 2023.
- ³⁶ Ivermectin is pediculicidal but not ovicidal; more than 1 dose is generally necessary to eradicate the infestation. The number of doses and the interval between doses have not been established; animal studies have shown adverse effects on the fetus. A single oral dose of 200 µg/kg, repeated in 7–10 days, has been shown to be effective against head lice. Most recently, a single oral dose of 400 µg/kg, repeated in 7 days, has been shown to be more effective than 0.5% malathion lotion.
- ³⁷ Diethylcarbamazine (DEC) is not approved by the FDA but is available through the CDC Drug Service under an IND protocol; questions should be directed to Parasitic Diseases Inquiries (404-718-4745; e-mail parasites@cdc.gov). DEC is contraindicated in patients who may also have onchocerciasis. Before DEC therapy for lymphatic filariasis or loiasis, onchocerciasis should be excluded in all patients with a consistent exposure history because of the possibility of severe exacerbations of skin and eye involvement (Mazzotti reaction). People coinfecting with *L. loa* and *O. volvulus* should not be treated with DEC until the onchocerciasis is treated; their onchocerciasis should not be treated with ivermectin if it is unsafe to treat their loiasis.
- ³⁸ Apheresis should be performed at an institution with experience in using this therapeutic modality for loiasis.
- ³⁹ Doxycycline is not standard treatment for lymphatic filariasis, but some studies have shown adult-worm killing with doxycycline therapy (200 mg/day for 4–6 weeks).
- ⁴⁰ If a person develops malaria despite taking chemoprophylaxis, that particular medicine should not be used as a part of his or her treatment regimen. Use one of the other options instead.
- ⁴¹ There are 4 options available for treatment of uncomplicated malaria caused by chloroquine-resistant *P. falciparum*. The first 3 options are equally recommended. Because of a higher rate of severe neuropsychiatric reactions seen at treatment doses, mefloquine is not recommended unless the other options cannot be used. Because there are more data on the efficacy of quinine in combination with doxycycline or tetracycline, these treatment combinations generally are preferred to quinine in combination with clindamycin.
- ⁴² Atovaquone-proguanil or artemether-lumefantrine should be taken with food or whole milk. If patient vomits within 30 minutes of taking a dose, the dose should be repeated. Atovaquone-proguanil not recommended during pregnancy or in people breastfeeding infants weighing <5 kg. May be considered if other treatment options are not available or not tolerated and benefits outweigh risks. Adult tablet = 250 mg atovaquone/100 mg proguanil. Pediatric tablet = 62.5 mg atovaquone/25 mg proguanil.

Table 4.11. Drugs for Parasitic Infections,¹ continued

- ⁴³ US-manufactured quinine sulfate capsule is in a 324-mg dosage; therefore, 2 capsules should be sufficient for adult dosing. Pediatric dosing may be difficult because of unavailability of noncapsule forms of quinine.
- ⁴⁴ For infections acquired in Southeast Asia, quinine treatment should continue for 7 days. For infections acquired elsewhere, quinine treatment should continue for 3 days.
- ⁴⁵ Tetracycline is not indicated for use in children younger than 8 years. Doxycycline can be administered without regard to the patient's age or required duration of therapy (see Tetracyclines, p 975). For children younger than 8 years and weighing >5 kg with chloroquine-resistant *P falciparum*, atovaquone-proguanil and artemether-lumefantrine are recommended treatment options; mefloquine can be considered if no other options are available. For children younger than 8 years with chloroquine-resistant *P vivax*, mefloquine, or in those weighing >5 kg, atovaquone-proguanil or artemether-lumefantrine, are treatment options.
- ⁴⁶ Treatment with mefloquine is not recommended in people who have acquired infections from Southeast Asia because of drug resistance.
- ⁴⁷ When treating chloroquine-sensitive infections, chloroquine and hydroxychloroquine are recommended options. Regimens used to treat chloroquine-resistant infections may also be used if available, more convenient, or preferred.
- ⁴⁸ Primaquine and tafenoquine are used to eradicate any hypnozoites that may remain dormant in the liver and, thus, prevent relapses in *P vivax* and *P ovale* infections. Because both drugs can cause hemolytic anemia in glucose-6-phosphate dehydrogenase (G6PD)-deficient people, G6PD screening must occur prior to starting treatment with primaquine or tafenoquine. For people with borderline G6PD deficiency or as an alternate to the above regimen, primaquine, 45 mg, orally, once per week for 8 weeks may be given; consultation with an expert in infectious disease and/or tropical medicine is advised if this alternative regimen is considered in G6PD-deficient people. Primaquine and tafenoquine must not be used during pregnancy. Tafenoquine can only be used in conjunction with chloroquine phosphate or hydroxychloroquine and is only approved for use in people 16 years and older. Dose of primaquine in patients ≥ 70 kg should be adjusted to a total dose of 6 mg/kg, divided into doses of 30 mg per day.
- ⁴⁹ Four options are available for treatment of uncomplicated malaria caused by chloroquine-resistant *P vivax*. The first 3 options are equally recommended. Because of a higher rate of severe neuropsychiatric reactions seen at treatment doses, mefloquine is not recommended unless the other options cannot be used. High treatment failure rates attributable to chloroquine-resistant *P vivax* have been well documented in Papua New Guinea and Indonesia. Rare case reports of chloroquine-resistant *P vivax* also have been documented in Burma (Myanmar), India, and Central and South America. People acquiring *P vivax* infections outside of Papua New Guinea or Indonesia should be started on chloroquine. If the patient does not respond, treatment should be changed to a chloroquine-resistant *P vivax* regimen and the CDC should be notified (Malaria Hotline number listed previously).
- ⁵⁰ For pregnant people diagnosed with uncomplicated malaria caused by chloroquine-resistant *P falciparum* or chloroquine-resistant *P vivax* infection, treatment with doxycycline or tetracycline generally is not indicated. Doxycycline or tetracycline may be used in combination with quinine (as recommended for nonpregnant adults) if other treatment options are not available or are not being tolerated and the benefit is judged to outweigh the risks.
- ⁵¹ Atovaquone-proguanil generally is not recommended during pregnancy; artemether-lumefantrine is recommended in the second and third trimester and may be used in the first trimester when benefits outweigh risks.
- ⁵² For *P vivax* and *P ovale* infections, primaquine phosphate or tafenoquine for radical treatment of hypnozoites should not be given during pregnancy. Pregnant patients with *P vivax* and *P ovale* infections should be maintained on chloroquine prophylaxis for the duration of their pregnancy. The chemoprophylactic dose of chloroquine phosphate is 300 mg base (=500 mg salt), orally, once per week. After delivery, patients with normal G6PD activity may be treated with primaquine or tafenoquine, depending on breastfeeding, or continue with chloroquine prophylaxis for a total of 1 year from acute infection. Primaquine can be used during breastfeeding if the infant is found to have normal G6PD activity; tafenoquine is not recommended during breastfeeding.
- ⁵³ People with a positive blood smear OR history of recent possible exposure and no other recognized pathologic abnormality who have 1 or more of the following clinical criteria (impaired consciousness/coma, severe normocytic anemia, renal failure, pulmonary edema, acute respiratory distress syndrome, circulatory shock, disseminated intravascular coagulation, spontaneous bleeding, acidosis, hemoglobinuria, jaundice, repeated generalized convulsions, and/or parasitemia of $>5\%$) are considered to have manifestations of more severe disease. Severe malaria is most often caused by *P falciparum*.
- ⁵⁴ Patients with a diagnosis of severe malaria should be treated aggressively with parenteral antimalarial therapy. IV artesunate is now commercially available. If not in stock or available within 24 hours, contact CDC's Malaria Hotline.

Table 4.11. Drugs for Parasitic Infections,¹ continued

- ⁵⁵ Pregnant people diagnosed with severe malaria should be treated aggressively with parenteral antimalarial therapy.
- ⁵⁶ WHO guidelines recommend 3 mg/kg/dose IV artesunate for children <20 kg. See <https://app.magicapp.org/#/guideline/7661> and Haghir A, Price DJ, Fitzpatrick P, et al. Evidence Based Optimal Dosing of Intravenous Artesunate in Children with Severe Falciparum Malaria. *Clin Pharmacol Ther.* 2023;114(6):1304-1312.
- ⁵⁷ An investigational agent (non-FDA approved); not available in the United States at this time. For lesions attributable to *V. corneae*, topical therapy generally is not effective and keratoplasty may be required (RM Davis, Font RL, Keisler MS, Shadduck JA. Corneal microsporidiosis. A case report including ultrastructural observations. *Ophthalmology.* 1990;97[7]:953-957). Data are insufficient to make recommendations on the use of fumagillin in children (see Guidelines for the Prevention and Treatment of Opportunistic Infections in Children with and Exposed to HIV. Department of Health and Human Services. Available at: <https://clinicalinfo.hiv.gov/en/guidelines/pediatric-opportunistic-infection>)
- ⁵⁸ For gastrointestinal infections caused by *Enterocytozoon bienersi*, fumagillin, 20 mg, orally 3 times daily, is the only drug with proven efficacy. Its use is associated with severe thrombocytopenia in 30% to 50% of patients, which is reversible on discontinuation of treatment. The drug is not currently available in the United States.
- ⁵⁹ For intestinal infection without systemic involvement, albendazole should be taken on an empty stomach (for systemic infections, it should be taken with a fatty meal).
- ⁶⁰ There is no established treatment for *Pleistophora*. For disseminated disease attributable to *Trachipleistophora* or *Anncalia*, itraconazole, 400 mg, orally, once per day, plus albendazole 400 mg, orally, twice daily, may be tried.
- ⁶¹ Consultation with a specialist familiar with treatment of neurocysticercosis is advised. Although not all symptomatic patients with a single viable cyst of neurocysticercosis within brain parenchyma require antiparasitic medication, controlled studies demonstrate that clinical resolution and seizure recurrence rates are improved with albendazole. Two studies have demonstrated that in those with more than 2 viable intraparenchymal lesions, the response rate was better when albendazole was coadministered with praziquantel and corticosteroids. When a single agent is used, albendazole is preferred over praziquantel because it has fewer drug-drug interactions with anticonvulsants and steroids. The Centers for Disease Control and Prevention recommends 15 days of therapy, and suggests that more prolonged treatment courses (eg, 30 days of albendazole, which may be repeated) may be needed for extraparenchymal or extensive disease. Anti-inflammatory therapy is recommended when antiparasitic treatment is used though the optimal dose and duration have not been established. Commonly used regimens include dexamethasone 0.1 mg/kg/day (adult dose: 6 mg per day) or prednisone 1–2 mg/kg/day usually beginning at least 1 day before starting antiparasitic therapy, and continuing during treatment followed by a taper.
- ⁶² People coinfecting with *O. volvulus* and *L. loa* should not be treated with diethylcarbamazine (DEC) until the onchocerciasis is treated; their onchocerciasis should not be treated with ivermectin if it is unsafe to treat their loiasis. Patients should only be treated with doxycycline if they no longer live in areas with endemic infection unless there is a contraindication for ivermectin.
- ⁶³ Moxidectin approved in 2018 for children 12 years and older; not yet available commercially in the United States as of March 23, 2023. Screening for loiasis recommended before use. Safety and efficacy of repeat doses have not been studied. Safety and efficacy in children younger than 12 years have not been established.
- ⁶⁴ Doxycycline is not standard therapy, but several studies support its use and safety. Treatment with a single oral dose of ivermectin (150 µg/kg) should be given 1 week before treatment with doxycycline to provide symptom relief to the patient. If the patient cannot tolerate the dosage of 200 mg, orally, daily of doxycycline, 100 mg, orally, daily is sufficient to sterilize female *Onchocerca* organisms. A dose of 2.2 mg/kg twice daily may be used for children. The safety of ivermectin in children weighing less than 15 kg and in pregnant people has not been established.
- ⁶⁵ Albendazole preferred to mebendazole in ocular larva migrans (OLM) and CNS disease. Topical or systemic corticosteroids (prednisone 0.5–1 mg/kg/day) may be used to control inflammation in OLM and prednisone (0.5–1 mg/kg/day) may be used in severe visceral larva migrans. Length of therapy may be extended to 2 weeks in OLM; optimal dosing has not been established.
- ⁶⁶ For treatment and chronic suppression of toxoplasmosis in human immunodeficiency virus (HIV) infected children, see Guidelines for the Prevention and Treatment of Opportunistic Infections in Children with and Exposed to HIV. Department of Health and Human Services. Available at: <https://clinicalinfo.hiv.gov/en/guidelines/pediatric-opportunistic-infection>.
- ⁶⁷ In addition to antiparasitic medication, treatment with corticosteroids sometimes is required in more severe cases of trichinellosis.
- ⁶⁸ The 2 drugs used to treat infection with *T. cruzi* are benznidazole and nifurtimox. Benznidazole was approved in 2017 by the FDA for use in children 2–12 years of age for the treatment of Chagas disease. Use of benznidazole to treat a patient outside of the FDA-approved age range of 2–12 years is based on clinical diagnosis and decision making by a treating physician under practice of medicine. On August 6, 2020, the FDA announced approval of a nifurtimox product (LAMPIT [Bayer]) for treatment of Chagas disease in patients from birth to younger than 18 years weighing at least 2.5 kg. Use of nifurtimox to treat a patient outside of the FDA-approved age range of birth to younger than 18 years is based on clinical diagnosis and decision making by the treating physician under the practice of medicine. For both drugs, adverse effects are common and are more frequent and more severe with increasing age. Questions regarding treatment should be directed to Parasitic Diseases Public Inquiries (404-718-4745; email parasites@cdc.gov).

..... MEDWATCH—THE FDA SAFETY INFORMATION AND ADVERSE EVENT REPORTING PROGRAM

MedWatch, the Food and Drug Administration (FDA) Safety Information and Adverse Event Reporting Program, serves as a gateway for clinically important safety information and reporting of adverse events for human medical products, including FDA-regulated prescription and over-the-counter drugs, certain biologics (including gene therapies, human cells, tissues, and cellular and tissue-based products), medical devices (including in vitro diagnostics), special nutritional products, and cosmetics. MedWatch does not pertain to tobacco products, vaccines, or certain food products. MedWatch collects reports of drug adverse effects, product quality problems, product use errors, and therapeutic failures. Although reporting to MedWatch by health care professionals and consumers is voluntary, manufacturers of prescription medical products are required to submit adverse event reports to the FDA.

Because many prelicensure clinical trials are not large enough to reveal rare adverse events, postlicensure safety surveillance is used to identify and evaluate new safety concerns with drugs and devices after they are approved and widely used in clinical practice. MedWatch reports are used by the FDA as a pharmacovigilance data source. If a potential safety concern is identified through analysis of MedWatch reports, FDA's further evaluation might include conducting studies using other databases. On the basis of information from postmarketing safety surveillance, the FDA may take regulatory actions, such as revising and strengthening warnings, precautions, contraindications, and adverse reaction descriptions in medication package inserts or issuing "Dear Health Care Professional" letters. Safety alerts are published on the agency's website, and clinicians and the public can stay informed through email, X (formerly known as Twitter), and RSS feed updates. The FDA Adverse Event Reporting System (FAERS) Public Dashboard allows users to search publicly available information from adverse event reports submitted to the FDA.

Health care professionals and consumers are encouraged to report adverse events associated with medical products. Reports can be submitted online through the MedWatch Adverse Event Reporting system (www.fda.gov/MedWatch/report.htm) or the forms can be downloaded (www.fda.gov/safety/medical-product-safety-information/medwatch-forms-fda-safety-reporting) and sent by fax (800-FDA-0178) or mail. Phone reports can be made by calling 800-FDA-1088. A consumer-friendly reporting form (FDA3500B) is available to encourage increased reporting by patients. Vaccine-related adverse events should be reported to the Vaccine Adverse Event Reporting System (<http://vaers.hhs.gov/>).

..... ANTIMICROBIAL PROPHYLAXIS

Antimicrobial prophylaxis is defined as the use of antimicrobials in the absence of suspected or documented infection to prevent development of infection or disease. Antimicrobial prophylaxis is one of the most common indications for antimicrobial use in children, although its benefit has only been demonstrated for limited conditions or circumstances. Concerns about the emergence of resistant pathogens has led to a reexamination of the role of antimicrobial prophylaxis, especially for prevention of recurrent otitis media (OM) and urinary tract infection (UTI).

When using prophylactic antimicrobial therapy, the risks of development of antimicrobial resistance or having an adverse event from the antimicrobial must be weighed against potential benefits. Ideally, prophylactic agents should have a narrow spectrum of activity and be used for a brief period.

Infection-Prone Body Sites

Antimicrobial prophylaxis targeted at reducing infection at vulnerable body sites is most successful if the (1) period of risk is defined and brief; (2) expected pathogens have predictable antimicrobial susceptibility; and (3) antimicrobials achieve adequate concentrations in the targeted site.

ACUTE OTITIS MEDIA

Universal immunization of infants with pneumococcal conjugate vaccine has reduced the burden of acute otitis media (AOM) and recurrent OM and has altered the microbiology of AOM. The proportion of AOM attributable to *Streptococcus pneumoniae* has declined, while the proportion attributable to nontypeable *Haemophilus influenzae* and *Moraxella catarrhalis* has increased, potentially decreasing the effectiveness of antimicrobial prophylactic regimens relying on amoxicillin. Studies performed prior to the introduction of conjugate pneumococcal vaccines demonstrated that amoxicillin prophylaxis was modestly effective in reducing the frequency of recurrent episodes of OM in otitis-prone children, but once prophylaxis was discontinued, recurrent OM episodes occurred. In addition, greater understanding of the adverse impacts of antibiotic prophylaxis on the nasopharyngeal microbiome and colonization with resistant organisms has led to decreased use of antibiotic prophylaxis for the prevention of AOM.

No single strategy to prevent OM, including tympanostomy tube insertion, antimicrobial prophylaxis or episodic antimicrobial treatment, is superior and therefore an individualized approach for each child/family is appropriate. Guidelines for prevention of recurrent OM indicate that clinicians can offer tympanostomy tube insertion but should not prescribe antimicrobial prophylaxis, because it does not provide clear benefit and can cause development of antimicrobial resistance.¹

¹ Lieberthal AS, Carroll AE, Chonmaitree T, et al. The diagnosis and management of acute otitis media. *Pediatrics*. 2013;131(3):e964-e999

Table 5.1. Circumstances in Which Antimicrobial Prophylaxis May or Should Be Considered^a

Anatomic Site-Related Infections	Exposed Host; Time-Limited Exposure	Vulnerable Host (Pathogen); Ongoing Exposure
Urinary tract infection with vesicoureteral reflux (VUR)	<i>Bordetella pertussis</i> exposure <i>Neisseria meningitidis</i> exposure Perinatal group B <i>Streptococcus</i> (perinatal) exposure	Immunosuppressed patients, eg, oncologic, rheumatologic, solid organ and hematopoietic cell transplant patients (<i>Pneumocystis jirovecii</i> , fungi, CMV, HSV, bacteremia from mucositis)
Endocarditis with certain underlying cardiac conditions	Bite wound (human, animal, reptile)	HIV-infected children (<i>P jirovecii</i> , polysaccharide-encapsulated bacteria)
Recurrent otitis media in select children	Infants whose birthing parent has HIV, to decrease the risk of HIV transmission	Preterm neonates (<i>Candida</i> species)
	Influenza virus, following close family exposure in those unimmunized	Anatomic or functional asplenia (polysaccharide-encapsulated bacteria) ^c
	Susceptible contacts of index cases of invasive <i>Haemophilus influenzae</i> type b disease or <i>Neisseria meningitidis</i>	Chronic granulomatous disease (<i>Staphylococcus aureus</i> and other catalase-positive bacteria and fungi)
	Exposure to aerosolized spores of <i>Bacillus anthracis</i>	Congenital immune deficiencies (various pathogens)
	Exposure to tick bite in area with high prevalence of <i>Borrelia burgdorferi</i> ^b	Rheumatic fever (group A <i>Streptococcus</i>)
	Ophthalmia neonatorum prophylaxis (<i>Neisseria gonorrhoeae</i>)	Treatment with eculizumab (<i>Neisseria meningitidis</i>)
		IgG and IgG subclass deficiency (respiratory pathogens)

CMV indicates cytomegalovirus; HIV, HSV, herpes simplex virus; IgG, immunoglobulin G.

^aAntimicrobial prophylaxis regimens are described in each disease-specific chapter in Section 3.

^bProphylaxis of Lyme disease may be considered in specific circumstances (see Lyme Disease [p 549]).

^cSee Immunization and Other Considerations in Immunosuppressed Children (p 93).

URINARY TRACT INFECTION¹

The role of chemoprophylaxis for UTI remains controversial because risk may outweigh benefit. The decision to provide prophylaxis requires weighing the benefit of modest reduction in recurrent UTI episodes and possible subsequent renal scarring versus the risk of colonization and infection with resistant organisms that may emerge during prophylaxis. Rather than ongoing prophylaxis, some experts prefer prompt diagnosis and effective treatment of each febrile UTI recurrence. The anatomic abnormalities of the urinary tract, the consequences of recurrent infection, the risks of

¹ American Academy of Pediatrics, Subcommittee on Urinary Tract Infections, Steering Committee on Quality Improvement and Management. Urinary tract infection: clinical practice guideline for the diagnosis and management of the initial UTI in febrile infants and children 2 to 24 months. *Pediatrics*. 2011;128(3):595-610

infection caused by a resistant pathogen, and the anticipated duration of prophylaxis need to be carefully assessed for each patient.

Children at highest risk for recurrence include those with first symptomatic UTI early in life, higher grades of vesicoureteral reflux (VUR), bilateral VUR, urinary stasis related to incomplete bladder emptying or anatomic conditions such as hydro-ureteronephrosis, and infection caused by pathogens other than *Escherichia coli*. Data do not support use of antimicrobial prophylaxis to prevent febrile recurrent UTIs in infants without VUR or conditions causing significant urinary stasis. The Randomized Intervention for Children with Vesicoureteral Reflux (RIVUR) study among children with grade I through grade IV VUR reported that chemoprophylaxis with trimethoprim-sulfamethoxazole compared with placebo decreased recurrent UTI following a first or second febrile or symptomatic UTI by 50% but did not reduce renal scarring. Antibiotic prophylaxis to prevent recurrent UTI was most effective in children with bowel and bladder dysfunction and in those who were febrile at the time of presentation. However, among children who developed recurrent infection, those receiving prophylaxis had a higher rate of drug-resistant bacteria compared with children who did not receive prophylaxis. If prophylaxis is to be offered, children with high-grade reflux are most likely to benefit; low-grade reflux is believed to play little role in renal damage, and most studies show little benefit in prophylaxis with this group. Specific prophylaxis regimens should be based on antimicrobial susceptibility of prior infecting isolates. Trimethoprim-sulfamethoxazole or trimethoprim alone or nitrofurantoin can be used in infants and children over 2 months of age; beta-lactams are recommended for patients below 2 months of age.

Prophylaxis Following Exposure to Specific Pathogens

Prophylaxis may be indicated if an increased risk of serious infection with a specific pathogen exists and a specific antimicrobial agent has been demonstrated to decrease the risk of infection by that pathogen (eg, prophylaxis following exposure to *Neisseria meningitidis* [see Meningococcal Infections, p 585]). Pathogen-specific prophylaxis is addressed in Section 3. When prophylaxis is given, it is assumed that the benefit of prophylaxis is greater than the risk of adverse effects of the antimicrobial agent or the risk of subsequent infection by antimicrobial-resistant organisms. For some pathogens that colonize the upper respiratory tract, elimination of the carrier state can be difficult and may require use of a specific antimicrobial agent that achieves microbiologically effective concentrations in nasopharyngeal secretions (eg, rifampin).

Vulnerable Hosts

Attempts to prevent serious infections in immunocompromised patients with antimicrobial prophylaxis have been successful in some carefully defined at-risk populations. In some situations, such as prophylaxis of pneumococcal bacteremia/sepsis in children with asplenia or prophylaxis of sepsis caused by viridans group streptococci in children with leukemia, resistance to the prophylactic antibiotic may lead to decreased effectiveness of prophylaxis over time. In other situations, such as prophylaxis of *Pneumocystis* infection with trimethoprim-sulfamethoxazole in immunocompromised children, resistance has not developed despite years of continuous prophylaxis.

..... ANTIMICROBIAL PROPHYLAXIS IN PEDIATRIC SURGICAL PATIENTS

Surgical site infections (SSIs), which account for 20% of all hospital-acquired infections, prolong the length of hospitalization and increase the risk of death.¹ Prevention of SSIs are a priority for children's hospitals and surgical centers. Active surveillance targeting high-risk, high-volume procedures should be in place and requires education of surgeons and perioperative personnel, technological infrastructure, and use of a multidisciplinary team of trained personnel, including infection prevention specialists who are knowledgeable regarding SSI criteria. Institutions should monitor compliance with basic process measures and provide regular feedback to surgical personnel and hospital leadership.

Prevention of postoperative wound infections through perioperative prophylaxis is recommended for procedures with moderate or high infection rates or procedures in which a postoperative wound infection would have great consequences, such as implantation of prosthetic material into the heart. In contrast, for tissue sites already inoculated/infected, such as a ruptured appendix, antibiotics are used to treat rather than prevent infection. Consensus recommendations for prevention of SSIs in adults and children have been developed, although high-quality evidence for many of these recommendations is lacking. Although few data exist specifically for pediatric surgical prophylaxis, the principles of antimicrobial agent selection and exposure at surgical sites in adults should apply to children. Consequences of inappropriate use of prophylactic antimicrobial agents include increased costs, adverse events from toxicity, and emergence of resistant organisms. The emergence of drug-resistant organisms poses a risk not only to the recipient but also to other patients in whom a health care-associated infection could develop.

Guidelines for Appropriate Use

Guidelines for prevention of SSIs have been published.^{2,3} General principles include the concepts that agents used for antimicrobial prophylaxis should prevent SSIs and related morbidity and mortality, reduce the duration and cost of care, minimize risk of adverse effects, minimize adverse consequences on the microbial flora, and not create SSIs from alternative pathogens. Published guidelines address indications, appropriate drug selection, dosing, preoperative timing and need for intraoperative redosing, and duration of prophylaxis. The Centers for Disease Control and Prevention (CDC) tracks and reports SSIs through the National Healthcare Safety Network (NHSN) and provides advice to prevent SSIs (www.cdc.gov/hai/ssi/ssi.html).

Indications for Prophylaxis

Major determinants of SSIs include the number of microorganisms in the wound during the procedure, the virulence of the microorganisms, the presence of foreign material in the wound, and host risk factors, including preoperative health status. The

classification of surgical procedures is based on an estimation of bacterial contamination and, thus, risk of subsequent infection. The 4 classes are: (1) clean wounds; (2) clean-contaminated wounds; (3) contaminated wounds; and (4) dirty and infected wounds. Additional risk factors for SSIs include the operative site and the duration of the procedure. A patient risk index, which incorporates the preoperative physical status assessment score of the American Society of Anesthesiologists, the duration of the operation, and the aforementioned wound classification, has been demonstrated to be a good predictor of SSIs.¹ Others have summarized patients at “high risk” of surgical site infection.² Although a high-risk pediatric patient is not clearly defined, high-risk factors in adult patients include obesity, coexistent infections at a remote body site, altered immune response, colonization with pathogenic microorganisms, and diabetes mellitus.

CLEAN WOUNDS

Clean wounds are uninfected operative wounds in which no inflammation is encountered; the respiratory, alimentary, and genitourinary tracts or oropharyngeal cavity are not entered; and no break in aseptic technique occurred. The operative procedures usually are elective, and wounds are closed primarily and, if necessary, drained with closed drainage. Operative incisional wounds that follow nonpenetrating (blunt) trauma are included in this category, provided that the surgical procedure does not involve entry into the gastrointestinal or genitourinary tracts. The benefits of systemic antimicrobial prophylaxis do not justify the potential risks associated with antimicrobial use in most clean wound procedures, because the risk of infection is low (usually <1%). Some exceptions exist in which prophylaxis is administered because the risks or consequences of infection are high; examples include implantation of intravascular or deep tissue prosthetic material (eg, insertion of a prosthetic heart valve or a prosthetic joint), open-heart surgery for repair of structural defects, body cavity exploration in neonates, and most neurosurgical operations.

CLEAN-CONTAMINATED WOUNDS

In clean-contaminated wounds, the respiratory, alimentary, or genitourinary tracts are entered under controlled conditions without extensive contamination. Surgeries involving the gastrointestinal tract, biliary tract, appendix, vagina, or oropharynx, and urgent or emergency surgery in an otherwise clean procedure are included in this category, provided that no evidence of infection is encountered and no major break in aseptic technique occurs. Prophylaxis is limited to procedures in which a substantial amount of wound contamination is expected. The overall risk of infection for these surgical sites is 3% to 15%. On the basis of data from adults, procedures for which prophylaxis is indicated for pediatric patients include: (1) all gastrointestinal tract procedures in which there is obstruction, when the patient is receiving H₂ receptor

¹ Gaynes RP, Culver DH, Horan TC, Edwards JR, Richards C, Tolson JS. Surgical site infection (SSI) rates in the United States, 1992–1998: the National Nosocomial Surveillance System basic SSI risk index. *Clin Infect Dis*. 2001;33(Suppl 2):S69–S77

² Bratzler DW, Dellinger EP, Olsen KM, et al; American Society of Health-System Pharmacists; Infectious Disease Society of America; Surgical Infection Society; Society for Healthcare Epidemiology of America. Clinical practice guidelines for antimicrobial prophylaxis in surgery. *Am J Health Syst Pharm*. 2013;70(3):195–283

antagonists or proton pump blockers, or when the patient has a permanent foreign body; (2) selected biliary tract operations (eg, when there is obstruction from common bile duct stones); and (3) urinary tract surgery or instrumentation in the presence of bacteriuria or obstructive uropathy.

CONTAMINATED WOUNDS

Contaminated wounds are previously sterile tissue sites that are likely to be heavily contaminated with bacteria and include open, fresh wounds; operative wounds in the setting of major breaks in aseptic technique or gross spillage from the gastrointestinal tract; exposed viscera at birth from congenital anomalies; penetrating trauma of fewer than 4 hours duration; and incisions in which acute nonpurulent inflammation is encountered. The estimated rate of surgical site wound infection for these surgical sites is 15%, although it may be lower in healthy children. In wounds contaminated during procedures, antimicrobial prophylaxis is appropriate, but for those with acute nonpurulent inflammation isolated to, and contained within, an inflamed viscus (such as acute, nonperforated appendicitis or cholecystitis) with no wound contamination, prophylaxis is not necessary. For wounds in which contaminating bacteria have had an opportunity to establish inflammation and ongoing infection, antimicrobial use should be considered as treatment rather than prophylaxis.

DIRTY AND INFECTED WOUNDS

Dirty and infected wounds include penetrating trauma of more than 4 hours' duration from time of occurrence (the prolonged period assumes that the infection is already established), wounds with retained devitalized tissue, and wounds involving existing clinical infection or perforated viscera. This definition suggests that the organisms causing postoperative infection were present in the operative field before surgery, as noted above, and that antimicrobial use should be considered as treatment rather than prophylaxis. The estimated rate of infection for these surgical sites is 40%, although it may be lower in healthy children. In dirty and infected wound procedures, such as procedures for a perforated abdominal viscus (eg, ruptured appendix), a compound fracture, a laceration attributable to an animal or human bite >12 hours after injury, or when a major break in sterile technique occurs, antimicrobial agents are given as treatment rather than prophylaxis, although they may also prevent an infection of the surgical wound itself.

Surgical Site Infection Criteria

Specific classification criteria for SSIs have been developed by the National Healthcare Safety Network (NHSN) and are updated yearly (www.cdc.gov/nhsn/index.html). Reports from the NHSN are also posted periodically on the CDC website (www.cdc.gov/nhsn/datastat/index.html).

SUPERFICIAL INCISIONAL SSI

A superficial incisional SSI involves only the skin and subcutaneous layers of the incision and occurs within 30 days of the operation in a patient presenting with one of the following: (1) purulent drainage from the superficial incision; (2) an organism(s) that is (are) identified from an aseptically obtained specimen from the superficial incision or

subcutaneous tissue by culture or molecular analysis; (3) surgical wound exploration (in the absence of laboratory results) when the patient presents with one of the following signs or symptoms: pain or tenderness, localized swelling, erythema, or pain; or (4) diagnosis of superficial incisional SSI by a physician, nurse practitioner, or physician assistant.

DEEP INCISIONAL SSI

A deep incisional SSI occurs within 30 or 90 days after the operative procedure, depending on the surgery; involves only the fascial or muscle layers; and results in at least 1 of the following: (1) purulent drainage from the deep incision but not from the organ/space component of the surgical site; (2) a deep incision that spontaneously dehisces or is deliberately opened by a physician, nurse practitioner, or physician assistant and at least 1 of the following signs or symptoms: fever ($>38^{\circ}\text{C}$), localized pain, or localized tenderness; or (3) an abscess or other evidence of infection involving the deep incision that is found on direct examination, during reoperation, or by histopathologic or radiologic examination.

ORGAN/SPACE SSI

An organ or space SSI is defined by the specific site of infection that is opened and manipulated during the procedure (eg, endocarditis, mediastinitis, osteomyelitis). Organ/space SSI must occur within 30 or 90 days of the surgery (as defined by the specific procedure), and the patient must have 1 or more of the following: (1) purulent drainage from a drain that is placed through a stab wound into the organ/space; (2) organisms isolated from an aseptically obtained culture of fluid or tissue in the organ/space; or (3) an abscess or other evidence of infection involving the organ/space that is found on direct examination, during reoperation, or by histopathologic or radiologic examination.

Timing of Administration of Prophylactic Antimicrobial Agents

Effective chemoprophylaxis occurs only when the appropriate antimicrobial drug is present in tissues at sufficient local concentrations at the time of intraoperative bacterial contamination. Administration of an antimicrobial agent within 1 or 2 hours before surgery has been demonstrated to decrease the risk of wound infection. Accordingly, administration of the prophylactic agent is recommended within 60 minutes before surgical incision to ensure adequate tissue concentrations at the start of the procedure. When antimicrobial agents require longer administration times, such as glycopeptides (eg, vancomycin) or fluoroquinolones, administration should begin within 120 minutes prior to surgical incision.

Dosing and Duration of Administration of Antimicrobial Agents

Weight-based dosing for pediatric patients of all ages is routine. The preoperative doses should not exceed the usual dose for adults. Adequate antimicrobial concentrations should be maintained throughout the surgical procedure. In most instances, a single dose of an antimicrobial agent is sufficient, and the duration of prophylaxis after any procedure should not exceed 24 hours, with current data suggesting that no benefit can be documented for additional doses after surgery. Intraoperative dosing

is required if the duration of the procedure is greater than 2 times the half-life of the antimicrobial agent or if there is excessive blood loss (eg, >1500 mL in adults). For example, cefazolin may be administered every 3 to 4 hours during a prolonged surgical procedure or one that involves large-volume blood loss. Postoperative doses after closure generally are not recommended in clean and clean-contaminated procedures, even in the presence of a drain.

Preoperative Screening and Decolonization

The use of preoperative surveillance to identify carriers of methicillin-susceptible *Staphylococcus aureus* (MSSA) or methicillin-resistant *S aureus* (MRSA) has been explored in the adult population. Recent changes in the epidemiology of MRSA suggest that risk of MRSA infections in children has decreased in the past decade, suggesting the targeted prophylaxis for MRSA may no longer be warranted. Use of preoperative nasal mupirocin and chlorhexidine baths for *S aureus* carriers may reduce the risk of deep SSI and is recommended as an adjunct to intravenous prophylaxis in adult cardiac and orthopedic surgery patients. Several small studies in children undergoing cardiac surgery have suggested similar benefit in using perioperative mupirocin.

Recommended Antimicrobial Agents

An antimicrobial agent is chosen based on bacterial pathogens most likely to cause infectious complications during and after the specific procedure, the antimicrobial susceptibility pattern of these pathogens, and the safety and efficacy of the drug. Antimicrobial agents administered prophylactically do not have to be active in vitro against every potential organism to be effective, because it is unlikely that all potential organisms are contaminating the wound. Doses are determined based on the need to achieve therapeutic blood and tissue concentrations throughout the procedure. Antimicrobial prophylaxis for most surgical procedures, including gastric, biliary, thoracic (noncardiac), vascular, neurosurgical, and orthopedic operations, can be achieved effectively using an agent such as a first-generation cephalosporin (eg, cefazolin) unless the risk for MRSA infection is high, in which case vancomycin may be indicated. For colorectal surgery or appendectomy, effective prophylaxis requires antimicrobial agents that are active against aerobic and anaerobic intestinal flora. Table 5.2 provides recommendations for drugs to be used in children undergoing surgical manipulation or invasive procedures. Physicians should be aware of potential interactions and adverse effects associated with prophylactic antimicrobial agents and other medications the patient may be receiving. Routine use of broad-spectrum agents (extended-spectrum cephalosporins, beta-lactam/beta-lactamase combinations, and carbapenems) for surgical prophylaxis generally is not necessary. Hospital antimicrobial stewardship programs should regularly update and evaluate compliance with antimicrobial prophylaxis protocols. There are no data to support the practice of continuing antibiotic prophylaxis until all invasive lines, drains, and indwelling catheters have been removed.

Routine use of vancomycin for prophylaxis is not recommended. However, vancomycin prophylaxis may be considered for patients with congenital heart disease who undergo cardiac surgery, patients who undergo certain orthopedic procedures (eg, spinal procedures, implantation of foreign materials), children known to be colonized

Table 5.2. Recommendations for Preoperative Antimicrobial Prophylaxis

Operation	Likely Pathogens	Recommended Drugs	Preoperative Dose
Neonatal (≤ 72 h of age)— all major procedures	Group B streptococci, enteric gram-negative bacilli, ^a enterococci	Ampicillin PLUS Gentamicin	50 mg/kg 4 mg/kg
Neonatal (> 72 h of age)— all major procedures	Prophylaxis targeted to colonizing organisms, nosocomial organisms, and operative site		
Cardiac (cardiac surgical procedures, prosthetic valve or pacemaker, ventricular assist devices)	<i>Staphylococcus aureus</i> , <i>Corynebacterium</i> species, enteric gram-negative bacilli ^a	Cefazolin OR (if MRSA or MRSE is likely) Vancomycin	30 mg/kg (max 2 g; 3 g if ≥ 120 kg) 15 mg/kg
Gastrointestinal			
Esophageal and gastroduodenal	Enteric gram-negative bacilli, ^a gram-positive cocci	Cefazolin (high risk only ^b)	30 mg/kg (max 2 g; 3 g if ≥ 120 kg)
Biliary tract	Enteric gram-negative bacilli, ^a enterococci	Cefazolin ^c	30 mg/kg (max 2 g; 3 g if ≥ 120 kg)
Colorectal or appendectomy (uncomplicated, nonperforated)	Enteric gram-negative bacilli, ^a enterococci, anaerobes (<i>Bacteroides</i> species) ^d	Cefoxitin or cefotetan OR Metronidazole PLUS Gentamicin OR Cefazolin PLUS Metronidazole	40 mg/kg (max 2 g) 15 mg/kg (max 500 mg) 2.5 mg/kg 30 mg/kg (max 2 g; 3 g if ≥ 120 kg) 15 mg/kg (max 500 mg)

Table 5.2. Recommendations for Preoperative Antimicrobial Prophylaxis, continued

Operation	Likely Pathogens	Recommended Drugs	Preoperative Dose
Ruptured viscus (regarded as treatment, not prophylaxis)	Enteric gram-negative bacilli, ^a enterococci, anaerobes (<i>Bacteroides</i> species) ^d	Cefoxitin	40 mg/kg (max 2 g)
		WITH OR WITHOUT	
		Gentamicin	2.5 mg/kg
		OR	
		Gentamicin	2.5 mg/kg
		PLUS	
		Metronidazole	15 mg/kg (max 500 mg)
		PLUS	
		Ampicillin	50 mg/kg (max 2 g)
		OR	
Genitourinary	Enteric gram-negative bacilli, ^a enterococci, <i>S aureus</i>	Piperacillin/tazobactam	80–100 mg/kg (max 3.375 g)
		OR	
		Other regimens for complicated appendicitis ^e	
		Cefazolin	30 mg/kg (max 2 g; 3 g if ≥120 kg)
		OR	
		Trimethoprim-sulfamethoxazole	4 mg/kg trimethoprim (max 160 mg), 20 mg/kg sulfamethoxazole (max 400 mg)

Table 5.2. Recommendations for Preoperative Antimicrobial Prophylaxis, continued

Operation	Likely Pathogens	Recommended Drugs	Preoperative Dose
Head and neck surgery (incision through oral or pharyngeal mucosa)	Anaerobes, enteric gram-negative bacilli, ^a <i>S aureus</i>	Cefazolin	30 mg/kg (max 2 g; 3 g if ≥120 kg)
		PLUS	
		Metronidazole	15 mg/kg (max 500 mg)
		OR	
Neurosurgery (craniotomy, intrathecal baclofen shunt or ventricular shunt placement)	<i>S aureus</i>	Clindamycin	10 mg/kg (max 900 mg)
		WITH OR WITHOUT	
		Gentamicin	2.5 mg/kg
		OR	
		Ampicillin-sulbactam	50 mg/kg (max 3g)
		Cefazolin	30 mg/kg (max 2 g; 3 g if ≥120 kg)
		OR	
		(if MRSA or MRSE is likely) Vancomycin	15 mg/kg

Table 5.2. Recommendations for Preoperative Antimicrobial Prophylaxis, continued

Operation	Likely Pathogens	Recommended Drugs	Preoperative Dose
Ophthalmic	<i>S aureus</i> , streptococci, enteric gram-negative bacilli, ^a <i>Pseudomonas</i> species	Gentamicin, ciprofloxacin, ofloxacin, moxifloxacin, tobramycin	Multiple drops topically for 2–24 h before procedure
		OR	
		Neomycin-gramicidin-polymyxin B	Multiple drops topically for 2–24 h before procedure
		OR	
Orthopedic (internal fixation of fractures, implantation of materials including prosthetic joint and spinal procedures with and without instrumentation)	<i>S aureus</i>	Cefazolin	100 mg, subconjunctivally at the end of the procedure
		Cefazolin	30 mg/kg (max 2 g; 3 g if ≥120 kg)
		OR	
		(if MRSA or MRSE is likely) Vancomycin	15 mg/kg
Thoracic (noncardiac)	<i>S aureus</i> , streptococci, gram-negative enteric bacilli ^a	Cefazolin	30 mg/kg (max 2 g; 3 g if ≥120 kg)
		OR	
		(if MRSA is likely) Vancomycin	15 mg/kg

Table 5.2. Recommendations for Preoperative Antimicrobial Prophylaxis, continued

Operation	Likely Pathogens	Recommended Drugs	Preoperative Dose
Traumatic wound (exceptionally varied pathogens, based on the anatomic site injured, and the instrument causing the trauma, particularly for penetrating injuries such as motor vehicle accidents or farm injuries)	Skin: <i>S aureus</i> , group A streptococci	Cefazolin	30 mg/kg (max 2 g; 3 g if ≥ 120 kg)
	Perforated viscus: gram-negative enteric bacilli, <i>Clostridium</i> species	Cefoxitin	40 mg/kg (max 2 g)
		WITH OR WITHOUT Gentamicin	2.5 mg/kg
		OR	
		Gentamicin	2.5 mg/kg
		PLUS Metronidazole	10 mg/kg (max 500 mg)
		PLUS Ampicillin	50 mg/kg (max 2 g)
		OR	
		Piperacillin/tazobactam	80–100 mg/kg (max 3.375 g)
		OR	
		Other regimens for complicated appendicitis ^e	

MRSA indicates methicillin-resistant *Staphylococcus aureus*; MRSE, methicillin-resistant *Staphylococcus epidermidis*.

^aSelection of antibiotics should take into consideration the susceptibility patterns of isolates found in the patient and at the institution.

^bEsophageal obstruction, decreased gastric acidity, or gastrointestinal motility; see text for additional high risk factors.

^cAcute cholecystitis, nonfunctioning gallbladder, obstructive jaundice, common duct stones.

^dFor *Bacteroides fragilis* group: high rates of resistance to clindamycin (only 25%–30% susceptible); lowest rates of resistance to metronidazole, carbapenems, ampicillin/sulbactam, and piperacillin/tazobactam. Resistance to cefoxitin reported at 30%.

^eSolomkin JS, Mazuski JE, Bradley JS, et al. Diagnosis and management of complicated intra-abdominal infection in adults and children: guidelines by the Surgical Infection Society and the Infectious Diseases Society of America (erratum in *Clin Infect Dis*. 2010;50(12):1695; dosage error in article text). *Clin Infect Dis*. 2010;50(2):133–164.

or previously infected by MRSA, or children living in a community with a high rate of MRSA infections. Vancomycin is not as effective as cefazolin for the prevention of infection caused by many other organisms.

Misconceptions regarding penicillin allergies may result in patients receiving alternate and less-effective antibiotics for surgical prophylaxis. Efforts toward accurate labeling of patients with reported allergies include assessing the exact nature of the previous reaction, determining the likelihood that this reaction is a true immunoglobulin E (IgE)-mediated reaction, and determining the likelihood that the purported offending agent has cross-reactivity with the recommended perioperative antibiotic. Analysis of the chemical structure of the beta-lactams indicate little cross-reactivity between the penicillins and cefazolin, given differences in chemical side chains (see Fig 4.1, p 979). Institutions should develop programs (or at a minimum an algorithm) to assess, challenge (if appropriate) and delabel patients who do not have true penicillin allergy.

..... PREVENTION OF BACTERIAL ENDOCARDITIS

The Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease of the American Heart Association (AHA)'s Council on Cardiovascular Disease in the Young periodically issues detailed recommendations on the rationale, indications, and antimicrobial regimens for prevention of bacterial endocarditis for people at increased risk. The guidelines published in 2007¹ departed significantly from past recommendations in noting the lack of definitive evidence regarding the efficacy of antibiotic prophylaxis in preventing infective endocarditis (IE) after dental procedures. Bacteremia associated with most dental procedures represents only a very small fraction of bacteremia episodes that occur with events of daily living, such as brushing teeth, chewing, and other oral hygiene measures. The committee restricted recommendations for IE prophylaxis to a relatively narrow group of people who have certain cardiac abnormalities in which an episode of IE would likely carry a high risk of an adverse outcome. Additionally, IE prophylaxis was recommended for only a few procedures including only certain dental procedures and invasive airway procedures. Prophylaxis no longer is recommended for procedures involving the gastrointestinal and genitourinary tracts solely to prevent endocarditis.

In 2015, the AHA issued updated guidance on the epidemiology, clinical findings, pathogenesis, diagnosis, and treatment of pediatric bacterial endocarditis that included a short section on endocarditis prevention, which reiterated the 2007 published recommendations.² In 2017, a reconstituted expert AHA panel undertook a comprehensive review of the impact of 2007 endocarditis prophylaxis statement and whether, over the decade since original publication, the guidelines remained appropriate and valid.

Table 5.3. Regimens for Antimicrobial Prophylaxis for selected Dental Procedures^a

Clinical Circumstances	Regimen: Single Dose 30 to 60 min Before Procedure		
	Antibiotic	Children	Adults
Oral	Amoxicillin	50 mg/kg, PO	2 g, PO
Unable to take oral medication	Ampicillin	50 mg/kg, IM or IV	2 g, IM or IV
Allergic to penicillins or ampicillin	Cephalexin ^{b,c}	50 mg/kg, PO	2 g, PO
		OR	
	Clindamycin	20 mg/kg, PO	600 mg, PO
		OR	
	Azithromycin	15 mg/kg, PO	500 mg, PO
		OR	
	Clarithromycin	15 mg/kg, PO	500 mg, PO
		OR	
	Doxycycline	<45 kg, 2.2 mg/kg, PO ≥45 kg, 100 mg, PO	100 mg, PO
Allergic to penicillins or ampicillin and unable to take oral medication	Cefazolin or ceftriaxone ^c	50 mg/kg, IM (ceftriaxone) or IV (ceftriaxone or cefazolin)	1 g, IM or IV

IM, indicates intramuscular; IV, intravenous; PO, oral.

^aPediatric dosage should not exceed recommended adult dosage.

^bOr other first- or second-generation oral cephalosporin in equivalent pediatric or adult dosage.

^cCephalosporins should not be used in a person with a history of anaphylaxis, angioedema, or urticaria with penicillins or ampicillin. In such cases, vancomycin 15 mg/kg IV (max 1 g) may be used in children.

Adapted from: Wilson WR, Gewitz M, Lockhart PB, et al; American Heart Association Young Hearts Rheumatic Fever, Endocarditis and Kawasaki Disease Committee of the Council on Lifelong Congenital Heart Disease and Heart Health in the Young; Council on Cardiovascular and Stroke Nursing; and Council on Quality of Care and Outcomes research. Prevention of viridans group streptococcal infective endocarditis: a scientific statement from the American Heart Association. *Circulation*. 2021;143(20):e963-e978.

This updated statement from the AHA was published in 2021¹ and focused specifically on viridans streptococcal IE, because those organisms are the principal pathogens in oral flora. The panel confirmed that the vast majority of data collected since 2017 indicated that reducing the indications for IE resulted in no increase in viridans group endocarditis and has been widely accepted by the dental and medical communities. Physicians should consult the published recommendations for further details (<https://doi.org/10.1161/CIR.0000000000000969>).

Specific prophylactic regimens are presented in Table 5.3.

¹ Wilson WR, Gewitz M, Lockhart PB, et al; American Heart Association Young Hearts Rheumatic Fever, Endocarditis and Kawasaki Disease Committee of the Council on Lifelong Congenital Heart Disease and Heart Health in the Young; Council on Cardiovascular and Stroke Nursing; and Council on Quality of Care and Outcomes research. Prevention of viridans group streptococcal infective endocarditis: a scientific statement from the American Heart Association. *Circulation*. 2021;143(20):e963-e978

Cardiac conditions associated with the highest risk of an adverse outcome from endocarditis for which prophylaxis with dental procedures is reasonable include the following:

- Prosthetic cardiac valve or prosthetic material used for repair of valve.
- Durable mechanical circulatory support device (eg, ventricular assist device).
- Previous infective endocarditis.
- Congenital heart disease (CHD):
 - ♦ Unrepaired cyanotic CHD, including palliative shunts and conduits.
 - ♦ Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure.
 - ♦ Repaired CHD with residual defect(s) at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibits endothelialization).
 - ♦ Prosthetic pulmonary artery valve or conduit.
- Cardiac transplantation with subsequent cardiac valvulopathy.

Dental procedures for which endocarditis prophylaxis is reasonable for patients with a cardiac condition listed above include the following:

- All dental procedures that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa. These procedures include cleaning, extractions, abscess drainage, biopsies, suture removal, and placement of orthodontic bands.
- The following procedures and events **do not** require prophylaxis: routine anesthetic injections through noninfected tissue, taking dental radiographs, placement of removable prosthodontic or orthodontic appliances, adjustment of orthodontic appliances, placement of orthodontic brackets, shedding of deciduous teeth, and bleeding from trauma to the lips or oral mucosa.

In addition, antibiotic prophylaxis is reasonable for the patients with cardiac conditions listed above who undergo an invasive procedure of the respiratory tract that involves incision or biopsy of the respiratory tract mucosa.

NEONATAL OPHTHALMIA PREVENTION

Ophthalmia neonatorum is defined as conjunctivitis occurring within the first 4 weeks after birth. Infection usually is transmitted during passage through the birth canal. The causes and clinical characteristics of ophthalmia neonatorum are presented in Table 5.4. This chapter focuses on prevention of neonatal ophthalmia. Neonates with ophthalmia neonatorum disease require clinical evaluation with appropriate laboratory testing and prompt initiation of specific therapy if an infectious etiology is identified. See chapters on specific pathogens for appropriate laboratory testing, specific therapy, and other recommendations.

Primary Prevention

The current primary strategy for prevention of neonatal ophthalmia is based on antepartum identification and treatment of maternal infection, preventing exposure of the newborn infant. The Centers for Disease Control and Prevention (CDC) recommends routine first-trimester screening for chlamydia and gonorrhea in all

Table 5.4. Major and Minor Etiologies in Ophthalmia Neonatorum

Etiology of Ophthalmia Neonatorum	Proportion of Cases	Incubation Period (Days)	Severity of Conjunctivitis ^a	Associated Problems
<i>Chlamydia trachomatis</i>	2%–40%	5–12	+	Pneumonitis 3 wk–3 mo (see Chlamydial Infections, p 298)
<i>Neisseria gonorrhoeae</i>	Less than 1%	2–5	+++	Disseminated infection (see Gonococcal Infections, p 394)
<i>Pseudomonas aeruginosa</i>	Less than 1%	5–28	+++	Sepsis, meningitis
Other bacterial microbes ^b	30%–50%	5–14	+	Variable
Herpes simplex virus	Less than 1%	6–14	+ ^c	Disseminated infection, meningoencephalitis (see Herpes Simplex, p 467); keratitis and ulceration also possible

^a+ indicates mild; +++, severe.
^bIncludes skin, respiratory, vaginal, and gastrointestinal tract pathogens such as *Staphylococcus aureus*, *Streptococcus pneumoniae*, nontypeable *Haemophilus influenzae*; group A and B streptococci, *Corynebacterium* species, *Moraxella catarrhalis*, *Escherichia coli*, and *Klebsiella pneumoniae*.
^cDegree of purulence/local inflammatory response generally is not substantial, but consequences of untreated infection can be severe.

pregnant people 24 years or younger and older pregnant people at high-risk. Risk factors include having new or multiple sex partners, having a sex partner who has other concurrent partners or had a sexually transmitted infection, inconsistent condom use, previous or coexisting sexually transmitted infections, and exchanging sex for money or drugs. If there is uncertainty regarding risk during pregnancy, screening for *Chlamydia trachomatis* and *Neisseria gonorrhoeae* at the first prenatal visit can be considered, especially in areas of high prevalence of either pathogen. In addition, the CDC advises rescreening for chlamydia and gonorrhea during the third trimester for all pregnant people who remain at high risk as defined above, including all pregnant people 24 years and younger. When chlamydial infection is diagnosed during the first trimester, a test of cure to document chlamydial eradication should be performed approximately 4 weeks after treatment and repeated 3 months after treatment. When gonorrhea is diagnosed, it should be treated immediately, with repeat testing within 3 months.

Sex partners of infected individuals should also be tested and treated if positive. If a pregnant person has not been tested for *C trachomatis* and/or *N gonorrhoeae* before labor/delivery, testing should be performed during labor/delivery or immediately postpartum. If either pathogen is identified, the infant should receive therapy as outlined in the following sections.

Secondary Prevention

POSTEXPOSURE SYSTEMIC ANTIBIOTIC PROPHYLAXIS

To block transmission of infection, healthy infants whose birthing parent has untreated or inadequately treated gonococcal infection should receive 1 dose of ceftriaxone (25–50 mg/kg, intravenously [IV] or intramuscularly [IM], not to exceed 250 mg).¹ Ceftriaxone should be administered cautiously to hyperbilirubinemic infants, especially those born preterm. For infants in whom ceftriaxone is contraindicated (eg, receiving continuous intravenous calcium, as in parenteral nutrition), then 1 dose of cefotaxime (100 mg/kg, IV or IM), can be substituted for postexposure prophylaxis, if this agent is locally available. Other extended-spectrum cephalosporins, such as ceftazidime or cefepime, as a single dose, should be effective, although studies have not been performed. Note that gentamicin should not be used as treatment of neonates with gonococcal ocular disease because of inadequate penetration into the globe of the eye. Topical antimicrobial therapy alone is inadequate for *N gonorrhoeae*-exposed or -infected infants and is not necessary when systemic antimicrobial therapy is administered.

Infants whose birthing parent is known to have untreated chlamydial infection are at high risk of infection; however, prophylactic antimicrobial treatment is not indicated, because the efficacy of such treatment is unknown. Infants should be monitored clinically to ensure appropriate treatment if infection develops.

ROUTINE TOPICAL NEONATAL OPHTHALMIC PROPHYLAXIS

If gonorrhea is prevalent in the region and prenatal treatment cannot be ensured, or where required by law, a prophylactic agent of 0.5% erythromycin ointment should be instilled into the eyes of all newborn infants (including those born by cesarean delivery) to prevent sight-threatening gonococcal ophthalmia. Efficacy is unlikely to be influenced by delaying prophylaxis for as long as 1 hour to facilitate parent-infant bonding. Longer delays have not been studied for efficacy. Before administering local prophylaxis, each eyelid should be wiped gently with sterile cotton. A 1-cm ribbon of 0.5% erythromycin ointment should then be placed in each lower conjunctival sac. Ideally, ointment should be applied using single-use tubes or ampules rather than multiple-use tubes. The eyelids should then be massaged gently to spread the ointment. After 1 minute, excess ointment may be wiped away with sterile cotton. The ointment should not be flushed from the eyes after instillation, because flushing can decrease efficacy.

Periodic shortages of erythromycin ointment have occurred in recent years. If erythromycin ointment is not available, a birthing parent who is at risk for exposure to *N gonorrhoeae* or who had no prenatal care should be tested for *N gonorrhoeae* in the immediate peripartum setting using a nucleic acid amplification test (NAAT). If the birth parent's test is positive for gonorrheal infection or if the test result is pending at time of discharge with concerns for lack of follow-up, the neonate should receive ceftriaxone, 25 to 50 mg/kg of body weight, IV or IM, not to exceed 250 mg in a

single dose¹⁻³; if ceftriaxone is unavailable or contraindicated, a single dose of ceftazidime or cefepime may be substituted. Birthing parents at increased risk for gonococcal infection include those <25 years of age, and those 25 years or older who have a new partner; more than 1 sex partner; a sex partner with concurrent partners, or a sex partner who has an STI or lives in a community with high rates of gonorrhea; who practice inconsistent condom use when not in a mutually monogamous relationship; who have a previous or coexisting STI; who have a history of exchanging sex for money or drugs; or who have a history of incarceration. Information on current drug shortages in the United States can be found at www.ashp.org/shortages.^{1,3}

Legal Mandates for Topical Prophylaxis for Neonatal Ophthalmia

The American Academy of Pediatrics supports ongoing reevaluation of the continued necessity of legislative mandates in the United States for universal neonatal eye prophylaxis² and advocates for the following preventive strategies:

- Diligent compliance with CDC recommendations for prenatal screening for and treatment of *N gonorrhoeae* and *C trachomatis* to prevent intrapartum exposures.
- Testing of unscreened individuals for *N gonorrhoeae* and *C trachomatis* infection at the time of labor or delivery, with treatment of infected birthing parents and their infants.
- Counseling of parents to bring conjunctival discharge and inflammation to immediate medical attention, resulting in optimal treatment of neonatal ophthalmia.
- Education of newborn care providers to ensure awareness that purulent conjunctivitis in a newborn infant requires thorough diagnostic evaluation and prompt specific treatment.
- Continuation of mandatory reporting of cases of gonococcal ophthalmia neonatorum to identify patterns of failure of primary prevention measures.

In regions where gonorrhea remains prevalent and prenatal screening and treatment is not routinely achievable, neonatal topical prophylaxis remains appropriate.

Pseudomonal Ophthalmia Neonatorum

Neonatal ophthalmia attributable to *Pseudomonas aeruginosa* is infrequent but may now be as common as gonococcal ophthalmia. This form of neonatal ophthalmia has a predilection for preterm infants and presents with eyelid edema and erythema, purulent discharge, and pannus formation. Because superficial infection can progress rapidly to corneal perforation, endophthalmitis, blindness, serious systemic infection (sepsis, meningitis), and death, this form of bacterial neonatal ophthalmia urgently requires a combination of systemic and topical therapy, because systemic antibiotics

alone have poor penetration into the anterior chamber of the eye. The diagnosis should be suspected when Gram-stained specimens of exudate contain gram-negative bacilli and should be confirmed by culture. Until *Pseudomonas* infection is excluded, evaluation for systemic infection and topical and systemic therapy are recommended. Ophthalmology consultation is also recommended.

Other Nongonococcal, Nonchlamydial Ophthalmia

Neonatal ophthalmia can be caused by many other bacterial pathogens (see Table 5.4). In general, uncomplicated resolution can be expected with topical treatment of these infections.

Herpes simplex keratoconjunctivitis should be considered in neonates with conjunctival inflammation and discharge, particularly when tests for bacterial and chlamydial infection are negative. The diagnosis should be suspected if there are also cutaneous vesicles or oral ulcers or vesicles and can be confirmed by demonstration of dendritic keratitis (requiring ophthalmology consultation for examination with fluorescein staining), or by virologic testing (eg, nucleic acid amplification test [NAAT] or culture). Specific treatment is indicated (see Herpes Simplex, p 467). Conjunctivitis caused by other viruses generally resolves without specific treatment.

.....
APPENDIX II**Codes for Commonly Administered Pediatric Vaccines,
Toxoids, and Immune Globulins**

Vaccine, toxoid, and immune globulin codes use a specific vaccine *Current Procedural Terminology* (CPT) code to indicate which vaccine product was administered to the patient. A regularly updated listing of CPT product codes for commonly administered pediatric vaccines can be found at **https://downloads.aap.org/AAP/PDF/coding_vaccine_coding_table.pdf?_ga=2.32279294.1928077618.1652908186-1981473643.1640014472**.

CPT codes for vaccine administration (“Immunization Administration”) are reported in addition to the CPT codes for specific vaccines and toxoid products. Codes 90460 and 90461 are only reported when the physician or other qualified health care professional provides face-to-face counseling during the encounter when a vaccine is administered to a patient through 18 years of age. Code 90460 should be reported for each vaccine administered, as it accounts for counseling on the first (or only) vaccine component. For vaccines with more than one component, code 90460 should be reported for the first component in conjunction with code 90461 for each additional component in a given vaccine (eg, DTaP counseling and administration will be reported with 90460 x 1 plus 90461 x 2). Multivalent antigens or multiple serotypes of antigens against a single organism are considered a single component of vaccines (eg, PCV-13 administration should use only one 90460). Without counseling by the physician or qualified health care professional, or if the patient is 18 years or older, report administration codes 90471–90474 instead based on the number of vaccines administered and the route of administration.

ICD-10-CM has only a single diagnosis code for reporting vaccines and vaccine administration, Z23. When reporting vaccines administered, ICD-10-CM requires use of code Z23 regardless of the reason for the encounter. For example, if vaccines are given as part of a childhood preventive care visit, code Z23 should be reported in addition to code Z00.121 or Z00.129 (encounter for routine child health examination, with or without abnormal findings). Codes Z00.110 (health examination for newborn under 8 days old) and Z00.111 (health examination for newborn 8 to 28 days old) can be used when parents defer the birth dose of hepatitis B vaccine. When a vaccine like tetanus is given during wound management, the code for the wound is primary and Z23 is secondary.

Immune globulin products are not considered vaccines, and the administration code 96372, therapeutic injection given intramuscularly or subcutaneously, should be used in all cases. For perinatal hepatitis B exposure, hepatitis B immune globulin (HBIG), use CPT code 90371 for the immunoglobulin product, and ICD-10-CM codes P00.2 (for perinatal exposure to maternal infection) and Z20.5 (for exposure to viral hepatitis). For rabies immune globulin (RIG) and rabies vaccine administration, ICD-10-CM code Z20.3 (contact with and [suspected] exposure to rabies) should be reported as well as the ICD-10-CM codes describing the nature of the injuries and circumstances surrounding the injury, including type of animal involved (ie, codes found

in the V-Y categories). The ICD-10-CM code Z29.14, encounter for prophylactic RIG, can also be used.

For palivizumab (recombinant monoclonal RSV antibody), CPT code 90378 should be used for the product (with 1 unit per 50 mg administered), and the appropriate ICD-10-CM diagnoses of gestational age and/or other medical condition(s) that support the need to administer palivizumab should be reported. The ICD-10-CM code Z29.1, encounter for prophylactic immunotherapy, may be used in addition.

Although nirsevimab (the long-acting monoclonal RSV antibody) is categorized as a monoclonal antibody by CPT, ICD-10-CM's index suggests the appropriate diagnosis code is Z29.11, encounter for prophylactic immunotherapy for RSV. Report the administration of nirsevimab with code 96380 (administration of respiratory syncytial virus, monoclonal antibody, seasonal dose by intramuscular injection, with counseling by physician or other qualified health care professional) or with code 96381 (administration of respiratory syncytial virus, monoclonal antibody, seasonal dose by intramuscular injection). Do not report immunization administration codes 90461–90462 or 90471–90472 for the administration of nirsevimab, as these codes are limited to administering vaccine and toxoid products. To prevent cost share being passed on to the patient, append modifier 33 to the administration code to indicate to the payer that this was part of a preventive service.

.....

APPENDIX III

Nationally Notifiable Infectious Diseases in the United States

Nationally notifiable infectious diseases are those that public health officials from local, state, and territorial public health departments voluntarily report to the Centers for Disease Control and Prevention (CDC). Surveillance for nationally notifiable infectious diseases helps public health agencies monitor the occurrence and spread of disease across the nation and evaluate prevention and control measures, among other purposes. To ensure consistency in how the data are classified and enumerated, national surveillance case definitions are established and used for each disease. The Council of State and Territorial Epidemiologists (CSTE), with advice from the CDC, reviews the list of nationally notifiable infectious diseases on an annual basis and may recommend that a disease be added or deleted from the list or that a case definition be revised. Provisional nationally notifiable infectious disease data are published in weekly tables and finalized data are published in annual tables, available from the “Data and Statistics” section of the National Notifiable Diseases Surveillance System website (www.cdc.gov/nndss/data-statistics/index.html). The CDC receives either daily or weekly case notifications for approximately 120 nationally notifiable diseases from all states, Washington, DC, New York City, and 5 US territories. For a subset of cases that meet the criteria for being a potential public health emergency of international concern, as per the 2005 revised International Health Regulations (www.who.int/publications/i/item/9789241580496), the CDC Emergency Operations Center notifies the Department of Health and Human Services Secretary’s Operations Center, which in turn notifies the World Health Organization. The World Health Organization makes the final determination about whether a public health emergency of international concern exists. The 2023 list of nationally notifiable infectious diseases, most of which are infectious, is included in Table 1. Should a more current list of such diseases be needed, visit <https://ndc.services.cdc.gov/>, select year of interest for the notifiable condition list year, check “Infectious” conditions, and click “Get Notifiable List by Year.”

Case notifications submitted to the CDC are based on data collected at the local, state, and territorial levels as a result of legislation and regulations in those jurisdictions that require health care providers, clinical laboratories, hospitals, and other entities to submit health-related data on reportable diseases to public health departments. Case reporting to local, state, or territorial public health officials provides the information needed to investigate these diseases and to implement prevention and control strategies, among other purposes. Because the list of reportable infectious diseases is determined by local, state, and territorial law and varies by jurisdiction, health care providers, clinical laboratories, hospitals, and other required reporters are strongly encouraged to obtain specific reporting requirements from the appropriate public health department, including the timeliness required for case reporting.

If a reportable disease meets the criteria for a nationally notifiable infectious disease, the local, state, or territorial public health department will submit a case notification to the CDC. The timeliness of such case notifications to the CDC varies by disease, with some requiring notification within 4 hours of a case meeting the notification criteria. In addition, local or state reporting requirements for additional diseases may exist.

APPENDIX IV

Guide to Contraindications and Precautions to Immunizations

A **contraindication** to vaccination is a condition in a patient that increases the risk of a serious adverse reaction and for whom this increased risk of an adverse reaction outweighs the benefit of the vaccine. A vaccine should not be administered when a contraindication is present. The only contraindication applicable to all vaccines is a history of anaphylaxis to a previous dose or to a vaccine component, unless the patient has undergone desensitization. Refer to the Description section of manufacturers' package inserts for components of each vaccine; package inserts for vaccines that are licensed for use in the United States are available at www.fda.gov/BiologicsBloodVaccines/Vaccines/ApprovedProducts/ucm093833.htm.

The Centers for Disease Control and Prevention "Pink Book" (*Epidemiology and Prevention of Vaccine-Preventable Diseases* [www.cdc.gov/vaccines/pubs/pinkbook/genrec.html#contraindications]) is also a helpful resource.

A **precaution** is a condition in a recipient that might increase the risk or seriousness of an adverse reaction, might interfere with vaccine effectiveness, or might complicate making another diagnosis because of a possible vaccine-related reaction. The only precaution applicable to all vaccines is moderate or severe acute illness, with or without fever.

People who administer vaccines should screen recipients for contraindications and precautions before administering vaccines, and this screening should be documented (eg, in the electronic health record).

A table that lists contraindications and precautions for commonly used vaccines can be found at www.cdc.gov/vaccines/hcp/acip-recs/general-recs/contraindications.html. This information is based on recommendations of the Committee on Infectious Diseases of the American Academy of Pediatrics (AAP) and of the Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention (CDC). Sometimes, these recommendations differ from information in the manufacturers' package inserts. In addition, ACIP recommendations for influenza vaccine are updated on an annual basis and the most recent contraindications and precautions for influenza vaccines can be found at www.cdc.gov/vaccines/hcp/acip-recs/vacc-specific/flu.html. Information on discussing vaccine recommendations with patients and families can be found in Understanding Vaccine Evaluation and Safety as an Approach to Addressing Parental Concerns, p 27.

.....
APPENDIX V

Prevention of Infectious Disease From Contaminated Food Products

Foodborne diseases are associated with significant morbidity and mortality in people of all ages. The Foodborne Diseases Active Surveillance Network (FoodNet) of the CDC Emerging Infections Program conducts active, population-based surveillance at 10 sites in the United States, for all laboratory-diagnosed infections with select enteric pathogens transmitted commonly through food. The FoodNet program conducts surveillance for illnesses caused by *Campylobacter* species, *Cyclospora cayetanensis*, *Listeria monocytogenes*, *Salmonella* species, Shiga toxin-producing *Escherichia coli* (STEC) O157 and non-O157 STEC, *Shigella* species, *Vibrio* species, and enteric *Yersinia* species. FoodNet also conducts surveillance for hemolytic-uremic syndrome (HUS), which is a complication of STEC infection. In 2019, compared with the previous 3 years, the incidence of infections caused by pathogens transmitted commonly through food increased (for *Campylobacter*, *Cyclospora*, *Vibrio*, and *Yersinia* species, and STEC) or remained unchanged (for *Listeria*, *Salmonella*, and *Shigella* species).¹ Additional information about FoodNet can be found at www.cdc.gov/foodnet/index.html.

Outbreak surveillance provides insights into the causes of foodborne illness, types of implicated foods, and settings where transmission occurs. The CDC collects data on foodborne disease outbreaks submitted from all states and territories (www.cdc.gov/foodsafety/fdoss/index.html). In 2019, the Centers for Disease Control and Prevention (CDC) reported 873 foodborne disease outbreaks, resulting in roughly 12 000 illnesses, 1000 hospitalizations, and 2 deaths. Young children, pregnant people, elderly people, and immunocompromised people are especially susceptible to illnesses and complications caused by many of the organisms associated with foodborne illness.

Norovirus is the most common cause of outbreaks of foodborne illness in the United States. The system for surveillance and reporting for norovirus outbreak specimens is known as CaliciNet (www.cdc.gov/norovirus/reporting/calicinet/index.html).

Public health, regulatory, and agricultural professionals can use this information when creating targeted control strategies and to support efforts to promote safe food preparation practices among food industry employees and the public. Data on foodborne disease outbreaks are available online through the National Outbreak Reporting System Dashboard (wwwn.cdc.gov/norsdashboard).

Four general rules should be followed for food safety:

1. **Clean:** Wash hands and surfaces thoroughly and often.
2. **Separate:** Do not cross-contaminate.
3. **Chill:** Refrigerate foods promptly.
4. **Cook:** Prepare and heat food to the proper temperature.

The following preventive measures can be implemented to decrease the risk of infection from specific foods.

¹ Tack DM, Ray L, Griffin PM, et al. Preliminary incidence and trends of infections with pathogens transmitted commonly through food—Foodborne Diseases Active Surveillance Network, 10 U.S. Sites, 2016–2019. *MMWR Morb Mortal Wkly Rep*. 2020;69(17):509–514

UNPASTEURIZED MILK AND MILK PRODUCTS

The American Academy of Pediatrics (AAP) endorses the use of pasteurized milk and recommends that parents be fully informed of the important risks associated with consumption of unpasteurized milk.¹ Interstate sale of unpasteurized (raw) milk and products made from unpasteurized milk (with the exception of certain hard cheeses) is banned by the US Food and Drug Administration (FDA). The most vulnerable populations, such as children, pregnant people, elderly people, and immunocompromised people, should not consume unpasteurized milk or products made from unpasteurized milk, including cheese, butter, yogurt, pudding, or ice cream, from any species, including cows, sheep, and goats. Serious infections attributable to *Salmonella* species, *Campylobacter* species, *Mycobacterium bovis*, *L monocytogenes*, *Brucella* species, STEC, *Y enterocolitica*, and *Cryptosporidium parvum* have been linked to consumption of unpasteurized milk. Although some states allow the sale of raw milk that meets state-designated arbitrary standards (certified milk), “certified” raw milk has also been linked to outbreaks. A number of outbreaks of *Campylobacter* infection among children have been associated with school field trips to farms during which children consumed raw milk. School officials should take precautions to prevent raw milk from being served to children during educational trips. Cheeses made from unpasteurized milk also have been associated with illnesses attributable to *Brucella* species, *L monocytogenes*, *Salmonella* species, *Campylobacter* species, *Shigella* species, *M bovis*, and STEC. Soft cheese made from pasteurized milk can be contaminated during production. Outbreaks of *Listeria* infections have more often been linked to soft cheese made from pasteurized milk rather than raw milk (www.cdc.gov/national-surveillance/pdfs/listeria-annual-summary-2014-508.pdf).

RAW AND UNDERCOOKED EGGS

Children and other groups at high risk of severe foodborne disease should not eat raw or undercooked eggs, unpasteurized powdered eggs, or foods that may contain raw or undercooked eggs. Ingestion of raw or improperly cooked eggs can result in severe illness attributable to *Salmonella* species. Examples of foods that may contain raw or undercooked eggs include some homemade frostings and mayonnaise, homemade ice cream, tiramisu, eggs prepared “sunny-side up,” Caesar salad dressing, Hollandaise sauce, cookie dough, and cake batter.

RAW DOUGH

Children should not eat raw dough, including unbaked goods such as cookies, tortillas, pizza, biscuits, or pancakes. Children should not play with raw dough, such as at home for crafts or at restaurants. Several regional outbreaks have been linked to STEC present in raw flour. Cookie dough in ice cream sold commercially is now treated to prevent transmission of pathogens.

RAW AND UNDERCOOKED MEAT

Children should not eat raw or undercooked meat or meat products. Various raw or undercooked meat products can commonly harbor harmful bacteria, including STEC, *Salmonella* species, and *Campylobacter* species. Specific meat products have

¹ American Academy of Pediatrics, Committee on Infectious Diseases and Committee on Nutrition. Consumption of raw or unpasteurized milk and milk products by pregnant women and children. *Pediatrics*. 2014;133(1):175-179. Reaffirmed November 2019

been linked with certain infections (pathogen-commodity pair): ground beef with STEC and *Salmonella* species; hot dogs and deli meats with *L monocytogenes*; pork with *Trichinella* species; and wild game with *Brucella* species, *Francisella tularensis*, STEC, *Trichinella* species, and *Toxoplasma gondii*. Ground meats are especially risky, because contamination on the outside of a cut of meat can end up in the center of a hamburger, the part least likely to be well cooked. Ground meats should be cooked to an internal temperature of 160°F; roasts and steaks should be cooked to an internal temperature of 145°F; and poultry should be cooked to an internal temperature of 165°F. Use of a food thermometer is the only accurate means of knowing that meat has reached a high enough temperature to destroy pathogens. Color is not a reliable indicator that ground beef patties have been cooked to a temperature high enough to kill pathogens. Knives, cutting boards, plates, and other utensils used for raw meats should not be used for preparation of fresh fruits or vegetables or for placement of cooked meat until they have been cleaned properly (see websites at end of this Appendix for details).

UNPASTEURIZED JUICES

Children should drink only fruit or vegetable juice that has been pasteurized or that has been freshly squeezed from washed fruit or vegetables. Consumption of packaged fruit juices that have not undergone pasteurization or a comparable treatment has been associated with foodborne illness attributable to STEC, *Salmonella* species, and *Cryptosporidium parvum*. To identify a packaged juice that has not undergone pasteurization or a comparable treatment, consumers should look for a warning statement that the product has not been pasteurized.

RAW SEED SPROUTS

The CDC has reaffirmed health advisories that people who are at high risk of severe foodborne disease, including children, people with compromised immune systems, pregnant people, and elderly people, should avoid eating raw seed sprouts such as alfalfa sprouts. Raw seed sprouts have been associated with outbreaks of illness attributable to *Salmonella* species, STEC, and *L monocytogenes*. The seeds themselves can harbor the pathogen, and many pathogens grow well in the warm, humid environments in which seeds sprout.

FRESH FRUITS AND VEGETABLES AND RAW NUTS

Many fresh fruits and vegetables have been associated with illnesses caused by *Cryptosporidium* species, *Cyclospora cayetanensis*, norovirus, hepatitis A virus, *Giardia duodenalis*, STEC, *Salmonella* species, *L monocytogenes*, and *Shigella* species. Raw nuts, commercially processed vegetable snacks, spinach, lettuce, tomatoes, cucumbers, melons, basil, and cilantro have been associated with outbreaks of salmonellosis. Roasting or otherwise treating nuts can minimize the risk of foodborne illness. Washing can decrease bacterial contamination of fresh fruits and vegetables; however, washing even in high concentrations of chlorine or other disinfectant is not guaranteed to remove all pathogens, because pathogens can stick to surfaces and internalize into food items. Knives, cutting boards, utensils, and plates used for raw meats should not be used for preparation of fresh fruits or vegetables until the utensils have been cleaned properly (see websites at end of this Appendix for details).

RAW SHELLFISH AND FISH

Children should not eat raw shellfish. Raw shellfish, including mussels, clams, oysters, scallops, and other mollusks, can carry many pathogens, including norovirus, *Vibrio* species, and hepatitis A virus as well as toxins (see Appendix VI, p 1150). *Vibrio* species contaminating raw shellfish may cause severe disease in people with liver disease or other conditions associated with decreased immune function. *Vibrio* species abundance appears to be increasing because of sea surface warming, thus posing increasing concern for these infections. Some experts caution against children ingesting raw fish, which has been associated with transmission of helminths (eg, *Anisakis simplex*, *Diphyllobothrium latum*).

HONEY

Children younger than 1 year should not consume honey. Honey is a raw agricultural product that can contain spores of *Clostridium botulinum*, the agent of botulism. The organism can grow and produce toxin in an infant's intestine; this type of pathogenesis is extremely rare in people beyond infancy.

POWDERED INFANT FORMULA

For many reasons, infants should be fed human milk rather than infant formula whenever possible. Powdered infant formula is not a sterile product and has been associated with severe illnesses attributable to *Cronobacter sakazakii* and *Salmonella* species. If infant formula is used, caregivers can reduce the risk of infection by choosing sterile, liquid formula products rather than powdered products, although this may not be practical for families with limited resources. This may be particularly important for those at greatest risk of severe infection, such as neonates and infants with immunocompromising conditions. Otherwise, water used for mixing infant formula must be from a safe water source, as defined by the state or local health department.^{1,2} If there is concern or uncertainty about the safety of tap water, bottled water or cold tap water that has been brought to a rolling boil for 1 minute, then cooled to room temperature for no more than 30 minutes, may be used.

Prepared formula (including ready-to-feed products) must be discarded within 1 hour after serving to an infant. Prepared formula made from powder that has not been given to an infant may be stored in the refrigerator for 24 hours.

FOOD IRRADIATION³

Irradiation of food can be an effective tool to decrease transmission of pathogens. Irradiation involves exposing food briefly to ionizing radiation (eg, gamma rays, x-rays, or high-voltage electrons). More than 40 countries worldwide, including the United

³ www.fsis.usda.gov/wps/portal/fsis/topics/food-safety-education/get-answers/food-safety-fact-sheets/production-and-inspection/irradiation-resources/irradiation-resources

States, have approved the use of irradiation for various types of foods. Every governmental and professional organization that has reviewed the efficacy and safety of food irradiation has endorsed its use. Meat, spices, shell eggs, seeds for sprouting, and some produce items may be irradiated for sale in the United States. The risk of foodborne illness could be decreased significantly with the routine consumption of irradiated meat, poultry, and produce.

In addition to the websites previously cited in this section, detailed information on food safety issues and practices, including steps which consumers can take to protect themselves, is available on the following web sites:

APPENDIX VI

Clinical Syndromes Associated With Foodborne Diseases^{1,2}

Foodborne disease results from consumption of contaminated foods or beverages and causes morbidity and mortality in children and adults. The epidemiology of foodborne disease is complex and dynamic because of numerous possible pathogens, the variety of disease manifestations, the increasing prevalence of immunocompromised children and adults, dietary habit changes, and trends toward centralized food production and widespread distribution. The cultural diversity of foods and food practices and international travel are also likely impacting the epidemiology of foodborne disease. Widespread availability of multiplex molecular diagnostic tests for gastrointestinal illness may lead to co-identification of multiple potential pathogens, complicating evaluation and treatment of diarrhea.

Consideration of a foodborne etiology is important in any patient with a gastrointestinal tract illness, as well as those with certain acute neurologic findings. Obtaining a detailed history is essential to assess time of onset and duration of symptoms, history of recent travel or antimicrobial use, food and water exposures, and presence of blood or mucus in stool. To aid in diagnosis, foodborne disease syndromes have been categorized by incubation period, predominant symptoms, causative agent, and foods commonly associated with specific etiologic agents (food vehicles) (see Table 1; also www.cdc.gov/foodsafety/outbreaks/investigating-outbreaks/confirming_diagnosis.html). Diagnosis can be confirmed by laboratory testing of stool, vomitus, or blood, depending on the causative agent. The Infectious Diseases Society of America Clinical Practice Guidelines for the Diagnosis and Management of Infectious Diarrhea can be found at <https://academic.oup.com/cid/article/65/12/e45/4557073>.

Sporadic (ie, non-outbreak-associated) cases account for the majority of foodborne illnesses. In localized outbreaks that affect individuals who shared a common meal, the incubation period can be estimated. In more widely dispersed outbreaks and in sporadic cases, the incubation period typically is unknown.

An outbreak should be considered when 2 or more people who have ingested the same food develop an acute illness characterized by nausea, vomiting, diarrhea, or neurologic signs or symptoms. If an outbreak is suspected, public health officials should be notified immediately to initiate an epidemiologic investigation, including diagnostic and management interventions, to curtail the outbreak.

Table 1. Clinical Syndromes Associated With Foodborne Diseases

Clinical Syndrome	Incubation Period	Causative Agents	Commonly Associated Vehicles ^a
Nausea and vomiting	2–4 h	<i>Staphylococcus aureus</i> (preformed enterotoxins, A through V but excluding F)	Food contaminated by infected food handler that is not cooked or is improperly cooked and stored, including ham, poultry, beef, cream-filled pastries, potato and egg salads, mushrooms, unpasteurized cheese
	<1–6 h	Preformed <i>Bacillus cereus</i> (emetic toxin cereulide)	Contaminated food that is improperly stored after cooking, including rice
	<1 h	Heavy metals (copper, tin, cadmium, iron, zinc)	Acidic beverages, metallic container
	1 h	Vomitoxin (deoxynivalenol)	Foods made from grains such as wheat, corn, barley
	12–48 h	Astrovirus	Bivalve mollusks grown in polluted waters, fresh produce (greens, berries) irrigated with contaminated water, food contaminated by infected food handler that is not cooked or is improperly cooked and stored (ready-to-eat salads/sandwiches)
Flushing, dizziness, burning of mouth and throat, headache, gastrointestinal tract symptoms, urticaria and generalized pruritis	<1 h	Histamine (scombroid toxin)	Fish (bluefish, bonita, mackerel, mahi-mahi, marlin, tuna, skipjack, and many other fish types)
Usually gastrointestinal symptoms followed by neurologic symptoms (including facial and extremity paresthesias) and reversal of hot and cold temperature sensation (characteristic of ciguatera toxin) ^c	2–8 h ^b (can be up to 48 h)	Ciguatera toxin	Large reef-dwelling carnivorous fish (eg, amberjack, barracuda, grouper, snapper)
	Up to 18 h	Neurotoxic shellfish toxin (brevetoxin)	Shellfish (eg, mussels, oysters, clams)

Table 1. Clinical Syndromes Associated With Foodborne Diseases, continued

Clinical Syndrome	Incubation Period	Causative Agents	Commonly Associated Vehicles ^a
Symptoms similar to ciguatera and neurotoxic shellfish toxin, plus short-term memory loss ^b	1 day	Domoic acid (amnesic shellfish toxin)	Mussels, clams
Neurologic, including confusion, salivation, hallucinations; gastrointestinal tract manifestations	0–2 h	Mushroom toxins (short-acting)	Mushrooms
Neuromuscular weakness, symmetric descending paralysis, respiratory weakness, neurologic symptoms may be preceded by gastrointestinal tract manifestations ^d	18–36 h	<i>Clostridium botulinum</i> (preformed toxin)	Home-canned vegetables, fruits and fish, salted fish, meats, bottled garlic, potatoes baked in aluminum foil, cheese sauce
Neurologic, constipation in infant younger than 1 y ^d	3–30 days	<i>Clostridium botulinum</i> (ingestion of spores with production of toxin in the intestine)	Honey
Neurologic, gastrointestinal tract ^b	10–45 min	Tetrodotoxin (ascending paralysis)	Puffer fish
	0.5–3 h	Paralytic shellfish toxins (saxitoxins, etc)	Shellfish (clams, mussels, oysters, scallops, other mollusks)
Abdominal cramps and watery diarrhea, vomiting	6–24 h	<i>Bacillus cereus</i> (diarrheal enterotoxin)	Meats, stews, gravies, vanilla sauce
	6–24 h	<i>Clostridium perfringens</i>	Meat, poultry, gravy, dried or precooked foods
	12–48 h	Norovirus	Feces-contaminated shellfish, salads, ice, cookies, water, sandwiches, fruit, leafy vegetables, ready-to-eat foods handled by infected food worker
	1–3 days	Rotavirus	Feces-contaminated salads, fruits, ready-to-eat foods handled by infected food worker

Table 1. Clinical Syndromes Associated With Foodborne Diseases, continued

Clinical Syndrome	Incubation Period	Causative Agents	Commonly Associated Vehicles ^a
Abdominal cramps, watery diarrhea	1–3 days ^e	Enterotoxigenic <i>Escherichia coli</i>	Feces-contaminated seafood, herbs, fruits, vegetables, water, often acquired abroad—“travelers’ diarrhea”
	Unknown	<i>Listeria monocytogenes</i>	Soft cheeses, raw milk, hot dogs, cole slaw, ready-to eat delicatessen meats, produce (eg, sprouts, cantaloupe)
	4–30 h	<i>Vibrio parahaemolyticus</i>	Shellfish, especially oysters
	12–72 h	<i>Vibrio vulnificus</i>	Shellfish, especially oysters
	1–5 days	<i>Vibrio cholerae</i> O1 and O139	Shellfish (including crabs and shrimp), fish, water
	1–5 days	<i>V. cholerae</i> non-O1 and non-O139	Shellfish, especially oysters
	1–14 days	<i>Cyclospora</i> species	Raspberries, vegetables, fresh herbs, water
	2–28 days	<i>Cryptosporidium</i> species	Vegetables, fruits, milk, water, in particular recreational water exposures
Diarrhea, fever, abdominal cramps, blood and mucus in stools, bacteremia	1–3 weeks	<i>Giardia duodenalis</i>	Water, ready-to-eat foods handled by infected food worker
	6–48 h	<i>Salmonella</i> species (nontyphoidal)	Poultry; pork; beef; eggs; dairy products, including ice cream; raw vegetables, alfalfa sprouts; fruit, including unpasteurized juices; peanut butter
	2–4 days	<i>Shigella</i> species	Feces-contaminated lettuce-based salads, potato and egg salads, salsas, dips, and oysters, ready-to-eat foods handled by infected food worker
	7–14 days	<i>Salmonella</i> Typhi	Food contaminated by infected food handler (acutely ill or chronic carrier)
	2–4 wk	Amebiasis (<i>Entamoeba histolytica</i>)	Feces-contaminated food or water

Table 1. Clinical Syndromes Associated With Foodborne Diseases, continued

Clinical Syndrome	Incubation Period	Causative Agents	Commonly Associated Vehicles ^a
Bloody diarrhea, abdominal cramps, hemolytic-uremic syndrome (HUS)	3–4 days	Shiga toxin-producing <i>E coli</i> (STEC)	Undercooked beef (hamburger); raw milk; roast beef; salami; salad dressings; lettuce and other leafy greens; game meats, unpasteurized juices, including apple cider; sprouts; water
Febrile diarrhea or, especially in older children, abdominal pain resembling that of appendicitis	4–6 days	<i>Yersinia enterocolitica</i>	Pork chitterlings, other pork products, tofu, milk
Hepatorenal failure, watery diarrhea	6–24 h	Mushroom toxins (long-acting)	Mushrooms (especially <i>Amanita</i> species)
Other extraintestinal manifestations (fever, myalgias, arthralgias, fatigue)	Varied, up to months (usually >30 days)	<i>Brucella</i> species	Goat cheese, queso fresco, raw milk, meats
Fever, chills, headache, pharyngitis, arthralgia	1–4 days	Group A <i>Streptococcus</i>	Egg and potato salad, pasta
Fever, malaise, anorexia, jaundice	15–50 days	Hepatitis A virus	Shellfish, raw produce (eg, strawberries, lettuce, green onions)
Meningoencephalitis, sepsis, fetal loss	2–6 wk	<i>Listeria monocytogenes</i>	Soft cheeses, raw milk, hot dogs, coleslaw, ready-to eat delicatessen meats, produce (eg, sprouts, cantaloupe)
Muscle soreness and pain	Varied, up to 4 wk	<i>Trichinella spiralis</i>	Wild game, pork, meat

Table 1. Clinical Syndromes Associated With Foodborne Diseases, continued

Clinical Syndrome	Incubation Period	Causative Agents	Commonly Associated Vehicles ^a
Fever, lymphadenopathy, encephalitis, retinitis (may be reactivation disease for the latter two)	5–23 days	<i>Toxoplasma gondii</i>	Undercooked meat (especially pork, lamb, and game meat), fruits, vegetables, raw shellfish
Sepsis, meningitis among infants	Unknown	<i>Cronobacter sakazakii</i>	Powdered infant formula
	Unknown	<i>Salmonella</i> species	Powdered infant formula
Seizures, behavioral disturbances, and other neurologic signs and symptoms	Months	<i>Taenia solium</i> (neurocysticercosis)	Food contaminated with feces from a human carrier of adult pork tapeworm
Epigastric discomfort, abdominal pain, cholangitis, obstructive jaundice, pancreatitis	Varied (several days to months)	<i>Clonorchis sinensis</i> (liver fluke); <i>Opisthorchis</i> species (liver fluke)	Eating raw or undercooked infected freshwater fish, crabs, crayfish
Guillain-Barré syndrome (ascending paralysis)	2–10 days	<i>Campylobacter</i> species <i>Shigella</i> Enteroinvasive <i>E coli</i> <i>Yersinia enterocolitica</i> <i>Vibrio parahaemolyticus</i>	Poultry, raw milk, water Feces-contaminated food or water Vegetables, hamburger, raw milk Pork chitterlings, tofu, raw milk Fish, shellfish

Table 1. Clinical Syndromes Associated With Foodborne Diseases, continued

Clinical Syndrome	Incubation Period	Causative Agents	Commonly Associated Vehicles ^a
Postdiarrheal HUS (acute renal failure, hemolytic anemia, thrombocytopenia)	7 days–2 wk after onset of diarrhea	Shiga toxin-producing <i>E coli</i> (especially serotype O157:H7), or shiga-toxin 2-producing strains of non-O157 <i>E coli</i>	Beef (hamburger); raw milk; roast beef; salami; salad dressings; lettuce and other leafy greens; unpasteurized juices, including apple cider; alfalfa and radish sprouts; water
	1–5 days after onset of diarrhea	<i>Shigella dysenteriae</i> type 1	Water, milk, other contaminated food, rare in the United States
Reactive arthritis	Varies	<i>Campylobacter</i> species	Poultry, raw milk, water
	Varies	<i>Salmonella</i> species	Poultry, pork, beef, eggs, dairy products, including ice cream; vegetables (alfalfa sprouts and fresh produce); fruit, including unpasteurized juices; peanut butter
	Varies	<i>Shigella</i> species	Feces-contaminated food or water
	Varies	<i>Yersinia enterocolitica</i>	Pork chitterlings, tofu, raw milk

^aList of vehicles in several categories is not exhaustive, because any number of foods can be contaminated; current online literature may be helpful to sort through commonly associated vehicles.

APPENDIX VII

Diseases Transmitted by Animals (Zoonoses)

Morbidity resulting from selected zoonotic diseases in the United States is reported annually by the Centers for Disease Control and Prevention (CDC; see “Summary of Notifiable Diseases” at www.cdc.gov/mmwr/mmwr_nd/). Information also can be obtained via the website of the National Center for Emerging and Zoonotic Infectious Diseases (www.cdc.gov/ncezid/about-ncezid.html) or through the main CDC website (www.cdc.gov). There are many opportunities to acquire zoonotic diseases, including companion animal exposure and occupational, recreational, or other exposures to animals or their products. Zoonotic diseases also include vector-borne, foodborne, and waterborne diseases. Anthropogenic factors that contribute to the increasing spillover of zoonotic infections from animal reservoirs into humans include habitat destruction, which upsets the balance controlling animal vectors in healthy ecosystems; the increasing penetration of humans into once remote areas of the planet where they encounter previously sequestered species; the consumption of “bush meat;” and the clandestine global trade in endangered species.

Table 1. Diseases Transmitted by Animals

Disease and/or Organism	Animal Sources/Reservoirs	Vector or Modes of Transmission
Bacterial Diseases		
<i>Aeromonas</i> species	Aquatic animals, especially shellfish, fish, medical leeches; snakes; has also been isolated from feces of horses, pigs, sheep, and cows	Wound infection; ingestion of contaminated water or food, including seafood, meat and dairy products; direct contact with infected animals or their environment
Anthrax (<i>Bacillus anthracis</i>)	Domestic and wild herbivores (cattle, goats, horses, sheep, antelope, deer) Outbreaks associated with heavy rainfall, flooding, or drought; spores remain viable in soil or animal products, such as wool or hides, for decades	Direct contact with infected animals or their carcasses, or contact with products from infected animals (eg, meat, hides, hair, or wool) contaminated with <i>B anthracis</i> spores; ingestion of contaminated meat, inhalation of aerosolized spores from contaminated materials; injection of <i>B anthracis</i> contaminated materials (via injection drug use)
Bartonellosis		
Cat-scratch disease (<i>Bartonella henselae</i>)	Cats (especially kittens) and other felids, infrequently other animals	Scratches, bites, licks; fleas play a role in cat-to-cat transmission (evidence for transmission from cat fleas to humans is lacking)
<i>Bartonella quintana</i>	Cats, dogs, rodents, and nonhuman primates	Bite from human body louse, infestation in clothing or bedding in high density populations with poor access to hygienic services, sanitation
<i>Bartonella bacilliformis</i>	Unknown	Bite of sand flies
Brucellosis (<i>Brucella</i> species)	Cattle, coyotes, hares, chickens, goats, sheep, pigs, dogs, elk, bison, deer, camels, desert woodrats and other rodents, marine mammals	Direct or indirect contact with aborted fetuses, tissues, or fluids of infected animals; inoculation through mucous membranes or cuts or abrasions of the skin; inhalation of contaminated aerosols; ingestion of raw (unpasteurized) dairy products

Table 1. Diseases Transmitted by Animals, continued

Disease and/or Organism	Animal Sources/Reservoirs	Vector or Modes of Transmission
Campylobacteriosis (<i>Campylobacter jejuni</i>)	Poultry, dogs (especially puppies), kittens, ferrets, pigs, nonhuman primates, pet rodents, cattle, sheep, birds	Ingestion of contaminated food or water, improperly cooked poultry, raw dairy products, direct contact with animals or environment, person-to-person (fecal-oral), fomites
<i>Capnocytophaga canimorsus</i>	Dogs and cats	Wound infections, bites, scratches; prolonged contact with dogs and cats
Erysipeloid (<i>Erysipelothrix rhusiopathiae</i>)	Pigs, horses, dogs, cats, rats, sheep, cattle, wild and domestic birds (including poultry), fresh and saltwater fish, shellfish	Direct contact with animals or contaminated animal products or contaminated water
Hemolytic-uremic syndrome (eg, Shiga toxin-producing <i>Escherichia coli</i>) (STEC)	Cattle, sheep, goats, deer, pigs, and poultry	Ingestion of undercooked contaminated ground beef, raw milk or dairy products, unpasteurized ale cider, leafy vegetables, alfalfa sprouts; other contaminated foods or water; contact with infected animals or their environments (eg, farms and ranches); contact with animals in public settings including petting zoos and agricultural fairs; person-to-person (fecal-oral)
Leptospirosis (<i>Leptospira</i> species)	Cattle, sheep, goats, pigs, horses, dogs, rodents, and all other mammals (including aquatic species)	Contact with or ingestion of water, food, or soil contaminated with urine or body fluids from infected animals, or direct contact with infected animals or their organs; increased risk with seasonal flooding
Lyme disease (<i>Borrelia burgdorferi</i> , <i>Borrelia mayonii</i> in United States, <i>Borrelia afzelii</i> and <i>Borrelia garinii</i> in Eurasia)	White-footed mice, squirrels, shrews, and other small rodents; opossums, raccoons, birds; although deer are important in the life cycle of <i>Ixodes</i> ticks, deer do not get infected	Tick bite (blacklegged/deer tick [<i>Ixodes scapularis</i> or <i>Ixodes pacificus</i>] in United States, castor bean tick [<i>Ixodes ricinus</i>] in Europe, taiga tick [<i>Ixodes persulcatus</i>] in Asia)
<i>Mycobacterium marinum</i>	Fresh water, brackish water, and saltwater; fish	Contaminated water sources; skin injury or contamination of existing wound, cleaning aquariums

Table 1. Diseases Transmitted by Animals, continued

Disease and/or Organism	Animal Sources/Reservoirs	Vector or Modes of Transmission
<i>Mycobacterium bovis</i>	Cattle, sheep, goats, elephants, giraffes, rhinoceroses, bison, deer, elk, feral pigs, possums, nonhuman primates	Eating or drinking contaminated raw dairy products; direct contact with infected animals, wound infection; inhalation
<i>Mycobacterium tuberculosis</i>	Nonhuman primates, elephants, guinea pigs, swine, sporadic cases in other species, including cattle	<i>M tuberculosis</i> is uncommon in nonhuman species, although when it is identified it is typically found in nonhuman primates and elephants. Transmission is by the airborne route; other routes may be involved in zoonotic transmission (although these have not been documented)
Pasteurellosis (<i>Pasteurella multocida</i>)	Cats, dogs, rabbits, pigs, birds, many other wild and domestic animals	Bites, scratches, licks, saliva, respiratory droplets from animals (primarily cats and dogs), and contaminated meat
Plague (<i>Yersinia pestis</i>)	Rodents, (eg, prairie dogs, chipmunks, squirrels, mice, voles, rats) cats, dogs, rabbits, wild carnivores (eg, bobcats, coyotes)	Most commonly via bite of infected rodent fleas; direct contact with infected animals, including their tissues; inhalation of respiratory droplets from other human or animal (eg, cat) with pneumonic plague
Q fever (<i>Coxiella burnetii</i>)	Sheep, goats, cows, buffalo, and camels are primary reservoirs; cats, dogs, rabbits, rodents, horses, pigs, pigeons, geese, other wild fowl, ticks	Contact with birth products, urine, feces, milk of infected animals, inhalation of contaminated dust, ingestion of raw dairy products; and contact with contaminated materials (wool, straw, bedding); possible role of ticks not well defined; rarely by blood transfusions, sexual contact in humans, intrauterine transmission
Rat-bite fever (<i>Streptobacillus moniliformis</i> , <i>Spirillum minus</i>)	Rodents (especially rats, occasionally squirrels), gerbils, weasels, and rodent-eating animals	Bites, scratches, contact with urine and secretions, aerosols, direct contact with rodent, or its environment; contaminated food or water; raw milk

Table 1. Diseases Transmitted by Animals, continued

Disease and/or Organism	Animal Sources/Reservoirs	Vector or Modes of Transmission
Relapsing fever (Borrelioses)	Wild rodents	Bites from soft-bodied tick (<i>Ornithodoros</i> species) in rodent infested environments
Soft tick-borne relapsing fever (<i>Borrelia hermsii</i> ; <i>Borrelia turicatae</i>)	White-footed mice, squirrels, shrews, and other	Bites from blacklegged hard ticks (<i>Ixodes</i> species)
Hard tick-borne relapsing fever (<i>Borrelia miyamotoi</i>)	small rodents; opossums, raccoons, birds	
Salmonellosis (<i>Salmonella</i> species)	Cattle, poultry, turtles, frogs, lizards, snakes, salamanders, geckos, iguanas, fish, invertebrates, dogs, cats, pigs, sheep, horses, hedgehogs, hamsters, guinea pigs, mice, rats and other rodents, ferrets, other wild and domestic animals	Fecal-oral transmission most common; ingestion of contaminated food (eg, meat, poultry, dairy, eggs, produce, processed foods including nut butters), raw dairy products, or contaminated water; contact with infected animals or their environments (including healthy reptiles); contaminated animal products including dry dog and cat food and pet treats
<i>Streptococcus iniae</i>	Fish from many regions of the world	Skin wound during handling and preparation of infected fish
<i>Streptococcus suis</i>	Pigs	Direct contact; consumption of undercooked meat
Tetanus (<i>Clostridium tetani</i>)	Any animal indirectly via soil containing animal feces	Wounds, especially deep tissue, puncture or crush injuries or compound fractures with inoculation of bacterial spores (from contaminated soil, dust or other material)
Tularemia (<i>Francisella tularensis</i>)	Wild rabbits, hares, sheep, dogs, cats, pigs, horses, voles, squirrels, prairie dogs, beaver, lemmings, muskrats, moles, hamsters, birds, reptiles, and fish	Tick bites (wood tick [<i>Dermacentor andersoni</i>], dog tick [<i>D variabilis</i>], Lone-star tick [<i>Amblyomma americanum</i>]), deerfly bites; direct contact with infected animals or their tissues, ingestion of contaminated water or meat; mechanical transmission from claws or teeth (cats/dogs), inhalation

Table 1. Diseases Transmitted by Animals, continued

Disease and/or Organism	Animal Sources/Reservoirs	Vector or Modes of Transmission
<i>Vibrio</i> species	Shellfish	Ingestion of raw or undercooked seafood; skin injury or exposure of existing wound to contaminated seawater
Yersiniosis (<i>Yersinia enterocolitica</i> , <i>Yersinia pseudotuberculosis</i>)	Pigs, deer, elk, horses, goats, sheep, cattle, rodents, birds, rabbits, dogs	Ingestion of contaminated food (particularly raw or undercooked pork products such as chitterlings), raw dairy products, contaminated water; rarely direct contact
Fungal Diseases		
Cryptococcosis (<i>Cryptococcus neoformans</i>)	Excreta of birds, including pigeons, canaries, parakeets, and chickens	Inhalation of aerosols from accumulations of bird feces; can also be isolated from fruit and vegetables, house dust, air conditioners, air, and sawdust; can also enter body through skin
Histoplasmosis (<i>Histoplasma capsulatum</i>)	Excreta of bats or birds such as chickens, pigeons, and starlings	Inhalation of aerosolized spores from accumulations of bat or bird feces, including those released during construction involving old buildings; spores can also be ingested
Ringworm/tinea corporis (<i>Microsporum</i> and <i>Trichophyton</i> species)	Cats, dogs, chickens, pigs, mice, moles, guinea pigs, horses, rodents, cattle, monkeys, goats	Direct contact with animal or contaminated soil or fomite; pathogenic fungi found worldwide; hot and humid climates generally increase incidence
Parasitic Diseases		
<i>Angiostrongylus cantonensis</i> (rat lungworm)	Rodents and mollusks (eg, slugs and snails)	Ingestion of larvae in raw or undercooked snails or slugs, freshwater shrimp, land crabs or frogs or contaminated raw produce
Anisakiasis (<i>Anisakis</i> species) (herring worm disease)	Crustaceans eat infective larvae from marine mammal feces; fish or squid eat the infected crustaceans.	Ingestion of larvae in raw or undercooked fish or squid (eg, sushi)
Babesiosis (several <i>Babesia</i> species)	Mice, other rodents, and small mammals; wildlife	Tick bite (in the United States, <i>Babesia microti</i> is transmitted mainly by <i>Ixodes scapularis</i> ; in Europe, <i>Babesia divergens</i> is mainly transmitted by <i>Ixodes</i> tick bites)

Table 1. Diseases Transmitted by Animals, continued

Disease and/or Organism	Animal Sources/Reservoirs	Vector or Modes of Transmission
Balantidiasis (<i>Balantidium coli</i>)	Pigs	Ingestion of contaminated food or water
Baylisascariasis (<i>Baylisascaris procyonis</i>)	Raccoons	Ingestion of eggs shed in raccoon feces found in dirt or animal waste
Clonorchiasis/Opisthorchiasis (<i>Clonorchis</i> / <i>Opisthorchis</i> species)	Fish, crabs, crayfish, snails, cats, dogs	Ingestion of metacercariae in raw or undercooked fish, crabs, or crayfish
Cryptosporidiosis (<i>Cryptosporidium</i> species)	<i>Cryptosporidium parvum</i> can infect all mammals; common in calves and other young ruminants; pigs, rarely in cats, dogs, and horses; other <i>Cryptosporidium</i> species can infect birds and reptiles	Fecal-oral; ingestion of contaminated water (especially groundwater) or foods, contaminated soil or surfaces; infection by inhaling aerosols can also occur
Cutaneous larva migrans (primarily <i>Ancylostoma</i> species hookworms)	Dogs, cats	Penetration of skin by larvae, which develop in soil or sand contaminated with animal feces
Dog tapeworm (<i>Dipylidium caninum</i>)	Dogs and cats, other animals (eg, foxes) can also be hosts	Ingestion of fleas infected with cysticercoid stage
Dwarf tapeworm (<i>Hymenolepis nana</i>) and rat tapeworm (<i>Hymenolepis diminuta</i>)	Rodents (humans are more important reservoirs than rodents for <i>H nana</i> ; for <i>H diminuta</i> , rodents are primary and human infection is infrequent); arthropods including beetles and fleas can serve as intermediate hosts	Ingestion of eggs in contaminated food or water; animal-to-person (fecal-oral); person-to-person (fecal-oral); ingestion of cysticercoid-infected arthropods Autoinfection may also occur in humans if eggs remain in intestine (<i>H nana</i>)

Table 1. Diseases Transmitted by Animals, continued

Disease and/or Organism	Animal Sources/Reservoirs	Vector or Modes of Transmission
Echinococcosis, hydatid disease (<i>Echinococcus</i> species)	Definitive hosts are canids including dogs, coyotes, foxes, dingoes, jackals, hyenas, and wolves. Intermediate hosts encompass many domestic and wild animals, including herbivores such as sheep, goats, cattle, and deer; rodents	Ingestion of eggs shed in animal feces contaminating soil, water, or food
Fascioliasis (<i>Fasciola</i> species)	Sheep, cattle	Ingestion of larvae in contaminated water, on raw watercress and other contaminated water plants, vegetables, or eating raw or undercooked sheep or goat liver
Fish tapeworm (<i>Diphyllobothrium latum</i>)	Saltwater and freshwater fish	Ingestion of larvae in raw or undercooked fish (eg, sushi)
Giardiasis (<i>Giardia duodenalis</i>)	Wild and domestic animals, including dogs, cats, cattle, sheep, goats, pigs, beavers, muskrats, racoons, rats, pet rodents, rabbits, nonhuman primates	Ingestion of contaminated water or food, contact with contaminated surfaces, and animal-to-person and person to person (fecal-oral)
Leishmaniasis (<i>Leishmania</i> species)	Rodents, dogs, foxes, wolves, sloths, opossum, and other mammals (including humans) are reservoir hosts	Inoculation by bite of infected female phlebotomine sand fly
Myiasis (<i>Dermatobia</i> , <i>Cochliomyia</i> , <i>Chrysomya</i> , <i>Cordylobia</i> , <i>Cuterebra</i> , Oestrus, and <i>Wohlfahrtia</i> species)	Flies	Eggs laid near or on open wound or sore; accidental ingestion of larvae or transmission of larvae by mosquito or tick which harbors larvae; with <i>Chrysomya</i> screwworm flies, exposure of flies to unbroken soft skin

Table 1. Diseases Transmitted by Animals, continued

Disease and/or Organism	Animal Sources/Reservoirs	Vector or Modes of Transmission
Taeniasis/beef tapeworm (<i>Taenia saginata</i>)	Cattle (intermediate host)	Ingestion of larvae in raw or undercooked beef; cysticercosis in cattle is caused by ingestion of embryonated eggs excreted by humans with <i>Taenia</i> infection
Taeniasis and cysticercosis/pork tapeworm (<i>Taenia solium</i> ; <i>Taenia asiatica</i> less common)	Pigs (intermediate host)	Ingestion of larvae in raw or undercooked pork resulting in intestinal infection in humans with adult tapeworms (taeniasis); porcine cysticercosis (infection in pigs) is caused by ingestion of embryonated eggs excreted by humans with <i>Taenia</i> infection, human cysticercosis is caused by ingestion of eggs through fecal contamination of food or water, or by autoinfection
Toxocariasis ocular or visceral larva migrans (<i>Toxocara canis</i> and <i>Toxocara cati</i>)	Dogs, cats; puppies are a major source of environmental contamination	Ingestion of infected, larvated eggs, usually from soil, dirty hands, or food contaminated by animal feces
Toxoplasmosis (<i>Toxoplasma gondii</i>)	Members of the <i>Felidae</i> family (including domestic cats) are definitive hosts; many mammals (eg, sheep, goats, and swine) and birds can serve as intermediate hosts	Transmission can be foodborne, zoonotic, congenital, or in rare instances through organ transplantation Zoonotic transmission can occur through ingestion of infective oocysts from hands after cleaning litter boxes or gardening (soil), or ingestion of anything that has become contaminated with cat feces, such as ingestion of vegetables or low growing fruits; consumption of cysts in raw or undercooked meat (such as lamb, pork, venison) or shellfish (clams, mussels, oysters) Consumption of contaminated water, consumption of raw dairy products (particularly goat's milk)
Trichinellosis (<i>Trichinella spiralis</i> and other <i>Trichinella</i> species)	Pigs, bears, moose, wild boars, seals, walruses, rodents, horses, foxes, wolves	Ingestion of larvae in raw or undercooked meat, particularly pork or wild game meat

Table 1. Diseases Transmitted by Animals, continued

Disease and/or Organism	Animal Sources/Reservoirs	Vector or Modes of Transmission
Chlamydial and Rickettsial Diseases		
Human ehrlichiosis (<i>Ehrlichia chaffeensis</i> , <i>Ehrlichia ewingii</i> , and <i>Ehrlichia muris eauclairensis</i>)	Dogs, red foxes, deer, wolves, coyotes, sheep, goats, racoons, opossums, and lemurs (<i>E chaffeensis</i>); dogs may be reservoir hosts along with wolves and jackals (<i>Ehrlichia canis</i> and <i>E ewingii</i>); unknown (<i>E muris eauclairensis</i>)	Tick bites (Lone star tick [<i>A americanum</i>] for <i>E chaffeensis</i> , <i>E ewingii</i> ; blacklegged tick [<i>I scapularis</i>] for <i>E muris eauclairensis</i>); in rare cases <i>Ehrlichia</i> species have been spread through blood transfusion and organ transplantation
Human anaplasmosis (<i>Anaplasma phagocytophilum</i>)	Small mammals including woodrats and deer mice; larger mammals such as deer, elk, moose, and bison	Tick bites (<i>I scapularis</i> and <i>I pacificus</i>)
Psittacosis (<i>Chlamydia psittaci</i>)	Domestic and wild birds (especially psittacine birds such as parakeets, parrots, macaws, and cockatoos), including poultry	Inhalation of aerosols from feces or dried respiratory secretions of infected birds as well as fecal-oral transmission.
Rickettsialpox (<i>Rickettsia akari</i>)	Common house mouse	Mite bites (house mouse mite, <i>Liponyssoides sanguineus</i>)
Rocky Mountain spotted fever (<i>Rickettsia rickettsii</i>)	Dogs, wild rodents, rabbits	Tick bites (American dog tick, <i>Dermacentor variabilis</i> ; Rocky Mountain wood tick, <i>D andersoni</i> ; and brown dog tick, <i>Rhipicephalus sanguineus</i>)
<i>Rickettsia parkeri</i> infection (maculatum disease, American boutonneuse fever)	Unknown; perhaps cattle, dogs, small wild rodents	Tick bites (Gulf coast tick [<i>Amblyomma maculatum</i>])
Typhus, fleaborne endemic typhus, Murine typhus (<i>Rickettsia typhi</i>)	Rats, opossums, cats, dogs	Infected flea feces scratched into abrasions; oriental rat fleas (<i>Xenopsylla cheopis</i>) and cat fleas (<i>Ctenocephalides felis</i>) are vectors
Typhus, louseborne epidemic typhus (<i>Rickettsia prowazekii</i>)	Flying squirrels (sylvatic typhus)	Person-to-person via infected body louse, contact with flying squirrels, their nests, or ectoparasites (role and species of ectoparasites undefined)

Table 1. Diseases Transmitted by Animals, continued

Disease and/or Organism	Animal Sources/Reservoirs	Vector or Modes of Transmission
Viral Diseases		
B virus (formerly herpes B, monkey B virus, herpesvirus simiae, or herpesvirus B)	Macaque monkeys (excluding <i>Cynomolgus</i> macaques of Mauritian origin)	Bite or exposure to secretions or tissues
Cache Valley virus	Deer, cattle, horses, elk, and sheep	Mosquito bites (many species); rarely through blood transfusion
Colorado tick fever virus	Rodents (eg, squirrels, chipmunks, mice)	Tick bites (Rocky Mountain wood tick [<i>Dermacentor andersoni</i>]); rarely through blood transfusion
Crimean Congo hemorrhagic fever (orthonairovirus)	Many wild and domestic animals including cattle, hares, goats, sheep	Ixodid (hard) ticks, genus <i>Hyalomma</i> , are reservoir and vector; infection from tick bite or contact with infectious blood and body fluids from animal slaughter; person-to-person is possible via direct contact or contact with blood or bodily fluids of an infected person; improperly sterilized medical equipment
Eastern equine encephalitis virus	Birds; possibly rodents; horses and other domesticated mammals can become infected and develop disease but are not believed to amplify virus	Mosquito bites (<i>Coquillettidia</i> species, <i>Aedes</i> species, <i>Culex</i> species, <i>Ochlerotatus</i> species), rarely through organ transplantation
Ebola virus disease (Zaire ebolavirus, Sudan ebolavirus, Tai Forest ebolavirus, Bundibugyo ebolavirus)	Fruit bats; nonhuman primates and other animals may become infected	Direct contact with infected fruit bats or nonhuman primates; person-to-person transmission via direct contact or contact with blood or bodily fluids of an infected person or dead body; prolonged presence in semen of infected individuals (sexual transmission possible); intrauterine transmission; intrapartum transmission, transmission through human milk

Table 1. Diseases Transmitted by Animals, continued

Disease and/or Organism	Animal Sources/Reservoirs	Vector or Modes of Transmission
Hantaviruses	Wild and peridomestic rodents (cotton rat, deer mouse, rice rat, white-footed mouse)	Inhalation of aerosols of infected rodent secreta and excreta; contact with infected rodents or infected droppings and urine, contaminated food; person-to-person transmission of Andes virus (South America) is possible via close contact or inhalation of respiratory secretions from an infected person
Heartland virus	Unknown	Tick bites (Lone-star tick [<i>A. americanum</i>])
Hendra virus	Fruit bats (<i>Pteropus</i> genus) are the natural reservoir; horses can become infected	Contact with body fluids of infected horses, close contact with fruit bats
Novel influenza A viruses (eg, H5N1, H7N9, H9N2, H3N2 variant)	Chickens, birds, pigs	Contact with secretions of infected animals, contaminated surfaces or aerosols (markets, slaughterhouse)
Jamestown Canyon virus	Deer	Mosquito bites (many species)
Japanese encephalitis virus	Water birds; pigs and other mammals can become infected and develop disease but are not believed to amplify virus	Mosquito bites (<i>Culex tritaeniorhynchus</i>); rarely through blood transfusion
Kyasanur forest disease/ Alkhurma hemorrhagic fever (Flavivirus)	Monkeys, rodents, and shrews are common hosts after being bitten by infected ticks	Primarily tick bites (<i>Haemaphysalis spinigera</i>), contact with infected animal
La Crosse virus	Rodents (eg, chipmunks, squirrels)	Mosquito bites (<i>Aedes triseriatus</i>)
Langya henipavirus	Shrews	Unknown

Table 1. Diseases Transmitted by Animals, continued

Disease and/or Organism	Animal Sources/Reservoirs	Vector or Modes of Transmission
Lassa fever (Lassa virus)	Multimammate rat (<i>Mastomys natalensis</i>)	Inhalation of aerosols or direct contact with infected rodent secreta or excreta; consumption of food contaminated by rodents; person-to-person transmission is possible via direct contact or contact with blood or bodily fluids of an infected person
Lujo hemorrhagic fever (Lujo virus)	Rodents	Inhalation of aerosols or direct contact with infected rodent secreta or excreta; consumption of food contaminated by rodents; person-to-person transmission is possible via direct contact or contact with blood or bodily fluids of an infected person
Lymphocytic choriomeningitis virus	Rodents, particularly house mice and pet hamsters (includes feeder rodents used as reptile food), guinea pigs	Inhalation of aerosols; direct contact with infected rodent secreta or excreta; consumption of food contaminated by rodents; vertical transmission if infected during pregnancy
Marburg hemorrhagic fever (Marburg virus)	African fruit bat (<i>Rousettus aegyptiacus</i>), infected nonhuman primates	Contact with fruit bats, their excreta, saliva, or infectious aerosols (eg, entering caves or mines inhabited by bats); contact with infectious blood or tissue of infected monkeys; person-to-person transmission is possible via direct contact or contact with blood or bodily fluids of an infected person
Middle East respiratory syndrome (MERS coronavirus)	Camels are host species in several countries	Respiratory secretions, possible airborne transmission in some cases, direct contact
Monkeypox virus	Natural reservoir unknown; African rodent species and nonhuman primates play a role in transmission	Direct contact with an infected animal or person, including bites or scratches; contact with infected body fluids or lesions (including during sex), or contact with contaminated bedding; inhalation of respiratory droplets and aerosolized particles

Table 1. Diseases Transmitted by Animals, continued

Disease and/or Organism	Animal Sources/Reservoirs	Vector or Modes of Transmission
Nipah virus	Fruit bats; pigs can become infected	Direct contact with infected bats or pigs, or their body fluids; consumption of bat contaminated fruit/sap; person-to-person transmission is possible via direct contact or contact with blood or body fluids of an infected person
Omsk hemorrhagic fever virus	Infected rodents including muskrats and voles	Handling infected muskrats (eg, hunting, trapping, skinning), bites from infected ticks (<i>Dermacentor reticulatus</i> , <i>Ixodes persulcatus</i> , <i>Dermacentor marginatus</i>); raw dairy products from infected goats or sheep
Orf virus	Sheep, goats, and occasionally other ruminants	Direct contact with infected animals; contact with contaminated saliva or fomites, especially through damaged skin
Powassan virus	Small to medium-sized rodents (eg, groundhogs, squirrels, mice)	Tick bites (<i>Ixodes cookei</i> , <i>Ixodes marxi</i> , <i>I scapularis</i>); rarely through blood transfusion
Rabies (Lyssavirus)	In the United States, primarily mammalian wildlife (bats, raccoons, skunks, foxes, coyotes, mongooses) or, less frequently, domestic animals (dogs, cats, cattle, horses, sheep, goats, ferrets)	Bites from infected animals; rarely contact of open wounds, abrasions (including scratches), or mucous membranes with saliva or other infectious materials (eg, neural tissue), corneal and organ transplantation
Rift Valley fever virus	Domesticated livestock (eg, cattle, sheep, goats, buffalo, and camels)	Contact with blood, body fluids, or tissues of infected animals; bites from infected mosquitoes; rarely bites from other insects with virus on their mouthparts; possibly consumption of raw dairy products

Table 1. Diseases Transmitted by Animals, continued

Disease and/or Organism	Animal Sources/Reservoirs	Vector or Modes of Transmission
Severe acute respiratory virus-1 (SARS-CoV-1)	Bats, civet cats, potentially other animal species	Respiratory droplets (airborne transmission believed to occur in some cases), direct contact
Severe acute respiratory virus-2 (SARS-CoV-2)	Unknown	Respiratory secretions (droplets and aerosol particles, including airborne transmission); direct contact with exposed mucous membranes; risk of animal- to-human transmission is low
South American arenaviruses (Junin, Machupo, Guanarito, Sabia, Chapare)	Rodents	Inhalation of aerosols or direct contact with infected rodent secretions or excreta; consumption of food contaminated by rodents; person-to-person transmission is possible
St. Louis encephalitis virus	Birds	Mosquito bites (<i>Culex</i> species); rarely through blood transfusion
Tick-borne encephalitis virus	Primarily small rodents; large animals such as cows, goats and sheep become infected but do not play a role in virus maintenance	Tick bites (<i>Ixodes</i> species); consumption of infected raw dairy products; rarely intrauterine, blood transfusion, or organ transplantation transmission
Venezuelan equine encephalitis virus	Sylvatic rodents, possibly birds; horses are dead-end hosts	Mosquito bites (<i>Aedes</i> species, <i>Anopheles</i> species, <i>Culex</i> species, <i>Deinocerites</i> species, <i>Mansonia</i> species, and <i>Psorophora</i> species)
West Nile virus	Birds; horses and other mammals can become infected and develop disease but are not believed to amplify virus	Mosquito bites (<i>Culex</i> species); rarely through blood transfusion; organ transplantation; intrauterine; risk of transmission through human milk is unknown
Western equine encephalitis virus	Birds; possibly reptiles; horses and other mammals can become infected and develop disease but are not believed to amplify virus	Mosquito bites (<i>Culex tarsalis</i>)
Yellow fever virus	Nonhuman primates	Mosquito bites (<i>Haemagogus</i> species, <i>Sabethes</i> species, <i>Aedes [Stegomyia]</i> species); rarely intrapartum
