The recommendations in this publication do not indicate an exclusive course of treatment or serve as a standard of medical care. Variations, taking into account individual circumstances, may be appropriate.

Publications from the American Academy of Pediatrics benefit from expertise and resources of liaisons and internal (AAP) and external reviewers. However, publications from the American Academy of Pediatrics may not reflect the views of the liaisons of the organizations or government agencies that they represent.

Dr David Kimberlin has disclosed a financial relationship with Elsevier as an editor. Associate Editor disclosures were not relevant to their work related to the *Red Book*. Disclosures are reviewed and mitigated through a Conflict of Interest process approved by the AAP Board of Directors.

The American Academy of Pediatrics has neither solicited nor accepted any commercial involvement in the development of the content of this publication.

2024 *Red Book* Dedication for Sarah S. Long, MD, FAAP

In 1750 and living in Philadelphia, Benjamin Franklin is reported to have said: “Tell me and I forget. Teach me and I remember. Involve me and I learn.” These words likely resonate with each of us. As we think back across our careers, we marvel at our good fortune to have touched lives with gifted educators who inspired us by doing exactly this – teaching, involving, motivating us to realize our full potentials. For so many of us in pediatrics and pediatric infectious diseases, the name that is synonymous with gifted teacher is another Philadelphian—a woman who has blazed a path across decades and lit fires in our minds and our hearts. In recognition of her lifetime of commitment to children and those of us who take care of them, the 2024 *Red Book* is dedicated to Dr. Sarah Long.

Dr. Long’s infectious energy and high expectations are best understood through the lens of her origin. Born in Alaska 15 years before statehood, she has had a frontier spirit throughout all the journeys of her life. When Alaska became a state in 1959, she moved with her family to Washington, DC, where her father was Chief of Staff to Alaska’s first US Senator. From there, she moved to Pennsylvania and attended St. Francis College in the 1960s before entering Jefferson Medical College (now Sidney Kimmel Medical College) as one of only 10 women in a class of almost 200, graduating in 1970. She stayed in Philadelphia for her pediatric residency training at St. Christopher’s Hospital for Children. Always inquisitive, she spent her summers in medical school working at the National Institutes of Health, with a subsequent research fellowship as an NIH trainee at Temple University. She began her first faculty position in 1975 as Chief of Infectious Diseases at St. Christopher’s Hospital for Children, Temple University School of Medicine, and Drexel University College of Medicine in Philadelphia, a position that she held for the next 44 years.

Dr. Long’s recognition for her gifts as an educator are innumerable. She received outstanding teaching awards across every decade beginning in 1977, including the Infectious Diseases Society of America National Clinical Teacher Award in 2012. She was selected by the National Institutes of Health Medical Research Scholars Program to give the

2021 Great Teacher's Lecture. And across the decades, she has delivered over 90 named, memorial, and honorary society lectureships and visiting professorships across the globe, in addition to an average of more than 30 annual lectures nationally and internationally for more than 3 decades. She continues to serve in the IDWeek Clinical Educator Mentor Coaching Program.

In service to the American Academy of Pediatrics (AAP), Dr. Long served on the Committee on Infectious Diseases (COID, or the *Red Book* Committee) from 2002 through 2008. She was Associate Editor of the 2006, 2009, 2012, 2015, and 2018 editions of the *Red Book*. Across those 20 years, she established the doctrine (known by COID members and liaisons as the “Long Doctrine”) by which all current and future iterations of the *Red Book* are anchored, namely that the *Red Book* represents settled science upon which sound clinical decision making can be based. She received the AAP Section on Infectious Diseases Lifetime Contribution to Infectious Diseases Award in 2009, a full decade before she closed out her chapter of service to the Academy.

Dr. Long also served the American Board of Pediatrics (ABP) across the 1990s and into the 2000s, as a member of the ABP Board of Directors, as Secretary-Treasurer, and ultimately as Board Chair. She was the inaugural Chair of the ABP Subspecialty Board of Infectious Diseases when pediatric infectious diseases was designated a subspecialty of pediatrics, where she literally wrote the first pediatric infectious diseases subspecialty examination (her Board Certificate is, appropriately, #01). For all of these activities and more, she received the ABP Board of Directors Proclamation of Distinguished Service in 2015.

Dr. Long also provided key leadership to the Pediatric Infectious Diseases Society (PIDS) and the Infectious Diseases Society of America (IDSA), serving on PIDS Council (now called the PIDS Board of Directors) from 1989 through 1993 and as PIDS President from 1999 through 2001. She Co-Chaired the 48th ICAAC/46th IDSA joint meeting with incredible dexterity and has served as Director of the IDSA Foundation Board of Directors since 2019. She received the PIDS Distinguished Service Award in 2003 and the PIDS Distinguished Physician Award in 2016.

In the mid-1990s, Dr. Long developed the seminal textbook in the field, *Principles and Practice of Pediatric Infectious Diseases*, literally creating it from scratch. Before stepping down in 2023, she served as the Chief Editor for each of its 6 editions published to date (1997, 2003, 2008, 2012, 2018, and 2023), and very appropriately, the 7th edition will now officially be known as *Long's Principles and Practice of Pediatric Infectious Diseases* (which is what we've all been calling it from the beginning!). She has served as Associate Editor of *The Journal of Pediatrics* since 1996 and has published over 320 peer-reviewed publications and close to 200 book chapters. Since 2020, Dr. Long has been a member of the Centers for Disease Control and Prevention (CDC) Advisory Committee on Immunization Practices (ACIP), on which she adroitly helped guide COVID-19 vaccine recommendations across the course of the worst pandemic the world has seen in over a century, in addition to chairing the Maternal/Child RSV Work Group as it developed recommendations for use of the first licensed RSV vaccines.

Even with all of these accomplishments and more not listed, Dr. Long's most meaningful contributions are really at the one-on-one level. Since 2013, she has served on the Program Committee for the Infectious Diseases in Children Symposium held in New York City each November. Even among the tremendously talented speakers featured at

that meeting each year, Dr. Long's lectures are head and shoulders above the rest. It is common to see her surrounded by literally scores of meeting attendees who are general pediatricians and nurse practitioners from around the country, hanging on each clinical insight or teaching point that she provides. Watching these interactions and others at large meetings across the country, I cannot help but think back to Mr. Franklin's words. Sarah teaches them, and they remember. Sarah involves them, and they learn.

Sarah's first fellow was Margaret (Meg) C. Fisher, MD, FAAP, who herself went on to be a tremendous pediatric infectious diseases physician, educator, and AAP Board of Directors member. In 2019, Sarah received the Margaret C. Fisher Eternal Spirit of St. Christopher's Award, from the house staff of St. Christopher's Hospital for Children, taking her contributions full circle. She started at St. Christopher's, she reached out and changed the world, and her hometown family said thank you. Dr. Long, we join in that chorus. Thank you for teaching and involving us all.

2000 Edgar O. Ledbetter, MD, FAAP

1997 Georges Peter, MD, FAAP

1988 Jean D. Lockhart, MD, FAAP

Preface

The *Red Book*, now in its 33rd edition, has been a unique and valuable source of information on infectious diseases and immunizations for pediatric practitioners since 1938. With the practice of pediatrics and pediatric infectious diseases changing rapidly and the limited time available to the practitioner, the *Red Book* remains an essential resource to quickly obtain current, accurate, and easily accessible information about vaccines and vaccine recommendations, emerging infectious diseases, diagnostic modalities, and treatment recommendations. The Committee on Infectious Diseases of the American Academy of Pediatrics (AAP), the editors of the *Red Book*, and the 500 *Red Book* contributors are dedicated to providing the most current and accurate information available in the concise, practical format for which the *Red Book* is known.

As with the 2021 edition, the print version of the *Red Book* will be provided to every AAP member as part of their member benefit. This commitment reflects the Academy's strong interest in its members' needs. In addition, AAP members also will continue to have access to *Red Book* content on *Red Book Online* (www.aapredbook.org). AAP policy statements, clinical reports, and technical reports as well as recommendations endorsed by the AAP are posted on *Red Book Online* as they become available during the 3 years between *Red Book* editions, and online chapters are modified as needed to reflect these changes. The Outbreaks section of *Red Book Online* is a valuable resource that concisely summarizes current infectious disease outbreaks that affect the pediatric population and that have been identified in multiple US states; other outbreak types may be covered occasionally as situations warrant. *Red Book* users also are encouraged to sign up for e-mail alerts on www.aapredbook.org to receive new information and policy updates between editions. In the 2021 *Red Book*, we introduced the Systems-Based Treatment Table, available in both the print edition and *Red Book Online*. The Systems-Based Treatment Table has quickly become a valuable and highly used resource among pediatric practitioners. With this edition, we have expanded and updated the table to include more conditions and the latest information on optimal treatments and durations for specific conditions, and the table has been placed at the beginning of the book before Section 1 for ease of reference. Another important resource is the visual library of *Red Book Online*, which is continually updated and expanded to include more images of infectious diseases, examples of classic radiologic and other findings, and recent information on epidemiology of infectious diseases.

The Committee on Infectious Diseases relies on information and advice from many experts, as evidenced by the lengthy list of contributors to *Red Book*. We especially are indebted to the many contributors from other AAP Committees, Sections, and Councils; the American Academy of Family Physicians; the American College of Obstetricians and Gynecologists; the American Thoracic Society; the Canadian Paediatric Society; the Centers for Disease Control and Prevention; the US Food and Drug Administration; the National Institutes of Health; the National Vaccine Program Office; the Pediatric Infectious Diseases Society; la Sociedad Latinoamericana de Infectología Pediátrica; the World Health Organization; and many other organizations and individuals who have

made this edition possible. In addition, suggestions made by individual AAP members to improve the presentation of information on specific issues and on topic selection have been incorporated whenever possible.

Most important to the success of this edition is the dedication and work of the editors, whose commitment to excellence is unparalleled. This new edition was made possible under the able leadership of David W. Kimberlin, MD, Editor, along with Associate Editors Ritu Banerjee, MD, PhD, Elizabeth D. Barnett, MD, Ruth Lynfield, MD, and Mark H. Sawyer, MD. We also are indebted to Tina Tan, MD, for her work on the *Red Book Atlas of Pediatric Infectious Diseases* and *Red Book: A Quick Diagnosis Deck*, and to Kristina Bryant, MD, for her extensive efforts on *Red Book Online*. We also extend heartfelt thanks to Henry H. Bernstein, DO, MHCM, for his many years of service as Editor of *Red Book Online*. Finally, we would like to extend our thanks to many staff at the AAP who contribute to the production of the *Red Book*. Specifically, we would like to thank Jennifer Frantz, MPH, for her many years of service as Senior Manager of Infectious Diseases Policy and Programs; Gillian Gibbs, MPH, who now serves in that role; Linda Rutt, for keeping all of the draft chapters flowing through a very complex production sequence; and Jennifer Shaw, for her extraordinary copyediting skills.

As noted in previous editions of the *Red Book*, some omissions and errors are inevitable in a book of this type. We ask that AAP members continue to assist the committee actively by suggesting specific ways to improve the quality of future editions. The committee membership and editorial staff hope that the 2024 *Red Book* will enhance your practice and benefit the children you serve.

Sean T. O’Leary, MD, MPH, FAAP
Chairperson, Committee on Infectious Diseases

Introduction

The Committee on Infectious Diseases (COID) of the American Academy of Pediatrics (AAP) is responsible for developing and revising guidance from the AAP for management and control of infectious diseases in infants, children, and adolescents. Every 3 years, the COID issues the *Red Book: Report of the Committee on Infectious Diseases*, which contains a composite summary of current recommendations representing the policy of the AAP on various aspects of infectious diseases, including updated vaccine recommendations for the most recent US Food and Drug Administration (FDA)-licensed vaccines for infants, children, and adolescents. These recommendations represent a consensus of opinions based on consideration of the best available evidence by members of the COID, in conjunction with liaison representatives from the Centers for Disease Control and Prevention (CDC), the FDA, the National Institutes of Health (NIH), the National Vaccine Program Office, the Canadian Paediatric Society, the American Thoracic Society, the Pediatric Infectious Diseases Society, the American Academy of Family Physicians, the American College of Obstetricians and Gynecologists, *Red Book* consultants, and scores of collaborators. This edition of the *Red Book* is based on information available as of February 2024.

To aid physicians and other health care professionals in assimilating current changes in recommendations in the *Red Book*, a listing of major changes between the 2021 and 2024 editions has been compiled (see Summary of Major Changes, p xxxvii). However, this list only begins to cover the many in-depth changes that have occurred in each chapter and section. Throughout the *Red Book*, internet addresses enable rapid access to new information available following the publication date. In addition, specific chapters within the *Red Book* may be updated prior to the publication of the next edition to incorporate new information from AAP policy statements and clinical reports, publications in the CDC *Morbidity and Mortality Weekly Report (MMWR)*, society guidelines (eg, from the Infectious Diseases Society of America or the American Thoracic Society), management recommendations from the World Health Organization, and similar authoritative guidance documents from organizations of similar stature. When updates to existing *Red Book* chapters are made, the new material is posted on *Red Book Online* with clear delineation of how the chapter has been updated with the new information. This and other *Red Book Online* content can be accessed at **www.publications.aap.org/redbook**.

The *Red Book* is your personal access to literally hundreds of pediatric infectious disease consultant, on your bookshelf and ready for you 24 hours a day, 7 days a week. Arguably, it is most valuable in those circumstances in which definitive data from randomized controlled trials are lacking. It is in those situations that guidance from experts in the field is most critical, and the COID has literally thousands of years of cumulative expertise to bring to bear on such recommendations. This is all the more important as we move into the post-pandemic era, in which the rapid retrieval of accurate and reliable information is critical to the care of patients and the workflow of physician practices. A major emphasis of the 2024 *Red Book* is to provide more guidance in the format of tables, figures, and algorithms to allow for busy clinicians in offices, hospitals, and via telehealth

to quickly find management recommendations from the hundreds of contributors to *Red Book* content.

One significant change since the publication of the 2021 *Red Book* is our appreciation that “Words Matter,” to use the phrase embraced by the AAP.¹ Throughout the 2024 edition of the *Red Book*, we have sought to use inclusive, anti-biased language contextualized to the unique moment in history in which we practice medicine. For some chapters, however, the terms “male” and “female” are used for clarity of recommendations; when so utilized, a footnote has been added at the beginning of the chapter to indicate that these terms refer to the sex assigned at birth. Likewise, the word chestfeeding may be used by nonbinary, transgender, and other parents to identify how they feed their infants. It may refer to human milk or human milk substitute feeding, from a person who lactates or not. Because of this broad and variable definition, chestfeeding and breastfeeding are not always synonymous, and the words are not interchangeable. Published literature findings on breastfeeding may not hold the same outcomes for chestfeeding, so throughout the 2024 edition, the words breastfeeding and human milk are used.

Preparation of the *Red Book* is a team effort in the truest sense of the term. Within weeks following the publication of each *Red Book* edition, all *Red Book* chapters are sent for updates to primary reviewers who are leading national and international experts in their specific areas. For the 2024 *Red Book*, one third of primary reviewers were new to this process, ensuring that the most up-to-date information has been included in this new edition. Following review by the primary reviewer, each chapter is returned to the assigned Associate Editor for incorporation of the reviewer’s edits. The chapter then is disseminated to content experts at the CDC, NIH, and FDA and to members of all AAP Sections, Committees, and Councils who agree to review specific chapters for their additional edits as needed, after which it again is returned to the assigned Associate Editor for harmonization and incorporation of edits as appropriate. Two designated COID reviewers then complete a final review of the chapter, and it is returned to the assigned Associate Editor for inclusion of any needed additional modifications. Chapters requiring consideration by the full committee then are debated at the COID “Marathon Meeting,” where the chapters are finalized. Copyediting by the Editor and Senior Medical Copy Editor, Jennifer Shaw, follows, and the book then is reviewed by the *Red Book* reviewers appointed by the AAP Board of Directors. In all, over 1000 hands have touched the 2024 *Red Book* prior to its publication! That so many contributors dedicate so much time and expertise to this product is a testament to the role the *Red Book* plays in the care of children.

Through the deliberative and inclusive process that defines the production of the *Red Book*, the COID endeavors to provide current, relevant, evidence-based recommendations for the prevention and management of infectious diseases in infants, children, and adolescents. Seemingly unanswerable scientific questions, the complexity of medical practice, ongoing innovative technology, continuous new information, and inevitable

¹ American Academy of Pediatrics. Words Matter: AAP Guidance on Inclusive, Anti-biased Language. May 14, 2021. Available at: www.aap.org/en/about-the-aap/american-academy-of-pediatrics-equity-and-inclusion-efforts/words-matter-aap-guidance-on-inclusive-anti-biased-language/

differences of opinion among experts all are addressed during production of the *Red Book*. In some cases, other committees and experts may differ in their interpretation of data and resulting recommendations, and occasionally no single recommendation can be made because several options for management are equally acceptable. In such circumstances, the language incorporated in the chapter acknowledges these differing acceptable management options by use of the phrases “most experts recommend...” and “some experts recommend...” Both phrases indicate valid recommendations, but the first phrase signifies more agreement and support among the experts. Inevitably in clinical practice, questions arise that cannot be answered easily on the basis of currently available data. When this happens, the COID still provides guidance and information that, coupled with clinical judgment, will facilitate well-reasoned, clinically relevant decisions. Through this process of lifelong learning, the committee seeks to provide a practical guide for physicians and other health care professionals in their care of infants, children, and adolescents.

Information on use of antimicrobial agents is included in the package inserts (product labels) prepared by manufacturers, including contraindications and adverse events. The *Red Book* does not attempt to provide this information comprehensively, because it is available readily in package inserts. As in previous editions of the *Red Book*, recommended dosage schedules for antimicrobial agents are provided (see Section 4, Antimicrobial Agents and Related Therapy) and may differ from those of the manufacturer as provided in the package insert. Antimicrobial agents recommended for specific infections in the *Red Book* may or may not have an FDA indication for treatment of that infection. Physicians also can reference additional information in the package inserts of vaccines licensed by the FDA (which also may differ from COID and CDC recommendations for use) and of immune globulins, as well as recommendations of other committees (see Sources of Information About Vaccines and Immunization, p 21), many of which are included in the *Red Book*.

This book could not have been prepared without the dedicated professional competence of numerous people. The AAP staff has been outstanding in its committed work and contributions, particularly Jennifer Shaw, Senior Medical Copy Editor; Linda Rutt, Division Coordinator; Jennifer Frantz and Gillian Gibbs, Senior Managers, who served as the administrative directors for the COID and coordinated preparation of the *Red Book*; Theresa Wiener, Manager of Publishing and Production Services; and all of the directors and staff of the AAP publishing and marketing groups who make the full *Red Book* product line possible.

Lakshmi Panagiotakopoulos, MD, of the CDC, and Karen M. Farizo, MD, of the FDA, devoted time and effort in providing significant input from their organizations. Patricia Flanagan, MD, Yasuko Fukuda, MD, and Warren Seigel, MD, served as *Red Book* reviewers appointed by the AAP Board of Directors, spending scores of hours reviewing the final chapters for consistency and accuracy. I am especially indebted to the Associate Editors, Ritu Banerjee, MD, PhD, Elizabeth D. Barnett, MD, Ruth Lynfield, MD, and Mark H. Sawyer, MD, for their expertise, tireless work, good humor, and immense contributions in their editorial and committee work. Members of the COID contributed countless hours and deserve appropriate recognition for their patience, dedication, revisions, and reviews. The COID appreciates the guidance and dedication of Sean O’Leary, MD,

COID Chairperson, whose knowledge, dedication, insight, and leadership are reflected in the quality and productivity of the committee's work. There are many additional contributors whose professional work and commitment have been essential in the committee's preparation of the *Red Book*. Please forgive any omissions I have made in expressing my gratitude.

And last but certainly not least, I thank my wife, Kim, for always being there and for her patience, understanding, and never-ending support as this edition of the *Red Book* came to fruition.

David W. Kimberlin, MD, FAAP, Editor

Summary of Major Changes in the 2024 *Red Book*

SYSTEMS-BASED TREATMENT TABLE.....1

SECTION 1

ACTIVE AND PASSIVE IMMUNIZATION

Prologue	19
Sources of Information About Vaccines and Immunization	21
Discussing Vaccines With Patients and Parents	25
Vaccine Uptake: Definitions and Understanding Common Influences of Vaccine Behavior.....	25
Understanding Vaccine Evaluation and Safety as an Approach to Addressing Parental Concerns.....	27
Evidence-Based Communication Strategies to Increase Uptake of Childhood Vaccines	32
Use a Strong Vaccine Recommendation and the Presumptive Format for Initiating the Vaccine Discussion	34
For Parents Who Express Hesitancy, Use Additional Evidence-Based Communication Strategies	35
Leverage Systems, Organizational Approaches, and Community Initiatives to Improve Parental Access to Vaccines.....	36
Policies for Families Who Refuse or Delay Vaccination.....	36
Vaccine Injury Compensation.....	36
Active Immunization.....	38
Vaccine Ingredients	42
Vaccine Handling and Storage.....	45
Vaccine Administration	52
Managing Injection Pain	57
Immunization Schedule and Timing of Vaccines	58
Minimum Ages and Minimum Intervals Between Vaccine Doses	61
Interchangeability of Vaccine Products	62
Simultaneous Administration of Multiple Vaccines.....	63
Combination Vaccines.....	65
Lapsed Immunizations	66
Unknown or Uncertain Immunization Status.....	67
Vaccine Dose	68
Active Immunization After Receipt of Antibody-Containing Products.....	68
Hypersensitivity Reactions After Immunization	71
Immediate-Type Allergic Reactions.....	71
Delayed-Type Allergic Reactions	72
Other Vaccine Reactions	73
Passive Immunization.....	73

Immune Globulin Intramuscular (IGIM).....	74
Immune Globulin Intravenous (IGIV)	77
Immune Globulin Subcutaneous (IGSC).....	82
Treatment of Anaphylactic Reactions.....	84
Immunization in Special Clinical Circumstances	87
Immunization in Preterm and Low Birth Weight Infants	87
Immunization in Pregnancy	89
Immunization and Other Considerations in Immunocompromised Children	93
Immunization in Children With a Personal or Family History of Seizures	109
Immunization in Children With Chronic Diseases	110
Immunization in American Indian/Alaska Native Children and Adolescents	111
Immunization in Adolescent and College Populations.....	114
Immunization in Health Care Personnel	115
Children Who Received Immunizations Outside the United States or Whose Immunization Status is Unknown or Uncertain.....	119
International Travel.....	126

SECTION 2

RECOMMENDATIONS FOR CARE OF CHILDREN IN SPECIAL CIRCUMSTANCES

Breastfeeding and Human Milk.....	135
AAP Recommendations on Breastfeeding	135
Contraindications to Breastfeeding	136
Transmission of Infectious Agents via Human Milk.....	136
Immunization of Breastfeeding Parents and Infants.....	141
Human Milk Banks	143
Inadvertent Human Milk Exposure	143
Antimicrobial Agents and Other Drugs in Human Milk.....	144
Anti-TNF Biologic Response Modifiers in Human Milk	144
Children in Group Child Care and Schools	145
Modes of Spread of Infectious Diseases	145
Respiratory Tract Diseases.....	145
Enteric Diseases	147
Bloodborne Infections.....	148
Other Infections	157
Management and Prevention of Infectious Diseases	158
Immunization.....	158
Infection Prevention and Control	159
Exclusion and Return to Care or School	161
Infection Prevention and Control for Hospitalized Children	163
Infection Prevention and Control Precautions	164
Strategies to Prevent Health Care-Associated Infections	171
Occupational Health.....	172
Sibling Visitation	173
Adult Visitation.....	174
Pet Visitation.....	174
Infection Prevention and Control in Ambulatory Settings	175

Sexually Transmitted Infections in Adolescents and Children	179
STIs During Preventive Health Care of Adolescents	180
Sexual Assault and Abuse in Children and Adolescents/Young Adults.....	182
Medical Evaluation for Infectious Diseases for Internationally Adopted, Refugee, and Other Immigrant Children.....	189
Internationally Adopted Children	190
Refugees.....	190
Immigrants	191
Consideration for Testing for Infectious Agents.....	191

SECTION 3

SUMMARIES OF INFECTIOUS DISEASES

Actinomycosis.....	221
Adenovirus Infections.....	222
Amebiasis	225
Amebic Meningoencephalitis and Keratitis (<i>Naegleria fowleri</i> , <i>Acanthamoeba</i> species, and <i>Balamuthia mandrillaris</i>)	228
Anthrax.....	232
Arboviruses (Including Cache Valley, Colorado Tick Fever, Eastern Equine Encephalitis, Heartland, Jamestown Canyon, Japanese Encephalitis, La Crosse, Powassan, St. Louis Encephalitis, Tick-borne Encephalitis, and Yellow Fever Viruses)	237
<i>Arcanobacterium haemolyticum</i> Infections.....	244
<i>Ascaris lumbricoides</i> Infections	246

Aspergillosis.....	247
Astrovirus Infections.....	252
Babesiosis	253
<i>Bacillus cereus</i> Infections and Intoxications	256
Bacterial Vaginosis	258
<i>Bacteroides</i> , <i>Prevotella</i> , and Other Anaerobic Gram-Negative Bacilli Infections	261
<i>Balantidium coli</i> Infections (Balantidiasis).....	262
<i>Bartonella henselae</i> (Cat-Scratch Disease)	263
<i>Baylisascaris</i> Infections.....	266
Infections With <i>Blastocystis</i> Species	268
Blastomycosis.....	270
Bocavirus.....	272
<i>Borrelia</i> Infections Other Than Lyme Disease (Relapsing Fever)	274
Brucellosis	277
<i>Burkholderia</i> Infections	280
<i>Campylobacter</i> Infections.....	283
Candidiasis	286
Chancroid and Cutaneous Ulcers.....	293
Chikungunya.....	295
Chlamydial Infections	298
<i>Chlamydia pneumoniae</i>	298
<i>Chlamydia psittaci</i> (Psittacosis, Ornithosis, Parrot Fever)	299
<i>Chlamydia trachomatis</i>	301
Clostridial Infections	308
Botulism and Infant Botulism (<i>Clostridium botulinum</i>).....	308
Clostridial Myonecrosis (Gas Gangrene)	312
<i>Clostridioides difficile</i> (Formerly <i>Clostridium difficile</i>)	313
<i>Clostridium perfringens</i> Foodborne Illness	319
Coccidioidomycosis.....	320
Coronavirus Disease 2019 (COVID-19).....	324
Coronaviruses, Including MERS-CoV and SARS-CoV-1	332
<i>Cryptococcus neoformans</i> and <i>Cryptococcus gattii</i> Infections (Cryptococcosis)	334
Cryptosporidiosis	338
Cutaneous Larva Migrans	341
Cyclosporiasis.....	342
Cystoisosporiasis (Formerly Isosporiasis).....	343
Cytomegalovirus Infection	344
Dengue.....	352
Diphtheria.....	357
<i>Ehrlichia</i> , <i>Anaplasma</i> , and Related Infections (Human Ehrlichiosis, Anaplasmosis, and Related Infections Attributable to Bacteria in the Family <i>Anaplasmataceae</i>)	361
Serious Neonatal Bacterial Infections Caused by <i>Enterobacterales</i> (Including Septicemia and Meningitis)	365
Enterovirus (Nonpoliovirus) (Group A and B Coxsackieviruses, Echoviruses, Numbered Enteroviruses)	369
Epstein-Barr Virus Infections (Infectious Mononucleosis)	372
<i>Escherichia coli</i> Diarrhea (Including Hemolytic-Uremic Syndrome)	376

Other Fungal Diseases	382
<i>Fusobacterium</i> Infections (Including Lemierre Syndrome)	388
<i>Giardia duodenalis</i> (Formerly <i>Giardia lamblia</i> and <i>Giardia intestinalis</i>) Infections (Giardiasis).....	390
Gonococcal Infections.....	394
Granuloma Inguinale (Donovanosis)	399
<i>Haemophilus influenzae</i> Infections	400
Hantavirus Pulmonary Syndrome	409
<i>Helicobacter pylori</i> Infections	412
Hemorrhagic Fevers Caused by Arenaviruses.....	417
Hemorrhagic Fevers Caused by Bunyaviruses	420
Hemorrhagic Fevers Caused by Filoviruses: Ebola and Marburg	423
Hepatitis A	430
Hepatitis B	437
Hepatitis C	458
Hepatitis D	464
Hepatitis E	465
Herpes Simplex.....	467
Histoplasmosis.....	478
Hookworm Infections (<i>Necator americanus</i> and <i>Ancylostoma</i> species).....	482
Human Herpesvirus 6 (Including Roseola) and 7.....	484
Human Herpesvirus 8.....	487
Human Immunodeficiency Virus Infection	489
Human Papillomaviruses	503
Influenza	511
Kawasaki Disease	522
<i>Kingella kingae</i> Infections	529
<i>Legionella</i> Infections	531
Leishmaniasis	535
Leprosy.....	539
Leptospirosis.....	542
<i>Listeria monocytogenes</i> Infections (Listeriosis).....	545
Lyme Disease (Lyme Borreliosis, <i>Borrelia burgdorferi</i> sensu lato Infection).....	549
Lymphatic Filariasis (Bancroftian, Malayan, and Timorian).....	557
Lymphocytic Choriomeningitis Virus.....	559
Malaria.....	561
Measles.....	570
Meningococcal Infections	585
Human Metapneumovirus.....	599
Microsporidia Infections (Microsporidiosis).....	601
Molluscum Contagiosum	603
<i>Moraxella catarrhalis</i> Infections	604
Mpox.....	606
Mumps.....	611
<i>Mycoplasma pneumoniae</i> and Other <i>Mycoplasma</i> Species Infections.....	616
Nocardiosis.....	620
Norovirus and Sapovirus Infections	622

Onchocerciasis (River Blindness, Filariasis)	624
Paracoccidioidomycosis (Formerly Known as South American Blastomycosis).....	626
Paragonimiasis	628
Parainfluenza Viral Infections.....	630
Parasitic Diseases.....	632
Parechovirus Infections	637
Parvovirus B19 (Erythema Infectiosum, Fifth Disease).....	638
<i>Pasteurella</i> Infections	642
Pediculosis Capitis (Head Lice)	644
Pediculosis Corporis (Body Lice).....	649
Pediculosis Pubis (Pubic Lice, Crab Lice)	650
Pelvic Inflammatory Disease	652
Pertussis (Whooping Cough)	656
Pinworm Infection (<i>Enterobius vermicularis</i>).....	667
Pityriasis Versicolor (Formerly Tinea Versicolor).....	669
Plague.....	671
<i>Pneumocystis jirovecii</i> Infections.....	676
Poliovirus Infections	682
Polyomaviruses (BK, JC, and Other Polyomaviruses).....	689
Prion Diseases: Transmissible Spongiform Encephalopathies	692
<i>Pseudomonas aeruginosa</i> Infections	697
Q Fever (<i>Coxiella burnetii</i> Infection).....	699
Rabies.....	702
Rat-Bite Fever	711
Respiratory Syncytial Virus	713
Rhinovirus Infections	721
Rickettsial Diseases	723
Rickettsialpox.....	726
Rocky Mountain Spotted Fever	727
Rotavirus Infections	730
Rubella.....	735
<i>Salmonella</i> Infections.....	742
Scabies.....	750
Schistosomiasis	753
<i>Shigella</i> Infections	756
Smallpox (Variola).....	760
Sporotrichosis.....	764
Staphylococcal Food Poisoning	766
<i>Staphylococcus aureus</i>	767
Coagulase-Negative Staphylococcal Infections.....	782
Group A Streptococcal Infections.....	785
Group B Streptococcal Infections	799
Non-Group A or B Streptococcal and Enterococcal Infections	806
<i>Streptococcus pneumoniae</i> (Pneumococcal) Infections	810
Strongyloidiasis (<i>Strongyloides stercoralis</i>)	822
Syphilis.....	825
Tapeworm Diseases (Taeniasis and Cysticercosis)	842

Other Tapeworm Infections (Including Hydatid Disease).....	845
Tetanus (Lockjaw)	848
Tinea Capitis (Ringworm of the Scalp).....	854
Tinea Corporis (Ringworm of the Body)	858
Tinea Cruris (Jock Itch).....	861
Tinea Pedis and Tinea Unguium (Onychomycosis) (Athlete's Foot, Ringworm of the Feet).....	863
Toxocariasis.....	865
<i>Toxoplasma gondii</i> Infections (Toxoplasmosis).....	867
Trichinellosis (<i>Trichinella spiralis</i> and Other Species).....	875
<i>Trichomonas vaginalis</i> Infections (Trichomoniasis).....	877
Trichuriasis (Whipworm Infection).....	880
African Trypanosomiasis (Sleeping Sickness).....	881
American Trypanosomiasis (Chagas Disease).....	884
Tuberculosis	888
Nontuberculous Mycobacteria (Environmental Mycobacteria, Mycobacteria Other Than <i>Mycobacterium tuberculosis</i>).....	920
Tularemia.....	929
Louse-borne Typhus (Epidemic or Sylvatic Typhus).....	932
Murine Typhus (Endemic or Flea-borne Typhus).....	934
<i>Ureaplasma urealyticum</i> and <i>Ureaplasma parvum</i> Infections.....	936
Varicella-Zoster Virus Infections.....	938
<i>Vibrio</i> Infections	952
Cholera (<i>Vibrio cholerae</i>)	952
Other <i>Vibrio</i> Infections.....	955
West Nile Virus	957
<i>Yersinia enterocolitica</i> and <i>Yersinia pseudotuberculosis</i> Infections (Enteritis and Other Illnesses)	960
Zika	963

IV	Guide to Contraindications and Precautions to Immunizations	1144
V	Prevention of Infectious Disease From Contaminated Food Products.....	1145
VI	Clinical Syndromes Associated With Foodborne Diseases	1150
VII	Diseases Transmitted by Animals (Zoonoses).....	1157

Summary of Major Changes in the 2024 *Red Book*

MAJOR CHANGES: GENERAL

1. All chapters in the last edition of the *Red Book* were assessed for relevance in the dynamic environment that is the practice of pediatric medicine today. The revisions to the **Discussing Vaccines With Patients and Parents** chapter included discussions of safety monitoring mechanisms, allowing for elimination of 6 chapters included in the last *Red Book* that reviewed each of these safety systems separately. Chapters on **COVID-19** and **Mpox** have been broken out from the chapters in which they were discussed in the 2021 edition, creating 2 new chapters. This means we have a net decrease of 4 chapters in the 2024 *Red Book* compared with the prior edition.
2. Every chapter in the 2024 *Red Book* has been modified since the last edition. The listing below outlines the more major changes throughout the 2014 edition.
3. A major focus of the 2024 *Red Book* is to streamline the retrieval of information needed to care for the patient sitting in front of the clinician, either in the office or hospital room or remotely via telehealth. To accomplish this, we have greatly expanded the use of tables, figures, and algorithms that can rapidly be accessed to gather the information needed at that moment.
4. Appropriate chapters throughout the *Red Book* have been updated to be consistent with 2024 American Academy of Pediatrics (AAP) and Centers for Disease Control and Prevention (CDC) vaccine recommendations, CDC recommendations for immunization of health care personnel, and drug recommendations from 2024 *Nelson's Pediatric Antimicrobial Therapy*.¹
5. To ensure that the information presented in the *Red Book* is based on the most accurate and up-to-date scientific data, the primary reviewers of each *Red Book* chapter were selected for their specific academic expertise in each particular area. In this edition of the *Red Book*, 35% of the primary reviewers were new for their assigned chapters. This ensures that the *Red Book* content is viewed with fresh eyes with each publication cycle.
6. Throughout the *Red Book*, the number of websites where additional current and future information can be obtained has been updated. All websites are in bold type for ease of reference, and all have been verified for accuracy and accessibility.
7. Reference to evidence-based policy recommendations from the AAP, the Advisory Committee on Immunization Practices (ACIP) of the CDC, the National Institutes of Health (NIH), and other select professional organizations have been updated throughout the *Red Book*.

¹ Bradley JS, Nelson JD, Barnett ED, et al, eds. 2024 *Nelson's Pediatric Antimicrobial Therapy*. 30th ed. Itasca, IL: American Academy of Pediatrics; 2024

8. Standardized approaches to disease prevention through immunizations, antimicrobial prophylaxis, and infection-control practices have been updated throughout the *Red Book*.
9. Policy updates released after publication of this edition of the *Red Book* will be posted on *Red Book Online*.

SYSTEMS-BASED TREATMENT TABLE

1. The **Systems-Based Treatment Table** that was introduced in Section 4 of the 2021 edition of the *Red Book* has been moved to the front of the book for easier access. It also has been reordered so that the grouped recommendations by body system are more easily and quickly accessed. Empiric antibiotic options for several of the infections in this table have been expanded.

SECTION 1. ACTIVE AND PASSIVE IMMUNIZATION

1. Internet resources for vaccine information have been updated in **Sources of Information About Immunization**.
2. The **Discussing Vaccines With Patients and Parents** chapter has been completely rewritten to align with the forthcoming AAP clinical report “Strategies for Improving Vaccine Communication and Uptake.” This chapter includes discussion of safety surveillance systems, allowing for elimination of separate chapters covering these in the prior edition of the *Red Book*.
3. In the **Active Immunization** chapter and across the *Red Book*, terminology has changed from “live and inactivated vaccines” to “live and non-live vaccines.” In addition, detailed information on mRNA vaccines has been added.
4. New-generation vaccines containing mRNA encoding for antigens or viral vectors that express antigens have been added to the **Vaccine Ingredients** chapter.
5. Guidance on storage of a frozen vaccine that has been thawed and on beyond-use date/time (BUD) has been added to the **Vaccine Handling and Storage** chapter.
6. In the **Vaccine Administration** chapter, a Vaccine Administration Errors section has been added, and the Patient Care Before, During, and After Vaccine Administration section has been expanded.
7. A listing of vaccines that are more likely to be painful has been added to the **Managing Injection Pain** chapter.
8. A strong statement discouraging creation of unique vaccination schedules outside of the reviewed and recommended schedules has been added to the **Immunization Schedule and Timing of Vaccines** chapter.
9. Recommendation has been added to **Minimum Ages and Minimum Intervals Between Vaccine Doses** for what to do if intervals between doses are longer than recommended.
10. *Haemophilus influenzae* type b, rotavirus, and quadrivalent meningococcal vaccines have been added to the list of approved vaccines in the **Interchangeability of Vaccine Products** chapter that may be used interchangeably during a vaccine series from different manufacturers.

11. Recommendations have been added to the chapter on **Simultaneous Administration of Multiple Vaccines** for spacing between mpox vaccine and COVID-19 vaccines.
12. In the **Combination Vaccines** chapter, use of DTaP-IPV (Quadracel) as a 4th or 5th dose in the IPV series has been expanded to include patients who previously had received Vaxelis.
13. In the **Unknown or Uncertain Immunization Status** chapter, specific acceptable approaches are provided for when the immunogenicity of vaccines or the completeness of the vaccine series are unknown, especially for vaccines administered outside of the United States.
14. Guidance is provided in the **Vaccine Dose** chapter on appropriate dosing for a child receiving a COVID-19 vaccine when the child's age changes between doses.
15. The chapter on **Active Immunization After Receipt of Antibody-Containing Products** has been modified to better reflect the chapter contents. An interval between receipt of an antibody product and administration of dengue vaccine has been added. "Different anatomic site" language for hepatitis B vaccine (HepB) and hepatitis B immune globulin (HBIG) has been clarified.
16. Recommendations have been updated to the **Hypersensitivity Reactions After Immunization** chapter for skin testing for reactions to excipients in vaccines.
17. Bioavailability adjustments for immune globulin subcutaneous (IGSC) compared with immune globulin intravenous (IGIV) are provided in the **Passive Immunization** chapter.
18. A link to a listing of all immune globulin intramuscular (IGIM) products available in the United States has been added to the **Immune Globulin Intramuscular** chapter.
19. Use of IGIV in multisystem inflammatory syndrome in children (MIS-C) has been added to the **Immune Globulin Intravenous** chapter.
20. Dose-adjustment instructions on transitioning from IGIV to IGSC are provided in the **Immune Globulin Subcutaneous** chapter.
21. Language has been added to **Immunization in Special Clinical Circumstances** chapter stressing the need for caregivers of preterm and very low birth weight infants to receive COVID-19 vaccine.
22. In the **Immunization in Pregnancy** chapter, COVID-19 vaccine has been added to the list of vaccines specifically recommended for routine administration during pregnancy. Tdap vaccines have been approved by the US Food and Drug Administration (FDA) for use in pregnancy since the last edition, and these have been added. Guidance on use of mpox vaccine during pregnancy has been added.
23. The definition of severe immunosuppression from human immunodeficiency virus (HIV) has been standardized across the *Red Book*, including the chapter on **Immunization and Other Considerations in Immunocompromised Children**. Recommendations have been added for vaccine administration to persons who have received CD19-targeted chimeric antigen receptor (CAR) T-cell therapy.

24. Guidance is provided in the **Immunization in Children With a Personal or Family History of Seizures** chapter on what information should be provided to parents of children with a personal history of febrile seizures.
25. Asplenia and persistent complement component deficiency have been added to the **Immunization in Children With Chronic Diseases** chapter.
26. Discussion of pertussis and COVID-19 vaccination has been added to the chapter on **Immunization in American Indian/Alaska Native Children and Adolescents**.
27. Recent detections of circulating vaccine-derived poliovirus in the United States have been added to the **Immunization in Health Care Personnel** chapter. COVID-19 vaccination of health care personnel is addressed.
28. A new table has been added to the chapter on **Children Who Received Immunizations Outside the United States or Whose Immunization Status is Unknown or Uncertain** showing when antibody testing for vaccine-preventable diseases should be performed in unimmunized or underimmunized children.
29. Tick-borne encephalitis (TBE) and COVID-19 vaccines have been added to the **International Travel** chapter. Rabies preexposure prophylaxis recommendations have been updated. Availability of the yellow fever vaccine in the United States has been updated.

SECTION 2. RECOMMENDATIONS FOR CARE OF CHILDREN IN SPECIAL CLINICAL CIRCUMSTANCES

1. The **Breastfeeding and Human Milk** chapter was updated to align with information in the 2022 AAP policy statement on breastfeeding. This chapter includes recommendations on COVID-19, group B *Streptococcus*, cytomegalovirus (CMV), hepatitis C virus (HCV), HIV, mpox, and tick-borne encephalitis infections in breastfeeding individuals or transmission in human milk.
2. COVID-19 has been added to the **Children in Group Child Care and Schools** chapter.
3. On the basis of experience from the COVID-19 pandemic, recommendations on prevention of airborne and droplet transmission are presented in the **Infection Prevention and Control for Hospitalized Children** chapter more in terms of points along a continuum rather than discrete modes of transmission. Discussion of source control of sick visitors is expanded.
4. Identification of patients known to be infected or colonized with highly resistant organisms is emphasized in the **Infection Prevention and Control in Ambulatory Settings** chapter. Guidance on drawing up of medications is provided.
5. The preexposure HIV prophylaxis description has been expanded in the **Sexually Transmitted Infections in Adolescents and Children** chapter. *Trichomonas* treatment and expedited partner therapy information have been updated.
6. The **Medical Evaluation for Infectious Diseases for Internationally Adopted, Refugee, and Other Immigrant Children** chapter has had a number of modifications. When to test for hepatitis A has been clarified. Testing recommendations for syphilis have been updated. Acceptable assays for tuberculosis (TB) testing have been expanded. Circumstances in which repeat testing for HIV

following resettlement have been added. Presumptive treatment recommendations for malaria are provided.

7. Testing recommendations following possible exposure to HCV are updated and expanded in the **Injuries From Needles Discarded in the Community** chapter.
8. Risk of B virus infection following macaque bites, of *Salmonella* and *Aeromonas* infection following reptile bites, and of *Vibrio* species infection following shark bites has been added to the **Bite Wounds** chapter.
9. A table has been added to the **Prevention of Mosquito-borne and Tick-borne Infections** chapter summarizing mosquito- and tick-borne infections in the United States.

SECTION 3. SUMMARIES OF INFECTIOUS DISEASES

1. *Actinomyces* as a cause of adverse pregnancy outcomes and neonatal bacteremia has been added to the **Actinomycosis** chapter.
2. **Adenovirus** has been added as a cause of severe hepatitis and liver failure. Discussion of the antiviral treatment of adenovirus infections has been expanded. Management of adenovirus in immunocompromised patients has been added.
3. Secnidazole has been added as a treatment option for mild to moderate intestinal **Amebiasis**.
4. *Acanthamoeba* as a cause of rhinosinusitis has been added to the **Amebic Meningoencephalitis and Keratitis** chapter. Treatment options for *Acanthamoeba* infections have been expanded.
5. Treatment and postexposure prophylaxis of **Anthrax** has been aligned with new CDC recommendations. New vaccine information is also provided.
6. Dengue and yellow fever vaccine information has been updated in the **Arboviruses** chapter. Tick-borne encephalitis vaccine has been added. Cache Valley virus has been added.
7. Description of invasive disease, which occurs rarely, has been added to the ***Arcanobacterium haemolyticum* Infections** chapter.
8. Mention of the cost of albendazole and mebendazole for ***Ascaris lumbricoides* Infections** has been added.
9. Use of polymerase chain reaction (PCR) assay in patients with **Aspergillosis** who have underlying hematologic malignancies and hematopoietic cell transplantation recipients has been added.
10. Typing by amplification and sequencing of small regions of the **Astrovirus** capsid gene for assessment of outbreaks has been added.
11. The expanding geographic area with **Babesiosis** is detailed. New information is provided in the Diagnosis section.
12. The pathogenesis of disease caused by diarrheal toxins of ***Bacillus cereus*** has been clarified.
13. Discussion of nucleic acid amplification tests (NAATs) is expanded in the **Bacterial Vaginosis** chapter.
14. Antibacterial treatment options for ***Bacteroides*, *Prevotella*, and Other Anaerobic Gram-Negative Bacilli Infections** have been updated.

15. Descriptions of diagnostic modalities for ***Balantidium coli* Infections** have been expanded. Foodborne sources of infection have been updated.
16. Information on PCR diagnosis of ***Bartonella henselae* (Cat-Scratch Disease)** has been added. Antibiotics and prolonged treatment durations have been expanded.
17. The Clinical Manifestations and Epidemiology sections of the ***Baylisascaris Infections*** chapter have been greatly expanded.
18. Diagnostic approaches to detection and interpretation of ***Blastocystis* species** in stool have been updated.
19. Newer formulations of itraconazole with enhanced bioavailability are discussed in the **Blastomycosis** chapter.
20. Greater detail is provided on duration of shedding of **Bocavirus** and its impact on interpreting positive diagnostic tests.
21. The Clinical Manifestations, Epidemiology, and Treatment sections of ***Borrelia Infections Other Than Lyme Disease*** have been greatly expanded.
22. Clinical Manifestations of **Brucellosis** have been expanded. Secondary treatment options have been added.
23. *Burkholderia pseudomallei* epidemiology and chronicity are addressed more fully in the ***Burkholderia Infections*** chapter. Postexposure prophylaxis following laboratory exposure to *Burkholderia* species has been added.
24. Treatment recommendations for ***Campylobacter Infections*** are provided with greater specificity. Epidemiologic data have been updated.
25. Treatment recommendations for invasive **Candidiasis**, including congenital and neonatal *Candida* disease, have been updated. Diagnosis and Treatment of *Candida auris* have been expanded. Fluconazole prophylaxis recommendations for extremely low birthweight neonates have been updated.
26. Avoidance of corticosteroids during the acute phase of **Chikungunya** disease, and use of disease-modifying anti-rheumatic drugs (DMARDs) during the chronic phase, have been added. Clinical Manifestations in children have been enhanced.
27. Epidemiology and diagnosis of ***Chlamydia pneumoniae*** have been updated.
28. Mention and definition of Horder spots have been added to the ***Chlamydia psittaci*** chapter. Rare human-to-human spread has now been documented.
29. Routine screening recommendations for ***Chlamydia trachomatis*** have been updated.
30. Ancillary testing in patients with suspected **Botulism** has been outlined. A PCR assay to detect botulinum neurotoxin genes (BoNT) in clostridial species in cultures is discussed.
31. New data on the clinical effectiveness of fidaxomicin on lowering recurrence rates of ***Clostridioides difficile*** disease has been added. Success rates following fecal transplant have been updated.
32. Seasonal occurrence of ***Clostridium perfringens*** outbreaks has been added.
33. Serologic, molecular, and antigen detection testing availability and performance for **Coccidioidomycosis** have been updated.
34. Information on **COVID-19** has been moved to its own chapter. Discussion of the severity of disease caused by the other human **Coronaviruses**, especially in immunocompromised people, has been expanded.

35. Prevalence of **Cryptococcus** disease in children compared with adults has been added. Treatment of HIV-positive adults with a single dose of liposomal amphotericin following by flucytosine and fluconazole is mentioned.
36. Molecular diagnostic testing for **Cryptosporidiosis** has been updated. Antimicrobial options for immunocompromised hosts have been expanded.
37. Description of the skin rash of **Cutaneous Larva Migrans** has been expanded.
38. Additional treatment options in persons with HIV who are infected with **Cyclosporiasis** have been added.
39. Discussion of targeted screening for congenital **Cytomegalovirus** infection is expanded. Maribavir has been added to the list of approved CMV antiviral drugs. Treatment recommendations for congenital CMV have been liberalized with regard to timing of initiation of therapy and use in patients with isolated sensorineural hearing loss.
40. Recent CDC recommendations for use of Dengvaxia have been incorporated in the **Dengue** chapter. Diagnostic testing has been updated.
41. Antimicrobial treatment of **Diphtheria** is provided in greater detail. Treatment options for eradication of carriage have been expanded. Updates to national notification requirements have been added.
42. In the **Ehrlichia, Anaplasma, and Related Infections** chapter, the increasing number of cases of *Anaplasma* infections in the United States and the rarity of rash in these patients is emphasized. Hemophagocytic lymphohistiocytosis occurring with ehrlichiosis is described.
43. In the **Serious Neonatal Bacterial Infections Caused By Enterobacterales** chapter, the order name has been changed from *Enterobacteriaceae* to *Enterobacterales*. Treatment recommendations for extended-spectrum beta-lactamases and carbapenem-resistant *Enterobacterales* using new antibiotics and beta-lactamase inhibitor combinations are provided.
44. Clinical manifestations associated with specific **Enterovirus** types are added. Recommendations for return to school or child care are provided.
45. Etiology and treatment of **Epstein-Barr Virus**-associated post-transplant lymphoproliferative disease (PTLD) has been expanded.
46. In the **Escherichia coli Diarrhea** chapter, description of disease caused by enteropathogenic *E coli* (EPEC) is expanded. Long-term sequelae following hemolytic-uremic syndrome are added.
47. Treatment recommendations for **Other Fungal Diseases** have been modified for 8 of the 10 pathogens listed in the table that comprise this chapter.
48. Discussion of rapid diagnostic tests for **Fusobacterium** species has been added.
49. Sources of recent **Giardia duodenalis** outbreaks are updated.
50. Discussion of antibiotic resistance in **Gram-negative Coccal Infections** has been expanded. Routine screening recommendations have been updated.
51. Discussion of otitis media treatment has been streamlined in the **Haemophilus influenzae Infections** chapter.
52. The listing of characteristic laboratory findings in **Hantavirus Pulmonary Syndrome** is expanded.
53. Indications for testing for **Helicobacter pylori** have been added to the chapter.

54. In the **Hemorrhagic Fevers Caused by Arenaviruses** chapter, wording supporting the use of intravenous ribavirin for treatment of Lassa fever has been softened.
55. In the **Hemorrhagic Fevers Caused by Bunyaviruses** chapter, duration of observation following exposure to Crimean-Congo hemorrhagic fever (CCHF) has been modified. An inactivated vaccine for CCHF is available in Eastern Europe.
56. In the **Hemorrhagic Fevers Caused by Filoviruses: Ebola and Marburg** chapter, vaccine information against differing Ebola species has been updated.
57. Increasing cases of **Hepatitis A** infection among people using injection drugs and people lacking housing are described.
58. New **Hepatitis B** vaccines (for adults) have been added to the chapter. A statement has been added that routine nursery procedures, such as skin-to-skin care, delayed bathing, and breastfeeding within the first hour, may continue as recommended by the facility.
59. Antiviral treatments for **Hepatitis C** have been updated, including options for children as young as 3 years and for pregnant people. Testing recommendations for infants whose birthing parent is HCV positive have been updated.
60. Antiviral therapies for **Hepatitis D** have been added to the chapter.
61. In the **Herpes Simplex** chapter, exclusion of athletes with active herpes gladiatorum or rugbiorum infections is provided. Antiviral suppression in these athletes is endorsed. Management of neonates whose birthing parent has a first episode genital herpes in the final trimester of pregnancy but no lesions at delivery has been modified.
62. Details of central nervous system manifestations of **Histoplasmosis** have been added.
63. Diagnostic modalities for **Hookworm Infections** have been updated and expanded.
64. Description of diagnostic studies suggesting inherited chromosomally integrated HHV-6 (iciHHV6) has been expanded in the **Human Herpesvirus 6 (Including Roseola) and 7** chapter.
65. Diagnostic approaches for management in infants whose birthing parent has **Human Immunodeficiency Virus Infection** and in adolescents have been updated. Postexposure management of people with HIV following measles and varicella exposure has been clarified. Postexposure management following hepatitis A exposure has been added.
66. Epidemiologic information and cervical cancer screening recommendations in **Human Papillomaviruses** have been updated.
67. The **Influenza** chapter has been brought into alignment with the annual influenza policy statements published by the AAP since 2021.
68. Contrasts between **Kawasaki Disease** and MIS-C are provided. Descriptions of adjunctive therapies for primary treatment and management of IGIV resistance have both been expanded.
69. Management options for **Kingella kingae Infections** in outbreak settings have been added.
70. Diagnostic modalities for **Legionella pneumophila Infections** have been updated. Control measures for prevention of *Legionella* infections have been expanded.
71. Mention of cases of **Leishmaniasis** in Indigenous populations in the southwestern United States has been added.

72. The **Leprosy** chapter includes mention of the open-access *International Textbook of Leprosy* as a resource.
73. Use of matrix-assisted laser desorption/ionization–time-of-flight (MALDI-TOF) mass spectrometry for rapid identification of **Listeria monocytogenes Infections** is discussed.
74. The diagnostic testing required for **Lyme Disease** has been modified for greater clarity.
75. A listing of extracerebral involvement has been added to the **Lymphocytic Choriomeningitis Virus** chapter.
76. Clinical and laboratory parameters defining severe **Malaria** have been added. The need to confirm the diagnosis of malaria prior to initiating therapy has been emphasized.
77. Distinguishing between someone with fever and rash from measles, mumps, and rubella (MMR) vaccine versus someone with **Measles** infection has been added. The postexposure prophylaxis tables have been modified.
78. Text and a new table have been added to the **Meningococcal Infections** chapter providing guidance for when ciprofloxacin-resistant isolates are detected.
79. A diagnostic pearl to improve visualization of the umbilicated lesions of **Molluscum Contagiosum** is provided.
80. Wording has been added to distinguish between *Moraxella catarrhalis* respiratory colonization versus disease.
81. **Mpox** is an entirely new chapter to the 2024 *Red Book*.
82. In the **Mycoplasma pneumoniae and Other Mycoplasma Species Infections** chapter, disease caused by *Mycoplasma genitalium* has been expanded, as have treatment recommendations for this pathogen. The increasing antibiotic resistance of all *Mycoplasma* species is discussed.
83. Discussion of risk factors for **Nocardiosis** is expanded. Treatment options have been updated.
84. Mention of nitazoxanide as a possible treatment in immunocompromised transplant recipients has been added to the **Norovirus and Sapovirus Infections** chapter, albeit in “some experts recommend” language.
85. Treatment of **Onchocerciasis (River Blindness, Filariasis)** has been updated.
86. Sensitivity and specificity of diagnostic tests for **Paracoccidioidomycosis** have been added.
87. Cerebral **Paragonimiasis** is discussed in greater detail.
88. Use of corticosteroids and nebulized epinephrine in the management of **Parainfluenza Viral Infections** has been added.
89. Modes of human infection and clinical manifestations in humans have been updated for many of the **Parasitic Diseases** in the table of this chapter.
90. Molecular diagnostic testing for **Parechovirus Infections** has been updated.
91. Persistence of low concentrations of noninfectious **Parvovirus B19** DNA for months or years is emphasized.
92. Manifestations of **Pasteurella Infections** in neonates has been added. Treatment duration for endocarditis has been added.
93. The treatment section of the **Pediculosis Capitis** chapter has been updated with the recommendations from the 2022 clinical report published by the AAP. A new treatment algorithm figure has been added.

94. The cause of pruritis from body lice has been added to the **Pediculosis Corporis** chapter.
95. A time period has been added to the **Pediculosis Pubis** chapter for persistence of pubic lice on bedding, towels, and clothing.
96. Treatment recommendations for **Pelvic Inflammatory Disease** during pregnancy are provided.
97. Tdap vaccines have been approved by the FDA for use in pregnancy since the last edition of the *Red Book*, and the **Pertussis (Whooping Cough)** chapter has been updated accordingly.
98. Modes of transmission for **Pinworm Infections** have been updated.
99. Treatment of **Pityriasis Versicolor** with topical retinoids has been added.
100. The diagnosis and treatment sections of the **Plague** chapter have been aligned with the 2021 CDC recommendations.
101. Extrapulmonary manifestations of **Pneumocystis jirovecii Infections** have been added. Intravenous steroid dosing for people unable to take oral steroids has been added.
102. The **Poliovirus Infections** chapter has been updated to include risk of circulating vaccine-derived polioviruses to undervaccinated communities in the United States. Proof of vaccination that is accepted by the United States is listed.
103. Options for treatment of **Polyomaviruses** has been expanded.
104. The utility of brain magnetic resonance imaging (MRI) in Creutzfeldt-Jakob disease has been added to the **Prion Diseases** chapter.
105. Duration of therapy recommendations for **Pseudomonas aeruginosa Infections** have been updated.
106. Outcomes of **Q Fever** among pregnant people have been added. A treatment option for chronic Q fever in children is provided.
107. The pre- and postexposure prophylaxis sections of the **Rabies** chapter have been harmonized with recent CDC guidance. A new table on preexposure prophylaxis has been developed.
108. Information has been added to the **Rat-Bite Fever** chapter on anticoagulants in blood culture media that can inhibit growth of *Streptobacillus moniliformis*.
109. The unusual **Respiratory Syncytial Virus** circulation patterns in 2021 and 2022 are discussed. Precaution measures are updated. New active and passive immunization products that likely are nearing FDA approval are mentioned.
110. The average number of **Rhinovirus Infections** a child experiences each year is provided.
111. Guidance on duration of antibiotic therapy for **Rickettsialpox** has been updated.
112. Identification of groups at higher risk of death from **Rocky Mountain Spotted Fever**, including children younger than 10 years and patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency, has been added.
113. Reduction in risk of seizures with use of **Rotavirus** vaccine has been added to the chapter.
114. Manifestations of persistence of **Rubella** virus in patients with primary immunodeficiencies have been added.

115. Treatment options for *Salmonella* Typhi have been updated in the **Salmonella Infections** chapter. Details on the extensively drug-resistant (XDR) *S* Typhi outbreak in Pakistan, and its impact on international travelers, are updated as well.
116. The treatment section of the **Scabies** chapter has been updated to include additional alternative therapeutic options.
117. Information on hybridization and local transmission of *Schistosoma haematobium* and *Schistosoma bovis* has been added to the **Schistosomiasis** chapter.
118. The increasing number of antibiotic-resistant **Shigella** isolates detected in the United States is detailed, and treatment options updated accordingly.
119. Antiviral therapy options and new information on vaccines that protect against **Smallpox** have been added.
120. Hyperthermia has been added as a treatment option for pregnant people with **Sporotrichosis**, in whom antimicrobial therapy should be avoided.
121. Discussion of the enterotoxins that produce **Staphylococcal Food Poisoning** has been expanded.
122. Treatment durations for **Staphylococcus aureus** osteomyelitis have been decreased, in alignment with the Pediatric Infectious Diseases Society/Infectious Diseases Society of America guidance document that was recently published. Decolonization approaches are discussed in greater detail. New drugs with anti-staphylococcal activity are summarized.
123. New antibiotics with utility in **Coagulase-Negative Staphylococcal Infections** are listed. Situations in which combination therapy can be considered are provided. Durations of treatment are updated.
124. Diagnosis of poststreptococcal acute glomerulonephritis is specifically stated in the **Group A Streptococcal Infections** chapter. Eradication of nephritogenic strains has been added. The increasing degree of clindamycin resistance is addressed, and use of linezolid for blocking protein (toxin) production in cases of clindamycin resistance has been added.
125. New long-term outcome data for survivors of **Group B Streptococcal Infections** during infancy have been added. Treatment of sequential parenteral-oral therapy of bacteremia without a focus and isolated urinary tract infections has been liberalized somewhat. Testing of human milk for an infant with late-onset GBS is discouraged.
126. The treatment section of the **Non-Group A or B Streptococcal and Enterococcal Infections** chapter has been modified to include updated duration recommendations.
127. PCV15 and PCV20 have been added to the **Streptococcus pneumoniae (Pneumococcal) Infections** chapter. A table with susceptibility breakpoints by drug and site of infection has been added.
128. Treatment for suspected or confirmed hyperinfection/dissemination syndrome has been added to the **Strongyloidiasis** chapter. Management of eligible refugees who arrive in the United States through the US Refugee Resettlement Program versus other immigrants, including internationally adopted children, has been added.
129. The increasing incidence of **Syphilis** and congenital syphilis is documented. Performance characteristics of treponemal tests are discussed. Neonates known to be exposed to syphilis at delivery should not have delayed bathing.

130. Transmission and obligate versus intermediate host descriptions have been expanded in the **Tapeworm Diseases** chapter.
131. Treatment of *Echinococcus* has been updated in the **Other Tapeworm Infections** chapter.
132. Management of patients who experience anaphylactic reaction to **Tetanus** vaccine has been added. Progress toward global elimination of maternal and neonatal tetanus has been updated.
133. Treatment recommendations, including drugs available in the United States, have been updated in the **Tinea Capitis** and **Tinea Corporis** chapters.
134. Description of the clinical manifestations of **Tinea Cruris** have been expanded.
135. Use of efinaconazole and tavaborole in children as young as 6 years for **Tinea Pedis and Tinea Unguium** has been added.
136. The specific classes of immunoglobulin that constitute hypergammaglobulinemia for the diagnosis of **Toxocariasis** have been clarified.
137. Benefits of each type of imaging modality (ultrasonography, magnetic resonance imaging [MRI], computed tomography [CT]) for congenital **Toxoplasma gondii Infections** are provided.
138. Discussion of the role of steroids in severe systemic **Trichinellosis** has been added. Mention of the cost of albendazole and mebendazole has been included.
139. Use of NAAT for diagnosis of **Trichomonas vaginalis Infections** has been updated. Treatment options have been expanded, and discussion of management of recurrent infection is provided.
140. Combination therapy for **Trichuriasis** is added as a management option.
141. Fexinidazole has been added as a treatment option for some patients with **African Trypanosomiasis**.
142. Newer diagnostic modalities for **American Trypanosomiasis (Chagas Disease)**, including next-generation techniques using cell-free pathogen DNA and newer immunoassays, have been added.
143. New **Tuberculosis** treatment durations aligning with WHO recommendations have been added. IGRA testing at any pediatric age has been expanded (previously was 2 years and older). Terminology of TB infection versus TB disease is emphasized.
144. Identification of macrolide resistance in the treatment of **Nontuberculous Mycobacteria** through detection of the *erm* gene with sequencing or line-probe assay has been added. Initiation recommendations for *Mycobacterium avium* complex (MAC) prophylaxis in patients starting antiretroviral therapy (ART) are provided.
145. **Tularemia** treatment options have been reorganized for clarity.
146. Serologic responses in patients with Brill-Zinsser disease have been added to the **Louse-borne Typhus** chapter.
147. Sensitivity of PCR assay in whole blood, serum, and skin biopsies has been added to the **Murine Typhus** chapter.
148. The anti-inflammatory characteristics of azithromycin have been added to the **Ureaplasma urealyticum and Ureaplasma parvum Infections** chapter.
149. Birth in the United States before 1980 is added to those things that provide evidence of immunity to **Varicella-Zoster Virus Infections**. The types of highly immunocompromised patients who should not receive varicella vaccine are specifically listed.

150. Vaxchora now is available in children down to 2 years of age for the prevention of **Cholera**.
151. The anticipated impact of climate change on incidence of *Vibrio* infections has been added to the **Other *Vibrio* Infections** chapter.
152. Discussion of community-level mosquito control measures for prevention of **West Nile Virus** is expanded.
153. Description of disease caused by *Yersinia pseudotuberculosis* has been expanded in the ***Yersinia enterocolitica* and *Yersinia pseudotuberculosis* Infections** chapter.
154. Testing recommendations for **Zika** virus have been updated. A new table to aid with interpreting test results has been added. Restrictions on blood donations have been loosened.

SECTION 4. ANTIMICROBIAL AGENTS AND RELATED THERAPY

1. Adverse events from use of fluoroquinolones have been updated in **Antimicrobial Agents and Related Therapy**.
2. Recommendations are provided in the **Antimicrobial Resistance and Antimicrobial Stewardship: Appropriate and Judicious Use of Antimicrobial Agents** chapter to enhance clear and effective communication across clinical settings in order to improve antimicrobial stewardship efforts.
3. Several new antibiotics have been added to the **Tables of Antimicrobial Drug Dosages**. For the neonatal dosing table, gestational ages are provided with more precise breakpoints.
4. Treatment options for **Sexually Transmitted Infections** are now listed as those that are preferred and those that are alternatives to the preferred option.
5. Differences in formulations of posaconazole and itraconazole are provided in the **Antifungal Drugs for Systemic Fungal Infections** chapter. Ibrexafungerp has been added. The durations of time on drug before checking trough concentrations for the azoles and flucytosine are clarified.
6. New dosing recommendations are provided for many of the antifungal medications in the table that contains the **Recommended Doses of Parenteral and Oral Antifungal Drugs**.
7. The listing of drugs in the **Topical Drugs for Superficial Fungal Infections** table have been aligned with what is currently available in the United States.
8. Antivirals for COVID-19 and mpox have been added to the **Non-HIV Antiviral Drugs** table. Age indications for many antiviral drugs, including HCV and influenza drugs, have been lowered to reflect current indications for use by the FDA.
9. Updated dosing recommendations based on new guidance have been incorporated throughout the **Drugs for Parasitic Infections** table.

SECTION 5. ANTIMICROBIAL PROPHYLAXIS

1. Results of the NIH RIVUR study have been added to the discussion of UTI prophylaxis in the **Antimicrobial Prophylaxis** chapter.

2. The decline of MRSA infections in children and, therefore, a decreased need to cover for these resistant bacteria prophylactically is detailed in the **Antimicrobial Prophylaxis in Pediatric Surgical Patients** chapter.
3. The **Prevention of Bacterial Endocarditis** chapter has been harmonized with the 2021 updated statement on infectious endocarditis from the American Heart Association.
4. Options for periods of shortage of erythromycin ointment have been updated in the **Neonatal Ophthalmia Prevention** chapter.

APPENDICES

1. Web links have been updated in the **Directory of Resources**. A link to the CDC's website on vaccine shortages and delays has been added. The European Society for Pediatric Infectious Diseases has been added.
2. The listing of **Codes for Commonly Administered Pediatric Vaccines, Toxoids, and Immune Globulins** has been expanded to include specific codes for wound prophylaxis for tetanus, respiratory syncytial virus (RSV) prophylaxis with palivizumab, and hepatitis B immune globulin (HBIG) use in perinatal hepatitis B exposure.
3. The diseases listed in the **Nationally Notifiable Infectious Diseases in the United States** table have been updated to those required in 2023.
4. In the **Guide to Contraindications and Precautions to Immunizations** appendix, moderate or severe acute illness, with or without fever, has been identified as the only precaution applicable to all vaccines.
5. Sources of foodborne infections have been updated in the **Prevention of Disease From Contaminated Food Products** appendix.
6. The incubation periods for hemolytic-uremic syndrome and botulism have been tightened in the **Clinical Syndromes Associated With Foodborne Diseases** table.
7. Sources and modes of transmission have been updated throughout the **Diseases Transmitted by Animals (Zoonoses)** table. Leishmaniasis, *Streptococcus suis*, Cache Valley virus, Heartland virus, and Lujo hemorrhagic fever have been added.

Systems-Based Treatment Table^a

System	Condition	Common Pathogens	Empiric Antibiotic Therapy	Antibiotic Duration	Notes	Key Resources
Bloodstream Infection in Nonneonates (*uncomplicated) *Defined by ≤3 days bacteremia in nonneutropenic host without complex source (eg, endocarditis, septic thrombophlebitis, osteomyelitis) or ongoing undrained purulent focus	Common sources include vascular catheter-associated infection, urinary tract infection, intra-abdominal infection, pneumonia, skin/soft tissue infection	<i>Staphylococcus aureus</i>	<u>MSSA</u> Cefazolin OR Oxacillin OR Nafcillin <u>MRSA</u> Vancomycin OR Linezolid OR Daptomycin OR Ceftaroline	14 days from first negative blood culture	Vascular catheter removal generally recommended for persistent hemodynamic instability or ongoing (≥3 days) bacteremia	RCTs for duration of gram-negative BSI: Yahav et al ¹ von Dach et al ² Molina et al ³ Observational studies: Sutton et al ⁴ Punjabi et al ⁵ Tamma et al ⁶ Heil et al ⁷ Mponponsuo et al ⁸ Tamma et al ⁹
		<i>Enterococcus faecalis</i>	Ampicillin	7 days from first negative blood culture		
		<i>Enterococcus faecium</i>	Vancomycin OR Linezolid OR Daptomycin	7 days from first negative blood culture		

Systems-Based Treatment Table,^a continued

System	Condition	Common Pathogens	Empiric Antibiotic Therapy	Antibiotic Duration	Notes	Key Resources
Bloodstream Infection in Nonneonates (* uncomplicated) *Defined by ≤3 days bacteremia in nonneutropenic host without complex source (eg, endocarditis, septic thrombophlebitis, osteomyelitis) or ongoing undrained purulent focus		Enterobacterales (eg, <i>Escherichia coli</i> , <i>Klebsiella</i> species, <i>Enterobacter</i> species)	Choice depends on results of antibiotic susceptibility testing	7 days from first negative blood culture	Duration of therapy is regardless of whether vascular catheter is removed, and should not be extended solely based on presence of antibiotic resistance or retained vascular catheter	
		<i>Pseudomonas aeruginosa</i>	Choice depends on results of antibiotic susceptibility testing	7 days from first negative blood culture	Duration of therapy is based on duration of active therapy (ie, adequate dose and antibiotic susceptibility) Transition to oral antibiotics may be considered for uncomplicated gram-negative bacteremia if all of the following criteria are met: (1) susceptibility to an appropriate, highly available oral agent is demonstrated; (2) the patient is hemodynamically stable; (3) reasonable source control measures have occurred; (4) intestinal absorption is intact; and (5) there is confidence in patient adherence	

Systems-Based Treatment Table,^a continued

System	Condition	Common Pathogens	Empiric Antibiotic Therapy	Antibiotic Duration	Notes	Key Resources
		Coagulase-negative <i>Staphylococcus</i> (not including <i>Staphylococcus Lugdunensis</i> , which should be managed like <i>S aureus</i>)	Vancomycin OR Oxacillin (if susceptible)	5–7 days from first negative blood culture, OR observation following removal of foreign body source (eg, catheter)	A single positive culture absent hardware generally reflects skin contamination	
Bone/Joint	Osteomyelitis (acute, hematogenous)	<i>S aureus</i> <i>Streptococcus pyogenes</i> <i>Kingella kingae</i>	<u>Mild-Moderate</u> Cefazolin OR Oxacillin OR Nafcillin <u>Severe and low suspicion of MRSA</u> Cefazolin OR Oxacillin OR Nafcillin <u>Severe and high suspicion of MRSA</u> Vancomycin	3–4 wk Chronic osteomyelitis typically requires more prolonged antibiotic treatment and may require consideration of alternate antibiotic choice	<i>Kingella</i> infection not effectively treated by clindamycin and not reliably susceptible to oxacillin/nafcillin Early switch to oral route recommended with clinical improvement, even for patients with transient bacteremia For empiric management of children with osteomyelitis and severe sepsis, combination therapy of vancomycin PLUS oxacillin/nafcillin can be considered	Woods et al ¹⁰

Systems-Based Treatment Table,^a continued

System	Condition	Common Pathogens	Empiric Antibiotic Therapy	Antibiotic Duration	Notes	Key Resources
Bone/Joint			OR Clindamycin OR Linezolid OR Daptomycin			
	Septic arthritis	<i>S aureus</i> <i>S pyogenes</i> <i>K kingae</i>	<u>Mild-Moderate</u> Cefazolin OR Oxacillin OR Nafcillin <u>Severe and low suspicion of MRSA</u> Cefazolin OR Oxacillin OR Nafcillin <u>Severe and high suspicion of MRSA</u> Vancomycin OR Clindamycin OR Linezolid OR Daptomycin	2–3 wk	<i>Kingella</i> not effectively treated by clindamycin and not reliably susceptible to oxacillin/nafcillin Early switch to oral route recommended with clinical improvement, even for patients with transient bacteremia	Woods et al ¹¹

Systems-Based Treatment Table,^a continued

System	Condition	Common Pathogens	Empiric Antibiotic Therapy	Antibiotic Duration	Notes	Key Resources
Central Nervous System	Meningitis (non-neonates)	<i>Streptococcus pneumoniae</i> <i>Neisseria meningitidis</i> <i>Haemophilus influenzae</i>	Ceftriaxone PLUS Vancomycin	These are empiric recommendations; specific choice and duration of antibiotic therapy should be guided by culture and susceptibility results <i>S pneumoniae</i>: 10–14 days <i>H influenzae</i>: 7–10 days <i>N meningitidis</i>: 5–7 days	Longer courses are necessary for patients with parenchymal brain infection (cerebritis, rhombencephalitis, brain abscess) Dexamethasone is beneficial for treatment of infants and children with Hib meningitis to diminish the risk of hearing loss, if administered before or concurrently with the first dose of antimicrobial agent(s) For all children with bacterial meningitis presumed to be caused by <i>S pneumoniae</i>, vancomycin should be administered in addition to ceftriaxone because of the possibility of resistant <i>S pneumoniae</i> Consider adding acyclovir for patients with concurrent encephalitis	<i>Streptococcus pneumoniae</i> (Pneumococcal) Infections, p 810 Meningococcal Infections, p 585 <i>Haemophilus influenzae</i> Infections, p 400

Systems-Based Treatment Table,^a continued

System	Condition	Common Pathogens	Empiric Antibiotic Therapy	Antibiotic Duration	Notes	Key Resources
Ear, Nose, and Throat	Mastoiditis	<i>S pneumoniae</i> <i>S pyogenes</i> <i>S aureus</i> <i>H influenzae</i> <u>Also consider for chronic:</u> Microaerophilic streptococci <i>Fusobacterium</i> <i>P aeruginosa</i>	Consider surgical drainage/excision Ampicillin-sulbactam OR Ceftriaxone (Allergy^b: Clindamycin) <u>If follows chronic AOM:</u> Cefepime OR Levofloxacin Consider MRSA based on local prevalence	2–4 wk depending on adequate débridement, intracranial extension, extent of osteomyelitis, associated thrombosis	Transition to oral with clinical improvement Ampicillin-sulbactam may not be optimal for intracranial infections	<i>Haemophilus influenzae</i> Infections, p 400 <i>Fusobacterium</i> Infections, p 388 <i>Pseudomonas aeruginosa</i> Infections, p 697 <i>Staphylococcus aureus</i>, p 767 Group A Streptococcal Infections, p 785 Non-Group A or B Streptococcal and Enterococcal Infections, p 806 <i>Streptococcus pneumoniae</i> (Pneumococcal) Infections, p 810

Systems-Based Treatment Table,^a continued

System	Condition	Common Pathogens	Empiric Antibiotic Therapy	Antibiotic Duration	Notes	Key Resources
Ear, Nose, and Throat	Acute sinusitis	<i>S pneumoniae</i> <i>H influenzae</i> <i>Moraxella catarrhalis</i>	Amoxicillin OR Amoxicillin-clavulanate (Allergy ^b : Clindamycin OR Levofloxacin)	5–7 days	Diagnosis of acute bacterial sinusitis requires the presence of one of the following criteria: (1) persistent nasal discharge or daytime cough <u>without evidence of clinical improvement</u> for ≥10 days; consider watchful waiting in this scenario (2) worsening or new onset of nasal discharge, daytime cough, or fever after initial improvement (3) temperature ≥39°C with purulent nasal discharge and/or facial pain for at least 3 consecutive days	<i>Haemophilus influenzae</i> Infections, p 400 <i>Moraxella catarrhalis</i> Infections, p 604 <i>Streptococcus pneumoniae</i> (Pneumococcal) Infections, p 810 Chow et al ¹² Wald et al ¹³
	Acute otitis media	<i>S pneumoniae</i> <i>H influenzae</i> <i>M catarrhalis</i>	Amoxicillin OR Amoxicillin-clavulanate ^c (Allergy: Cefdinir OR Cefpodoxime OR Cefuroxime OR Ceftriaxone for 1 (first occurrence) to 3 (treatment failure) days	>6 y: 5 days 2–5 y: 7 days <2 y or severe symptoms: 10 days	Consider observation without antibiotics for 48–72 hours for children 24 months or older without severe symptoms; if symptoms persist or worsen, use same antibiotic recommendations as for those receiving immediate therapy Consider <i>S aureus</i> and <i>Pseudomonas</i> infection for chronic otitis media	<i>Haemophilus influenzae</i> Infections, p 400 <i>Moraxella catarrhalis</i> Infections, p 604 <i>Streptococcus pneumoniae</i> (Pneumococcal) Infections, p 810 Lieberthal et al ¹⁴ Rosenfeld et al ¹⁵

Systems-Based Treatment Table,^a continued

System	Condition	Common Pathogens	Empiric Antibiotic Therapy	Antibiotic Duration	Notes	Key Resources
Ear, Nose, and Throat	Streptococcal pharyngitis	<i>S pyogenes</i>	<u>First line:</u> Penicillin OR Amoxicillin (Allergy ^b : Cephalexin OR Clindamycin OR Azithromycin)	10 days	Children with rhinorrhea, cough, hoarseness, or oral ulcers should not be tested or treated for GAS infection; testing also generally is not recommended for children <3 y Management of recurrent GAS pharyngitis and pharyngeal carriers is detailed in Group A Streptococcal Infections (p 785) Tetracyclines, TMP-SMX, and fluoroquinolones should not be used for treating GAS pharyngitis Return to school after afebrile and ≥12 h of antibiotic therapy	Group A Streptococcal Infections, p 785 Shulman et al ¹⁶
	Retropharyngeal abscess	<i>S aureus</i> <i>S pyogenes</i> Anaerobes <i>Streptococcus anginosus</i> <i>H influenzae</i> (often polymicrobial)	<u>Mild-moderate:</u> Ampicillin/sulbactam OR Clindamycin <u>Severe:</u> Ampicillin/sulbactam PLUS EITHER Vancomycin OR Linezolid	14 days	Longer duration of therapy may be required for complex infections with insufficient source control	

Systems-Based Treatment Table,^a continued

System	Condition	Common Pathogens	Empiric Antibiotic Therapy	Antibiotic Duration	Notes	Key Resources
Genitourinary	UTI - pyelonephritis	<i>E coli</i> <i>Klebsiella</i> species <i>Proteus</i> species <i>Enterobacter</i> species <i>Citrobacter</i> species <i>Enterococcus</i> species <i>Staphylococcus saprophyticus</i>	Cephalexin OR TMP-SMX OR Ampicillin PLUS Gentamicin OR Ceftriaxone OR Ciprofloxacin	7–10 days (hospitalized) 5–10 days (outpatient) 3–5 days (simple cystitis in adolescents) Longer durations may be required for complicated cases such as renal abscess without drainage	Drug selection should be based on local antibiogram or patient's prior urine isolates Initial short course of IV therapy (2–4 days) is as effective as longer courses of IV therapy Avoid nitrofurantoin for upper urinary tract infection or bacteremia	Mattoo et al ¹⁷ Gupta et al ¹⁸
Intra-abdominal	Intra-abdominal infection	<i>E coli</i> Anaerobes <i>Klebsiella</i> species (often polymicrobial)	Drainage <u>Mild-moderate:</u> Ceftriaxone PLUS Metronidazole <u>Severe or hospital onset:</u> Piperacillin- tazobactam OR Ciprofloxacin PLUS Metronidazole	4–7 days (from source control)	May need longer duration if insufficient source control Mild-moderate infection includes complicated appendicitis with rupture, absent sepsis	Mazuski et al ¹⁹

Skin and Soft Tissue Infections	Purulent cellulitis/ Abscess	<i>S aureus</i>	Drainage <u>Mild-moderate:</u> Cefazolin/cephalexin OR TMP/SMX OR Clindamycin OR Doxycycline Consider MRSA based on local prevalence <u>Severe:</u> Vancomycin OR Linezolid OR Ceftaroline OR Daptomycin	5–7 days Tailor duration based on resolution of signs and symptoms Surgical drainage alone may be adequate for small, completely drained abscesses	Conversion to oral antibiotic therapy after transient ^d <i>S aureus</i> bacteremia with source control is appropriate but might warrant more prolonged therapy	<i>Staphylococcus aureus</i> , p 767 Stevens et al ²³

Systems-Based Treatment Table,^a continued

System	Condition	Common Pathogens	Empiric Antibiotic Therapy	Antibiotic Duration	Notes	Key Resources
	Lymphadenitis	<u>Acute/unilateral:</u> <i>S pyogenes</i> <i>S aureus</i> <u>Subacute/chronic:</u> <i>Bartonella</i> species Nontuberculous mycobacteria (NTM)	For acute/unilateral lymphadenitis: Consider surgical drainage Cefazolin/ Cephalexin (Allergy ^b : Clindamycin) Consider MRSA based on local prevalence	5–7 days Tailor duration based on resolution of signs and symptoms	For management of NTM or <i>Bartonella</i> infection, please see those chapters (p 920 and p 263) Bacterial adenitis is typically unilateral; bilateral disease is typically viral in etiology	<i>Bartonella henselae</i> (Cat-Scratch Disease), p 263 <i>Staphylococcus aureus</i> , p 767 Group A Streptococcal Infections, p 785 Nontuberculous Mycobacteria, p 920

AAP indicates American Academy of Pediatrics; AOM, acute otitis media; CAP, community-acquired pneumonia; CSF, cerebrospinal fluid; GAS, group A *Streptococcus*; GBS, group B *Streptococcus*; HSV, herpes simplex virus; IV, intravenous; MRSA, methicillin-resistant *Staphylococcus aureus*; MSSA, methicillin-susceptible *Staphylococcus aureus*; NTM, nontuberculous mycobacteria; PCN, penicillin; TMP-SMX, trimethoprim-sulfamethoxazole; UTI, urinary tract infection.

Boldface indicates primary pathogen(s) targeted by empiric antibiotic therapy.

^aEmpiric antibiotic selection should be based on local antibiotic resistance prevalence.

^bAntibiotic allergy includes anaphylaxis or cutaneous response (eg, hives) within 6 hours of drug exposure, or severe cutaneous reaction at any time (eg, Steven Johnson syndrome [SJS], toxic epidermal necrolysis [TEN], drug reaction w/eosinophilia and systemic symptoms [DRESS], erythema multiforme, or serum sickness like reaction). Isolated gastrointestinal tract symptoms, family history of drug allergy, or later-onset nonspecific maculopapular rash do not indicate IgE-mediated drug allergy (see www.allergyparameters.org/published-practice-parameters-guidelines/alphabetical-listing/drug-allergy-download/).

^cAmoxicillin-clavulanate should be used if the patient has received amoxicillin treatment in last 30 days, has concurrent purulent conjunctivitis, or has a history of recurrent AOM unresponsive to amoxicillin.

^dOral antibiotics may be considered for bacteremia if bacteremia clears within 72 hours of source control and initiation of effective antibiotic therapy.

Active and Passive Immunization

.....
PROLOGUE

Vaccination is the act of introducing a vaccine into the body to stimulate the immune system to produce protection from a specific disease. Immunization is the process by which a person becomes protected against a disease through vaccination. The ultimate goal of immunization is elimination of disease, decrease of infection transmission, and ideally, eradication of the pathogen that causes the infection and disease; the immediate goal is prevention of disease in people or groups. To accomplish these goals, physicians must make timely immunization a high priority in the care of infants, children, adolescents, and adults. The global eradication of smallpox in 1977, elimination of poliomyelitis disease from the Americas in 1991, elimination of endemic measles transmission in the United States in 2000 and in the Americas in 2002, elimination of rubella and congenital rubella syndrome from the United States in 2004 and from the Americas in 2015, and global eradication of type 2 wild poliovirus in 2015 and type 3 wild poliovirus in 2019 serve as models for fulfilling the promise of disease control through immunization. These accomplishments were achieved by combining a comprehensive immunization program providing consistent, high levels of vaccine coverage with intensive surveillance and effective public health disease-control measures. The resurgence of measles and mumps over recent years and the 2022 case of paralytic poliomyelitis in the United States, however, illustrate how precarious the substantial gains to date can be without vigilant commitment by physicians, public health officials, and members of the public. Worldwide eradication of polio, measles, and rubella remains possible through implementation of proven prevention strategies, and in the case of polio even now is tantalizingly close, but diligence must prevail until eradication is achieved, or success itself is imperiled.

High immunization rates, in general, have reduced dramatically the incidence of all vaccine-preventable diseases (see Table 1.1) in the United States. Yet, because pathogens that cause vaccine-preventable diseases persist in the United States and elsewhere around the world, ongoing immunization efforts must be not only maintained but also strengthened. All vaccine-preventable diseases are, at most, 18 hours away by air travel from any part of the world.

Discoveries in immunology, molecular biology, and medical genetics have resulted in groundbreaking advances in vaccine research. Licensing of new, improved, and even more safe vaccines; establishment of an adolescent immunization platform; development of vaccines against cancer (eg, human papillomavirus and hepatitis B vaccines); and application of novel vaccine-delivery systems promise to continue the advances in preventive medicine achieved during the latter half of the 20th century. The extremely rapid pace of development of COVID-19 vaccines beginning in early 2020 is a testament to the scientific investments in vaccinology over 70 years. From the launch of the COVID-19 vaccination program in December 2020 through November 2022, an estimated 3.2 million American lives and \$1.15 trillion were saved. The advent of population-based postlicensure studies of vaccines facilitates detection of rare adverse

Table 1.1. Comparison of Prevaccine Era Estimated Average Annual Morbidity With Current Estimates

Disease	Prevaccine Era Annual Case Estimate ^a	2020 Reported Cases ^b	Percent Decrease

events temporally associated with immunization that were undetected during large pre-licensure clinical trials as well as detection of changes over time in vaccine effectiveness that directly inform recommendations on use of specific vaccines.

Each edition of the *Red Book* provides recommendations for immunization of infants, children, adolescents, and young adults. These recommendations, which are harmonized among the American Academy of Pediatrics (AAP), the Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention (CDC), and the American Academy of Family Physicians (AAFP), are based on careful analysis of disease epidemiology, benefits, and risks of immunization; feasibility of implementation; and cost-benefit analysis. ACIP recommendations utilize Grading of Recommendations Assessment, Development and Evaluation (GRADE), when feasible, in evaluating the evidence of benefits and risks for a given vaccine, further ensuring that the recommendations are evidence based and objectively assessed.

Use of trade names and commercial sources in the *Red Book* is for identification purposes only and does not imply endorsement by the AAP. Internet sites referenced in the *Red Book* are provided as a service to readers and may change without notice; citation of websites does not constitute AAP endorsement.

..... SOURCES OF INFORMATION ABOUT VACCINES AND IMMUNIZATION

In addition to the latest print edition of the *Red Book*, the following sources can assist providers in remaining up-to-date with information pertaining to vaccines and immunization recommendations and finding answers to questions that arise in practice. For many of these resources, providers can sign up for e-mail alerts to receive new information as soon as it is available.

- **American Academy of Pediatrics (AAP)—Red Book Online** includes the print edition content plus updates and is available on the Internet (<http://redbook.solutions.aap.org/Redbook.aspx>) to AAP members and subscribers. The website has links to the latest implementation guidance, immunization schedules, and the Vaccine Status Table, which provides information on recently submitted, approved, and recommended vaccines and biologics. New recommendations are summarized in *AAP News* (www.aappublications.org/news), the official newsmagazine of the AAP, and are published in *Pediatrics* (<http://pediatrics.aappublications.org>), the official journal of the Academy. The AAP also maintains a website (www.aap.org/en/patient-care/immunizations/) that contains useful links to immunization resources for providers as well as a website with information geared toward parents ([https://healthychildren.org/english/safety-prevention/immunizations/pages/default.aspx](http://healthychildren.org/english/safety-prevention/immunizations/pages/default.aspx)).
- **Centers for Disease Control and Prevention (CDC)**—The CDC Vaccines & Immunizations website (www.cdc.gov/vaccines/) contains a wealth of information, including annually updated immunization schedules; vaccine safety information; recommendations from the Advisory Committee on Immunization Practices (ACIP); vaccine supply updates; vaccine coverage and disease surveillance data; recommendations for specific patient populations; information about storage, handling, and administration of vaccines; legal requirements; and education and training. ACIP recommendations become “official” when they are published in the *Morbidity and Mortality Weekly Report (MMWR)*, but the CDC may post provisional recommendations that can assist providers in making decisions on use of new vaccines prior to the publication of final recommendations. Noteworthy CDC Internet resources are listed in Table 1.2. CDC experts also are available to answer immunization-related questions by email at nipinfo@cdc.gov.
- **Food and Drug Administration (FDA)**—The FDA website includes information on the scientific and regulatory vaccine development process, vaccine safety and effectiveness, vaccine shortages, advisory committee meetings, and a repository of current FDA-approved prescribing information (www.fda.gov/vaccines-blood-biologics/vaccines/). The FDA-approved prescribing information (also referred to as the “label” or “package insert”) contains detailed information for health care providers to ensure safe and effective use. The approved indications in the package insert are supported by the safety and effectiveness data evaluated by the FDA. The FDA does not issue guidelines or recommendations for vaccine use, and in some instances recommendations of the AAP or ACIP may differ from FDA-approved prescribing information.

DISCUSSING VACCINES WITH PATIENTS AND PARENTS¹

Vaccine Uptake: Definitions and Understanding Common Influences of Vaccine Behavior

It is critical to be clear about the terms used when discussing vaccine uptake. A helpful approach is to categorize terms within the attitudes, intentions, and behaviors framework. Vaccine attitudes signify how one thinks and feels about vaccination. Vaccine attitudes shape vaccine intentions, which reflect one's willingness to act on these attitudes. Vaccine intentions, in turn, shape vaccine behavior, which comprises the actions one takes with respect to vaccination. Vaccine confidence, which describes the belief that vaccines are safe, effective, and part of a trustworthy medical system, is a vaccine attitude. Vaccine hesitancy, a motivational state of being conflicted about or opposed to getting vaccinated, is a vaccine intention. And vaccine uptake, defined as receipt of a vaccine, is a vaccine behavior. Barriers to accessing vaccines as well as intentional vaccine refusal and delay are two important predictors of vaccine behavior.

Vaccine hesitancy may result in a range of behaviors, from refusal of all vaccinations, to receipt of all recommended vaccinations while still having concerns about vaccinations. In 2019, the Centers for Disease Control and Prevention (CDC) National Immunization Survey found that 20% of US parents reported that they were “hesitant about childhood shots.” Several frameworks for categorization of parents and caregivers with respect to their vaccine attitudes, intentions, and behaviors have emerged, with an example shown in Table 1.4. A small proportion of parents (1%–3%) refuse all vaccines and may have more fixed beliefs and attitudes about vaccines. On-time routine vaccination decreased in the years immediately following the COVID-19 pandemic; however, it is uncertain whether this decrease is more related to missed well-visit appointments rather than changes in vaccine hesitancy during the pandemic. Some US and Canadian surveys have shown that vaccine hesitancy has not changed significantly since the onset of the pandemic. In contrast to the small number who adamantly refuse any vaccine, the majority of hesitant parents likely have some ambivalence toward vaccination decisions and many may be receptive to information and guidance about routine childhood vaccines that improve their confidence and uptake for their children.

A World Health Organization framework organizes determinants of vaccine hesitancy into contextual, individual and group, and vaccine factors.² At the contextual level, both access to trusted sources of vaccine information and the spread of misinformation may influence beliefs about vaccines and the diseases they prevent. Individual and group preferences for “natural” or “organic” approaches to health are

**Table 1.4. Determinants of Vaccine Hesitancy Matrix
(World Health Organization)**

Contextual influences	• Communication and media environment • Influential leaders, immunization program gatekeepers, and anti- or provaccination groups • Historical influences • Religion/culture/gender/socioeconomic • Politics/policies • Geographic barriers • Perception of the pharmaceutical industry
Individual and group influences	• Influences from historic, sociocultural, environmental, health system/institutional, economic, or political factors • Personal, family, and/or community members' experience with vaccination, including pain • Beliefs, attitudes about health and prevention • Knowledge/awareness • Health system and providers—trust and personal experience • Risk/benefit (perceived, heuristic) • Immunization as a social norm vs not needed/harmful
Vaccine/vaccination-specific issues	• Directly related to vaccine or vaccination • Benefit/risk (epidemiologic and scientific evidence) • Introduction of a new vaccine or new formulation or a new recommendation for an existing vaccine • Mode of administration • Design of vaccination program/mode of delivery (eg, routine program or mass vaccination campaign) • Reliability and/or source of supply of vaccine and/or vaccination equipment • Vaccination schedule • Costs • The strength of the recommendation and/or knowledge base and/or attitude of health care professionals

Adapted from: World Health Organization, SAGE Working Group. *Report of the SAGE Working Group on Vaccine Hesitancy*. Geneva, Switzerland: World Health Organization; 2014.

also associated with vaccine hesitancy, and these preferences often overlap with distrust for health care professionals and medical systems. Psychological factors underlying vaccine attitudes include valuing autonomy, conspiratorial thinking, and cognitive biases in how people weigh probabilities of present and future risks. In contrast, social norms can help promote vaccine uptake.

Receiving a vaccine is strongly associated with perceived disease risk or susceptibility. Refusing a vaccine, conversely, may be associated with a lower perceived disease risk and has been linked to increased risk of diseases like measles, pertussis, and invasive pneumococcal infection at the individual and community level. Geographic clustering of vaccine refusal further increases the risk of communicable disease outbreaks in certain communities even when vaccination rates at a state or national level remain high overall. For example, large outbreaks of measles in the United States in the 2010s frequently occurred in undervaccinated communities with shared religious and cultural beliefs.

Disruption to routine pediatric vaccination during the COVID-19 pandemic has left many children vulnerable to vaccine-preventable diseases and more locations susceptible to outbreaks in the United States and around the world. Although evidence remains inconclusive, disease resurgence may help bolster vaccine uptake; media coverage of recent measles outbreaks has been associated with more provaccine communication and positive parental vaccine attitudes. In contrast, pediatric COVID-19 vaccine uptake has been slow as parents consider a new vaccine for a new disease amidst ongoing spread of both disease and misinformation. COVID-19 is a reminder that disease prevalence is only one of many factors that contribute to vaccine acceptance.

Distrust of health systems based on historic and ongoing discrimination and inequitable access to care are intertwined challenges that contribute to racial and ethnic disparities in vaccine uptake. Although there has been progress in reducing racial, ethnic, and socioeconomic disparities in childhood vaccination coverage, the COVID-19 pandemic made clear how much work is yet to be done. Solutions to reduce disparities and promote vaccine uptake must build trust, improve access to care and access to information for all communities, increase diversity and representation among the ranks of scientists and health care professionals, and acknowledge the contribution of structural and interpersonal racism to health disparities. Promising approaches include partnering with trusted messengers to promote vaccination as well as community engagement to understand barriers to vaccine uptake and to build on existing sources of information and connection. Vaccine conversations with parents from historically minoritized groups may also require more explicit acknowledgement of the medical mistreatment and exclusion experienced by these groups and the damaging effect this has had on trust in medical and public health authorities.

Understanding Vaccine Evaluation and Safety as an Approach to Addressing Parental Concerns

Among parents or caregivers who refuse or question vaccines, safety has consistently been shown to be a top concern. Therefore, it is important for pediatricians and other clinicians who care for children to have knowledge of the processes for vaccine licensure and vaccine safety monitoring in order to address parents' questions and concerns. Because vaccines are generally given to healthy individuals to prevent disease, they are held to a higher safety standard than other medications. Prior to a vaccine being added to the routine immunization schedule, there is a multistep process including preclinical animal studies, clinical trials in humans, submission of an application to the US Food and Drug Administration (FDA) for licensure (or, as in the case of COVID-19 vaccines, for emergency use authorization [EUA]), approval or authorization by the FDA, and recommendations for use by the Advisory Committee on Immunization Practices (ACIP). In each of these steps, safety is a top consideration.

Prelicensure clinical trials and progression through the phases of clinical development are under the oversight of FDA. Prelicensure, phase 1 trials are conducted for the purpose of understanding the safety profile and side effects of a vaccine generally among 20 to 100 healthy volunteers. If there are no safety concerns in this phase, a vaccine may move into phase 2 trials, generally among several hundred volunteers,

when, in addition to further expanding an understanding of the vaccine's safety profile, immunogenicity is assessed. For vaccines with acceptable phase 2 safety data and promising immunogenicity data, phase 3 trials may proceed, often with thousands of volunteers, to assess both effectiveness and detection of less common adverse events in a larger population. After completion of phase 3 trials, the manufacturer of the vaccine may submit an application to the FDA for licensure. The FDA then reviews the application; if it determines that the vaccine is safe and effective and confirms that the manufacturing and facility information assure product quality and consistency, it may grant a license for use. The reviews conducted by the FDA are publicly posted on the FDA website. The ACIP then examines the available data submitted to the FDA as well as other contributory data to decide whether the benefits of vaccination outweigh any possible risks for the target population. Although some of the deliberations are internal to the FDA and CDC, this process is highly transparent, with public ACIP meetings and the opportunity for written or oral public comment. The process for authorization of COVID-19 vaccines under EUA and subsequent ACIP recommendation was very similar to fully licensed vaccine products, albeit on an accelerated timeline because of the urgent nature of the emergency (eg, pandemic) under which they were being considered.

Although prelicensure trials can identify common adverse events within a limited timeframe after vaccination, it is not feasible to conduct clinical trials large enough to detect all rare vaccine-related events (ie, <1 event per 10 000 vaccinees). Therefore, the United States has developed a robust postlicensure vaccine safety surveillance system. Two of the most widely known components of this surveillance network are the **Vaccine Adverse Event Reporting System (VAERS)** and the **Vaccine Safety Datalink (VSD)**, both of which were established in 1990. A surveillance system managed by the CDC and FDA, VAERS is the US government's early warning system for vaccine adverse events. Although VAERS is crucial to vaccine safety surveillance, it cannot generally assess causality. It therefore serves as a *hypothesis-generating* system. On the other hand, the VSD, a collaboration between CDC and 13 integrated health care organizations, is a *hypothesis-testing* system and can assess causality. Using electronic health records (EHRs) with highly accurate data, if a signal for a possible vaccine adverse event is identified through VAERS or other monitoring sources, further studies can then be conducted in the VSD to determine whether an association with the vaccine in question exists using several different types of methods, such as case-control (comparing the incidence of the possible adverse event in vaccinated and unvaccinated individuals) and self-controlled case series (in which only individuals who experienced the outcome of interest are examined using risk intervals around the time of vaccination). The VSD has been able to identify rare adverse events after vaccination, such as the association between measles, mumps, and rubella vaccine (MMR) and immune thrombocytopenic purpura and the increased risk of febrile seizures after measles, mumps, rubella, and varicella vaccine (MMRV). Equally importantly, the VSD has been able to demonstrate the lack of association of numerous vaccines with purported vaccine adverse events.

In addition to VAERS and the VSD, the FDA has its own active surveillance effort involving the **Biologics Effectiveness and Safety (BEST)** system, which covers more than 100 million people and comprises large-scale claims data, EHRs, and linked claims-EHR databases. The system makes use of multiple data sources and enables

rapid queries to detect or evaluate adverse events as well as studies to answer specific safety questions for vaccines.

In addition to the VSD, VAERS, and BEST, the United States has several other important systems monitoring vaccine safety, including the **Clinical Immunization Safety Assessment Project (CISA)**, various surveillance systems through the US Department of Defense, and, with onset of the COVID-19 pandemic, **v-safe**, the after-vaccination checker. The United States also collaborates internationally to study vaccine safety through partnerships with the World Health Organization, the European Medicines Agency, and the Pan-American Health Organization, among others. Details of several of the major US vaccine safety surveillance systems are shown in Table 1.5.

The safety of the recommended childhood vaccines and the recommended schedule has been affirmed by multiple independent reviews, including from the National Academy of Medicine (NAM) and the Agency for Healthcare Research and Quality (AHRQ). The 2013 report from the NAM includes a review of the evidence for known vaccine adverse events and was used to inform the vaccine injury compensation program. The 2021 update to the AHRQ report identified no new safety risks associated with the recommended vaccination schedule, and pediatricians can use this information to explain the reasons for the timing of the recommended schedule. Many vaccine-preventable diseases like measles, pertussis, rotavirus, and pneumococcal and *Haemophilus influenzae* infection are associated with higher morbidity and mortality in infancy and early childhood. Delaying vaccination leaves children unprotected at the age when they are most at risk. Vaccines are studied to ensure safety and adequate immune response at the age when they are recommended. For example, immune response to human papillomavirus (HPV) vaccine is stronger when given at an earlier age, and delaying vaccination may result in the need for more doses to achieve adequate protection.

Pursuing a nonrecommended vaccination schedule is associated with lower likelihood of being up-to-date on early childhood vaccinations and involves using an approach that is less well studied than the recommended schedule. It is also important to have children fully vaccinated before they attend group settings with other children (eg, any type of group child care setting, preschool, or elementary school where the risk of exposure to a vaccine-preventable disease increases). When using a nonrecommended vaccine schedule, this goal can be compromised. Deviation from the recommended schedule, therefore, is generally discouraged. After making a reasonable effort to discuss the recommended vaccination schedule with a family, deviation from the recommended schedule may be considered if it is the only way to move forward to vaccinate a child.

Some parents and caregivers have concerns about the number of vaccinations children receive or the specific components in vaccines. Clinicians can respond to the concern among some parents that “too many” vaccines are given at once with evidence-based, valid, culturally sensitive statements to promote vaccine uptake. It may be helpful to explain that there are fewer antigens in the current schedule than historical schedules that included the whole-cell pertussis vaccine. The immune system has the capacity to respond to a large number of stimuli at once and responds to the many immunogenic substances it encounters outside vaccinations through routine childhood food, environmental, and circulating disease exposures.

Parents and caregivers sometimes raise concerns about vaccines causing the infection they are actually working to prevent. Pediatricians can explain that non-live vaccines contain only a portion of the bacteria or virus they are working to prevent and

Table 1.5. Examples of Major Vaccine Safety Surveillance Systems in the United States

Surveillance System	Data Source	Population Under Surveillance	Management	Characteristics	Strengths	Limitations
Vaccine Adverse Event Reporting System (VAERS)	Online reporting system Health care providers and vaccine manufacturers are required by law to report certain events after vaccination	Entire United States	FDA, CDC	• “Nation’s early warning system” • Passive, spontaneous reporting • Hypothesis-generating • 85%–90% of reports are nonserious • Serious reports are followed up	• Accepts reports from anyone • All data are publicly available	• Generally cannot assess causality • Prone to both overreporting and underreporting
Vaccine Safety Datalink (VSD)	Electronic health record data from 13 large health care organizations across the United States	12.5 million	CDC, in collaboration with integrated health care organizations	• Active surveillance system • Hypothesis-testing • Can conduct medical record review to verify outcomes • Multiple methods developed to conduct valid, accurate vaccine safety studies	• Can estimate potential causal associations • Capable of real-time monitoring • High-quality data	• Limited ability to assess adverse events with delayed or insidious onset • May not be able to control for all confounders • Represents an insured population

Table 1.5. Examples of Major Vaccine Safety Surveillance Systems in the United States, continued

Surveillance System	Data Source	Population Under Surveillance	Management	Characteristics	Strengths	Limitations
Biologics Effectiveness and Safety System (BEST)	Large-scale claims data, electronic health records (EHRs), and linked claims-EHR databases	100 million	FDA	• Enables rapid queries to detect or evaluate adverse events as well as studies to answer specific safety questions for vaccines	• Very large population • Possible to study the safety of vaccines in subpopulations with preexisting conditions or in pregnant persons	• Limited evaluation of pediatric vaccines to date • Statistical signals must be further evaluated through rigorous epidemiologic study
Clinical Immunization Safety Assessment (CISA)	Generally medical records from clinicians	Not applicable	CDC, in collaboration with medical research centers	• In depth clinical, pathophysiological, and vaccinology expertise to assess causal relationships between vaccines and adverse events	• US health care providers with a complex vaccine safety question about a specific patient may contact CISA to request a consult	• Limited in scope

BEST indicates Biologics Effectiveness and Safety System; CDC, Centers for Disease Control and Prevention; CISA, Clinical Immunization Safety Assessment; EHR, electronic health records; FDA, US Food and Drug Administration; VAERS, Vaccine Adverse Event Reporting System; VSD, Vaccine Safety Datalink.

that most common vaccine side effects are from the immune system response and are not a sign of infection. Some vaccines contain only the genetic material for a specific protein and direct the body to produce a small amount of that protein. Live vaccines are contraindicated for some immunocompromised people because of the risk of vaccine-strain viral replication causing vaccine associated disease; however, these vaccines do not cause infection or disease in immunocompetent people.

Other common concerns focus on specific vaccine ingredients. In the United States, mercury was removed from most vaccine products in the early 2000s. Thimerosal (which contains ethylmercury) is still used as a preservative to prevent contamination in some influenza vaccines supplied in multidose vials, but other routine childhood vaccines in the United States, including single-dose vial influenza vaccines, do not contain ethylmercury. Concerns about neurologic effects of mercury exposure are based on risks associated with methylmercury, whereas ethylmercury is metabolized more quickly and not associated with the same risks. Alleged correlations between methylmercury and autism have been debunked.

Aluminum is used in some vaccines as an adjuvant that facilitates a strong immune response. The amount of aluminum in vaccines is safe, regulated, and comparable to the amount of aluminum infants are exposed to through human milk and formula feeding.

Fetal cell lines have been used in the development, testing, and production of some vaccines and other medications, but vaccines do not contain cells or DNA from aborted fetuses. Most major religions have issued statements that the use of fetal cells in vaccine development does not prohibit use of these vaccines, and some have pointed out the moral good of vaccination to protect the health of children and the people around them.

The CDC's *Epidemiology of Vaccine Preventable Disease: The Pink Book* and collection of *Morbidity and Mortality Weekly Reports (MMWRs)* containing ACIP vaccination recommendations are useful resources for more detailed information about vaccine contraindications and precautions, ingredients, schedules, and side effects. A summary of common misconceptions with accompanying facts is provided in Table 1.6.

Evidence-Based Communication Strategies to Increase Uptake of Childhood Vaccines¹

Pediatricians are the most common source of vaccine information for parents and caregivers, are the most trusted source for vaccine-safety information, and can positively influence a parent's vaccine behavior, even among parents with concerns about vaccines. Vaccine-related facts that pediatricians may use when discussing vaccines with parents are important. How those facts are communicated is also important. It is important to establish an honest dialogue, take time to listen, and solicit and welcome questions. Recent evidence has further improved the understanding of specific clinician communication strategies that can improve uptake of childhood vaccines. Although many techniques for working with vaccine-hesitant parents have been suggested, relatively few have been studied to determine efficacy in improving vaccination uptake, although recent years have seen an uptick in large, funded randomized trials.

¹ American Academy of Pediatrics, Committee on Infectious Diseases, Committee on Practice and Ambulatory Medicine, Committee on Bioethics. Clinical report. Strategies for improving vaccine communication and uptake. Pediatrics. 2024; in press

Table 1.6. Common Misconceptions/Myths About Vaccines and Immunizations

Claims	Facts
“Natural” methods of enhancing immunity, such as contracting the disease, are better than vaccinations.	Vaccinations are the safest way to achieve immunity; having immunity the “natural way” means being sick with a potentially very serious, even lethal, infectious disease. Immunity from a preventive vaccine provides protection against disease when a person is exposed to it in the future. That immunity is usually similar to what is acquired from natural infection, although several doses of a vaccine may have to be administered for a child to develop an adequate immune response.
Giving multiple vaccines at the same time causes an “overload” of the immune system.	Vaccination does not overburden a child’s immune system; the recommended vaccines use only a small portion of the immune system’s “memory.” Although the number of unique vaccines administered has risen over recent decades, the number of antigens administered has decreased because of advances in science and manufacturing. The National Academy of Medicine (NAM) has concluded that there is no evidence that the immunization schedule is unsafe.
Vaccines are ineffective.	Vaccines have spared millions of people the effects of devastating diseases.
Prior to the use of vaccinations, these diseases had begun to decline because of improved nutrition and hygiene.	In the 19th and 20th centuries, some infectious diseases began to be better controlled because of improvements in sanitation, clean water, pasteurized milk, and pest control. However, vaccine-preventable diseases decreased dramatically after the vaccines for those diseases were approved and were administered to large numbers of children.
Vaccines cause poorly understood illnesses or disorders, such as autism, sudden infant death syndrome (SIDS), immune dysfunction, diabetes, neurologic disorders, allergic rhinitis, and eczema.	These claims are false. Multiple, high-quality scientific studies have failed to substantiate any link between vaccines and these health conditions. See NAM and Agency for Healthcare Research and Quality (AHRQ) reports. ^{a,b}
Vaccines weaken the immune system.	Vaccines strengthen the immune system. Vaccinated children have decreased risk of infections. Importantly, natural infections like influenza, measles, and chickenpox can weaken the immune system, increasing the risk of other infections.

Table 1.6. Common Misconceptions/Myths About Vaccines and Immunizations, continued

Claims	Facts
Giving many vaccines at the same time is untested.	With some exceptions, administering multiple vaccines at the same time is as effective and safe as administering vaccines separately. Routine administration of all age-appropriate doses of vaccines at the same time is important to keep children up-to-date with all recommended vaccines.
Vaccines can be delayed, separated, and spaced out without consequences.	Many vaccine-preventable diseases occur in early infancy. Optimal vaccine-induced immunity may require a series of vaccines over time. Any delay in receiving age-appropriate immunization increases the risk of diseases that vaccines are administered to prevent. Spacing out vaccine may also have psychological consequences, because many more office visits will be associated with injections.

USE A STRONG VACCINE RECOMMENDATION AND THE PRESUMPTIVE FORMAT FOR INITIATING THE VACCINE DISCUSSION

One of the clinician vaccine communication strategies with strong evidence for increased uptake of childhood and adolescent vaccines is providing a vaccine recommendation. The strength and quality of this recommendation is also important. There is higher vaccine receipt among children whose parents or caregivers receive a very strong clinician vaccine recommendation than those who do not. The ability to confidently provide such strong recommendations is based on decades of broad national and international pediatric health care experience, data collection, and rigorous, well-designed studies of vaccine safety, efficacy, and effectiveness.

A related communication strategy with similarly strong evidence for increased vaccine uptake is a clinician’s use of a presumptive format to initiate the vaccine discussion. A presumptive format is one in which the clinician asserts a position regarding vaccines using a closed-ended statement, such as “Sara is due for several vaccines today” or “Well, we have to do some shots.” This is in contrast to a participatory format, in which an open-ended question is used to more explicitly invite the parent to voice an opinion, such as “How do you feel about vaccines today?” Clinician use of a presumptive format is associated with increased vaccine uptake, even among vaccine-hesitant parents. In addition, clinicians’ repeated use of a presumptive (as compared with participatory) format with vaccine-hesitant parents or caregivers over several visits, given the longitudinal nature of vaccine administration and discussions, yields significantly less underimmunization among children. Overall, implementation of the presumptive format in practice has been perceived by clinicians as time-saving, easy

to use, and a way to promote vaccination as part of routine care. Engaging all team members in the office setting or inpatient unit who communicate with parents about vaccines on the rationale and technique for initiating the vaccine discussion using the presumptive format could maximize its effect.

FOR PARENTS WHO EXPRESS HESITANCY, USE ADDITIONAL EVIDENCE-BASED COMMUNICATION STRATEGIES

Although a strong recommendation and use of a presumptive format for initiating the vaccine discussion with parents and caregivers are effective, they are not a panacea; despite use of these strategies, a proportion of vaccine-hesitant parents will still voice initial resistance to vaccinating their child. There are additional vaccine communication strategies needed with parents who continue to express hesitancy. One such strategy is motivational interviewing. Motivational interviewing is a patient-centered framework for behavior change that helps leverage one's inherent motivation for behaviors. Evidence from observational studies to support the use of motivational interviewing in the vaccination context is growing. The strongest evidence for motivational interviewing has come from a large cluster randomized controlled trial.¹ Clinicians in intervention practices were trained to use the presumptive format for initiating the discussion for all parents regarding HPV vaccine, followed by use of motivational interviewing in discussions with parents who voiced initial reluctance in having their child receive the HPV vaccine. Clinicians in control practices provided usual care. Investigators found a significant increase in HPV vaccine initiation and completion among children of parents who received care in intervention (versus control) practices.

Other adjunctive clinician vaccine communication strategies with some evidence supporting their effectiveness include: (a) pursuing adherence to the recommended vaccines due for the child at a visit despite initial parental reluctance; and (b) bundling the discussion of all vaccines a child is eligible for at the visit at once. Pursuing adherence refers to responding immediately to a parent's initial reluctance to the vaccines for which their child is due with a reiteration of the importance of the recommended vaccines for the child, such as "Your child really needs these shots." In several observational studies, parental verbal acceptance of vaccines for their child was significantly higher when clinicians pursued their vaccine recommendations (versus acquiesced) after initial parent reluctance. Bundling the discussion of all vaccines for which a child is due at a visit at once is supported by observational work in which investigators found concurrent discussion of the influenza vaccine with other vaccines for which a child was also due was associated with higher influenza vaccine uptake. Clinicians may also mention that they use strategies to minimize the pain associated with vaccination, as this is a common concern among parents and caregivers.

Finally, clinicians can emphasize their own experiences when discussing the need for vaccination, including personal experience with vaccine-preventable diseases and the fact that they and their families are vaccinated because of their confidence in the safety and efficacy of the vaccines.

¹ Dempsey AF, Pyrznowski J, Lockhart S, et al. Effect of a health care professional communication training intervention on adolescent human papillomavirus vaccination: a cluster randomized clinical trial. *JAMA Pediatr.* 2018;172(5):e180016

LEVERAGE SYSTEMS, ORGANIZATIONAL APPROACHES, AND COMMUNITY INITIATIVES TO IMPROVE PARENTAL ACCESS TO VACCINES

Pediatrician-parent communication is only one of the many efforts required to achieve and maintain high vaccination coverage. There are many established and long-standing evidence-based practices for increasing vaccination coverage, such as standing orders for vaccination, reminder/recall, use of immunization information systems, school and child care entry requirements, and audit and feedback, among others. There are also emerging community-based approaches designed to build trust and address the concerns of specific populations, including religious and vulnerable populations. These may include community- and school-based vaccination programs, which may help to demonstrate vaccination as a social norm and encourage greater uptake. Effectively implementing these strategies has the potential to save time in the clinical encounter by reducing the time needed to discuss vaccines.

Policies for Families Who Refuse or Delay Vaccination

Dismissal of child patients of vaccine-refusing parents or caregivers can be a difficult decision arrived at after considering multiple factors and documented attempts to counsel vaccine-refusing families. However, if repeated attempts to help understand and address parental values and vaccine concerns fails to engender trust, move parents toward vaccine acceptance, or strengthen the therapeutic alliance, dismissal can be an acceptable option. When considering the dismissal of a vaccine-refusing parent, it is important to verify that less drastic alternatives are not feasible. The consideration, design, and implementation of office policies for dismissal will ideally take into account practice setting, patient population, availability of other nearby reputable sources of medical care for children, and the framing of the policy (stressing the importance of vaccination). Transparency and equitable application of such policies is also important. Dismissal must be conducted in a manner consistent with applicable state laws prohibiting abandonment of patients. Although these laws vary from state to state, official notification of the parents or legal guardian is required, along with the provision of information for finding a new physician. The parental refusal of recommended vaccines and attempts to counsel the family should be documented in the patient's medical record. Furthermore, the dismissing physician is obligated to continue current treatment and provide emergency care for a reasonable period of time, usually 30 days.

Vaccine Injury Compensation

Although vaccines are extremely safe products, serious adverse events, such as allergic reactions, are rare but can result from vaccine administration. The Vaccine Injury Compensation Program (VICP) was established in 1988 as an alternative to civil litigation and to simplify the process of settling vaccine injury claims. The VICP is a no-fault system in which compensation may be sought if people believe they have experienced an injury as a result of administration of a vaccine listed in the current Vaccine Injury Table, the link to which can be found at **www.hrsa.gov/vaccine-compensation**. People seeking compensation for alleged injuries from covered vaccines must first file claims with the VICP before pursuing civil litigation against

manufacturers or vaccine providers. If the claimant accepts the judgment of the VICP, neither vaccine providers nor manufacturers can be sued in civil litigation. If the claimant rejects the VICP judgment, he or she has the option of filing a claim against the vaccine company and the health care professional who administered the vaccine, although this seldom happens.

The VICP compensates for injuries that have occurred as a result of the administration of a vaccine routinely recommended for children and adolescents, although the vaccine recipient and beneficiary can be of any age. Vaccines not routinely recommended for children, including zoster vaccines, pneumococcal polysaccharide vaccine (PPSV23), and travel vaccines, are not covered by the VICP. The 21st Century Cures Act, signed into law in December 2016, amended the VICP to include coverage for vaccines recommended for routine use in pregnant people, ensuring that both a person who received a covered vaccine while pregnant and the child (in utero at the time) are covered by the program.

Claims must be filed within 36 months after the first symptom appeared following immunization, and death claims must be filed within 2 years of a death and within 4 years after the first symptom of the vaccine injury that resulted in the death. To ensure that legal expenses are not a barrier to entry into the program, the VICP may pay attorney's fees and other legal costs related to a claim, regardless of the judgment, if certain minimal requirements are met and the claim is determined to have been filed on a reasonable basis and in good faith.

The VICP compensates for vaccine-related injuries that are included on the Vaccine Injury Table, the link to which can be found at **www.hrsa.gov/vaccine-compensation**. The table lists the vaccines covered by the VICP as well as injuries, disabilities, illnesses, and conditions for which compensation may be awarded. The Vaccine Injury Table defines the time during which the first symptoms or significant aggravation of an injury must appear after immunization. If the claim pertains to conditions not listed in the Vaccine Injury Table, claimants still may file a claim. The average time from filing a claim to a judgement is under 3 years.

In 2009, a separate program, the Countermeasure Injury Compensation Program (CICP), was created to cover medical countermeasures developed and/or used in response to public health emergencies, such as in a pandemic (eg, COVID-19), epidemic, or security threat (eg, smallpox, anthrax, botulism) (**www.hrsa.gov/cicp**). CICP awards are paid by the Covered Countermeasure Process Fund, which is funded by Congress via emergency appropriations to the US Department of Health and Human Services. The CICP requires a higher burden of proof regarding injury causation, has a shorter time limit to file a claim (within 1 year following the date of vaccination), and does not compensate for pain, suffering, emotional distress, or attorney's fees. Denied claims cannot be appealed.

A vaccine covered by the CICP can be transferred to the VICP once the vaccine is approved by the US Food and Drug Administration (FDA) using the biologics license application (ie, the normal process), is recommended by the Centers for Disease Control and Prevention (CDC) Advisory Committee on Immunization Practices (ACIP) to be included in the CDC vaccine schedule, and is authorized by the Secretary of Health and Human Services. In addition, Congress has to authorize an excise tax on it.

Information about the VICP and the Vaccine Injury Table can be obtained from: Parklawn Building, 5600 Fishers Lane, 8N146B Rockville, MD 20857; telephone: 800-338-2382; email: vaccinecompensation@hrsa.gov; website: www.hrsa.gov/vaccine-compensation/index.html. People wishing to file a claim for a vaccine injury should telephone or write to: United States Court of Federal Claims, 717 Madison Place, NW, Washington, DC 20439; telephone: 202-357-6400. Information on the VICP is also available to caregivers through Vaccine Information Statements (www.cdc.gov/vaccines/hcp/vis/index.html), which are required to be provided before administering each dose of each vaccine covered by the program.

..... ACTIVE IMMUNIZATION

Active immunization involves administration of all or part of a microorganism or a modified product of a microorganism (eg, a toxoid, a purified antigen, an antigen produced by genetic engineering, or nucleic acid encoding an antigen) to evoke an immunologic response and clinical protection that mimics that of infection with the microorganism but usually presents little or no risk to the recipient. Immunization can result in antitoxin, anti-adherence, anti-invasive, or neutralizing activity or other types of protective humoral or cellular responses in the recipient. Some vaccines provide nearly complete and lifelong protection against disease, some provide protection against the more severe manifestations and/or consequences of the infection if exposed, and some must be readministered periodically to maintain protection. The immunologic response to vaccination is dependent on the type and dose of antigen, the effect of adjuvants, and host factors related to age, preexisting antibody, nutrition, concurrent disease, and genetics of the host. The effectiveness of a vaccine is assessed by evidence of protection against the disease it is designed to prevent. For some infectious diseases, induction of antibodies following vaccination is an indirect measure that predicts protection (eg, antitoxin against *Clostridium tetani* or neutralizing antibody against measles virus), but for others, serum antibody concentration does not always predict protection.

Vaccines are categorized as live (viral or bacterial microbes, which almost always are attenuated), or non-live (also viral or bacterial) vaccines. Non-live vaccines can include those produced by inactivating the entire microbe, or fractional vaccines such as recombinant vaccines produced through genetic technologies that contain a portion of the microbe. Also included under the category of non-live vaccines are toxoids, which generate an antibody response to toxins produced by a microbe rather than to the microbe itself. Several recently developed non-live vaccines do not contain antigen but employ DNA or RNA to instruct the recipient's own cellular mechanism to generate antigenic material, which then stimulates the immune response that confers protection against the pathogen.

Recommendations for vaccines routinely advised for immunocompetent and immunocompromised children and adolescents are updated annually in the harmonized schedule developed by the American Academy of Pediatrics (AAP), Centers for Disease Control and Prevention (CDC), American Academy of Family Physicians (AAFP), American College of Obstetricians and Gynecologists (ACOG), American College of Nurse Midwives (ACNM), American Academy of Physician Associates (AAPA), and National Association of Pediatric Nurse Practitioners (NAPNAP).

(http://redbook.solutions.aap.org/SS/Immunization_Schedules.aspx), and for simplicity are referred to as being “on the annual immunization schedule.” Vaccines approved for use in the United States are listed in Table 1.7. The US Food and Drug Administration (FDA) maintains and updates a website that lists vaccines approved for immunization and distribution in the United States with supporting documents (www.fda.gov/vaccines-blood-biologics/vaccines/vaccines-licensed-use-united-states). Appendix II (Codes for Commonly Administered Pediatric Vaccines, Toxoids, and Immune Globulins, p 1139) provides information on the billing codes for commonly administered pediatric vaccines and toxoids used for vaccine administration. A regularly updated listing of *Current Procedural Terminology* (CPT) product codes for commonly administered pediatric vaccines can be found at http://downloads.aap.org/AAP/PDF/coding_vaccine_coding_table.pdf.

Among currently approved vaccines in the United States, there are 3 live attenuated bacterial vaccines (oral typhoid, oral cholera, and bacille Calmette-Guérin vaccines) and several live attenuated viral vaccines. Although active bacterial or viral replication ensues after administration of these vaccines, few or no symptoms of illness occur because the pathogen has been attenuated. Sufficient antigenic characteristics of the virus or bacteria are retained during attenuation so that a protective immune response develops in the vaccine recipient.

A replication-incompetent virus that expresses an antigen of interest is another type of vaccine. An example is the adenovirus type 26-vectored COVID-19 vaccine, which expresses the SARS-CoV-2 spike protein, or the replication-deficient modified vaccinia Ankara smallpox and mpox vaccine (JYNNEOS).

Vaccines for some viruses (eg, hepatitis A, hepatitis B, human papillomavirus) and most bacteria are inactivated, component, subunit (purified components) preparations or inactivated toxins. Some vaccines contain purified bacterial polysaccharides conjugated chemically to immunobiologically active proteins (eg, tetanus toxoid, diphtheria toxoid, nontoxic variant of mutant diphtheria toxin, meningococcal outer membrane protein complex).

Viruses and bacteria in inactivated, subunit, and conjugate vaccine preparations are not capable of replicating in the host; therefore, these vaccines must contain sufficient antigen content and possibly include an adjuvant to stimulate a desired response. In the case of conjugate polysaccharide vaccines, the linkage between the polysaccharide and the carrier protein enhances vaccine immunogenicity by converting the vaccine from a T-lymphocyte-independent antigen to a T-lymphocyte-dependent antigen. Maintenance of long-lasting immunity with non-live viral or non-live bacterial vaccines (including toxoid vaccines) may require periodic administration of booster doses. Although non-live vaccines may not elicit the range of immunologic response provided by live attenuated agents, efficacy of approved non-live vaccines in children is high. For example, an injected non-live viral vaccine may evoke sufficient serum antibody or cell-mediated immunity but evoke only minimal mucosal antibody in the form of secretory immunoglobulin (Ig) A. Mucosal protection after administration of non-live vaccines generally is inferior to mucosal immunity induced by live attenuated vaccines. Nonetheless, the demonstrated efficacy for such vaccines against invasive infection is high. Bacterial polysaccharide conjugate vaccines (eg, *Haemophilus influenzae* type b, pneumococcal, and meningococcal ACWY conjugate vaccines) reduce nasopharyngeal colonization through exudated IgG.

Table 1.7. Vaccines Approved or Authorized by Emergency Use Authorization for Immunization and Distributed in the United States and Their Routes of Administration^a

Vaccine	Type	Route of Administration
Anthrax	Inactivated ^b	IM or SC
BCG	Live bacteria	Percutaneous using multiple puncture device
Cholera	Live attenuated bacteria	Oral
COVID-19	mRNA	IM
Dengue ^c	Live attenuated chimeric viruses	SC
DTaP	Toxoids and inactivated bacterial components	IM
DTaP, hepatitis B, and IPV	Toxoids and inactivated bacterial components, recombinant viral antigen, inactivated virus	IM
DTaP-IPV	Toxoids and inactivated bacterial components, inactivated virus	IM
DTaP, hepatitis B, Hib, and IPV	Toxoids and inactivated bacterial components, recombinant viral antigen, polysaccharide-protein conjugate, inactivated virus	IM
DTaP-IPV-Hib	Toxoids and inactivated bacterial components, inactivated virus, polysaccharide-protein conjugate	IM
Hepatitis A (HepA)	Inactivated virus	IM
Hepatitis B (HepB)	Recombinant viral antigen	IM
Hepatitis A-hepatitis B	Inactivated virus and recombinant viral antigens	IM
Hib conjugate (tetanus toxoid) ^d	Bacterial polysaccharide-protein conjugate	IM
Hib conjugate (meningococcal protein conjugate)	Bacterial polysaccharide-protein conjugate	IM
Human papillomavirus (9vHPV)	Recombinant viral antigens	IM
Influenza (IIV)	Inactivated viral components	IM
Influenza (IIV)	Inactivated viral components	ID ^e
Influenza (LAIV)	Live attenuated viruses	Intranasal
Japanese encephalitis	Inactivated virus	IM
Meningococcal ACWY conjugate (MCV4 or MenACWY)	Bacterial polysaccharide-protein conjugate	IM

Table 1.7. Vaccines Approved or Authorized by Emergency Use Authorization for Immunization and Distributed in the United States and Their Routes of Administration,^a continued

Vaccine	Type	Route of Administration
Meningococcal serogroup B (MenB)	Bacterial recombinant protein	IM
MMR	Live attenuated viruses	SC or IM ^f
MMRV	Live attenuated viruses	SC or IM
Pneumococcal polysaccharide (PPSV)	Bacterial polysaccharide	IM or SC
Pneumococcal conjugate (PCV)	Bacterial polysaccharide-protein conjugate	IM
Poliovirus (IPV)	Inactivated viruses	SC or IM
Rabies	Inactivated virus	IM
Rotavirus (RV1 and RV5)	Live attenuated virus	Oral
Tetanus-diphtheria (Td)	Toxoids	IM
Tdap	Toxoids and inactivated bacterial components	IM
Typhoid	Bacterial capsular polysaccharide	IM
Typhoid	Live attenuated bacteria	Oral
Varicella (VAR)	Live attenuated virus	SC or IM
Yellow fever	Live attenuated virus	SC
Zoster (RZV)	Recombinant viral antigens	IM

BCG indicates bacille Calmette-Guérin; ID, intradermal; SC, subcutaneous; IM, intramuscular; DTaP, diphtheria and tetanus toxoids and acellular pertussis, adsorbed; IPV, inactivated poliovirus; Hib, *Haemophilus influenzae* type b; PRP-T, polyribosylribitol phosphate-tetanus toxoid; HPV, human papillomavirus; MMR, live measles, mumps, rubella; MMRV, live measles, mumps, rubella, varicella (monovalent measles, mumps, and rubella components are not being produced in the United States); Td, tetanus and diphtheria toxoids (for children 7 years of age or older and adults); Tdap, tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis; RZV, recombinant zoster vaccine.

^aOther vaccines approved in the United States but not distributed include adenovirus (types 4, 7), anthrax, Ebola, plague, smallpox (ACAM2000), H5N1 influenza vaccines, influenza A (H1N1) monovalent 2009 vaccine, JE-virus vaccine (JE-VAX), pneumococcal conjugate vaccine (PCV7 and PCV13), HepB-Hib (Comvax), quadrivalent HPV vaccine (Gardasil), and bivalent HPV vaccine (Cervarix). The FDA maintains a website listing currently approved vaccines in the United States (www.fda.gov/vaccines-blood-biologics/vaccines/vaccines-licensed-use-united-states). The AAP maintains a website (<http://publications.aap.org/redbook/resources/15449>) showing status of licensure and recommendations for newer vaccines.

^bAnthrax vaccine is not approved for use in children (<https://pediatrics.aappublications.org/content/133/5/e1411>). Federal/state authorities would oversee emergency use under an investigational new drug application for children, should the need arise.

^cDengue vaccine is approved only for individuals 6 through 16 years of age with laboratory-confirmed prior dengue infection and living in areas with endemic infection.

^dSee Table 3.12, p 406.

^eIntradermal influenza vaccine is recommended only for people 18 through 64 years of age.

^fPRIORIX is administered only SC, while M-M-R-II can be administered SC or IM.

Viruses and bacteria in non-live vaccines cannot replicate in or be excreted by the vaccine recipient as infectious agents and, thus, do not present the same safety concerns for immunosuppressed vaccine recipients or contacts of vaccine recipients as might live attenuated vaccines. For example, live rotavirus vaccines pose risk and are contraindicated in children with severe combined immunodeficiency disease. Furthermore, the AAP, the Advisory Committee on Immunization Practices (ACIP) of the CDC, and the Healthcare Infection Control Practices Advisory Committee (HICPAC) recommend against administering live attenuated influenza vaccine to close contacts and caregivers of severely immunosuppressed people who require a protected environment.

Messenger RNA (mRNA) vaccines contain mRNA that encodes for an antigen based on a pathogen-specific protein (or portion of a protein), and expression of the antigen by host cells induces an immune response to the antigen. For example, mRNA COVID-19 vaccines encode for all or a portion of the spike protein of SARS-CoV-2.

Recommendations for dose, vaccine storage and handling (see Vaccine Handling and Storage, p 45), route and technique of administration (see Vaccine Administration, p 52), and immunization schedules should be followed for predictable, effective protection (also see disease-specific chapters in Section 3). Adherence to recommended guidance in terms of sequence, timing, route of administration, and dosage is critical to the success of immunization practices at both the individual and the societal levels.

Vaccine Ingredients

As part of the licensure process, the US Food and Drug Administration (FDA) reviews laboratory and clinical data on vaccines to ensure their safety and effectiveness. For each licensed vaccine, the FDA-approved prescribing information, commonly known as the package insert, contains information on the vaccine and lists antigens and other ingredients, each of which serves a specific purpose. A catalog of package inserts for vaccines currently licensed for use in the United States is available at www.fda.gov/vaccines-blood-biologics/vaccines/vaccines-licensed-use-united-states. A summary table of ingredients other than antigens (excipients) that are used in vaccines can be accessed at www.cdc.gov/vaccines/pubs/pinkbook/downloads/appendices/B/excipient-table-2.pdf. Additional information is available at www.fda.gov/vaccines-blood-biologics/safety-availability-biologics/common-ingredients-us-licensed-vaccines.

Allergic reactions may occur if the vaccine recipient is allergic to any ingredient in the vaccine. Therefore, careful screening for allergy to a vaccine or a vaccine component is indicated. Standardized screening checklists are available to assist clinicians in screening for allergies and other potential contraindications to vaccines. An example can be found at www.immunize.org/catg.d/p4060.pdf. The safety of vaccines licensed for use in the United States is continuously monitored by the FDA and the Centers for Disease Control and Prevention (CDC). In addition to antigens, vaccines may also contain conjugates, adjuvants, stabilizers, preservatives, antibiotics, and diluents. These and other vaccine ingredients (eg, cell culture media) are listed in vaccine package inserts. Vaccine package inserts can be found at www.fda.gov/vaccines-blood-biologics/vaccines/vaccines-licensed-use-united-states and www.immunize.org/fda/.

ANTIGENS

Antigens in vaccines, sometimes referred to as immunogens, are viruses, bacteria, viral or bacterial components, or toxoids that result in active immunization, which is the process by which a person becomes protected from a disease. New generation vaccines contain messenger RNA (mRNA) encoding for antigens or for viral vectors that express antigens. Some vaccines consist of one or more antigens that are highly defined constituents (eg, tetanus and diphtheria toxoids). Some vaccines consist of multiple antigens, which vary in chemical composition, structure, and number (eg, acellular components in pertussis vaccines; polysaccharide protein conjugates in multivalent pneumococcal conjugate vaccine and serogroups A, C, W, and Y meningococcal conjugate vaccines; and recombinant proteins in 9-valent human papillomavirus vaccine). Other vaccines contain live attenuated viruses (eg, measles, mumps, and rubella vaccine [MMR]), live reassorted viruses (eg, rotavirus vaccine [RV]), or killed whole cell viruses (eg, non-live poliovirus vaccine and hepatitis A vaccine [HepA]). FDA-approved or authorized vaccines to prevent COVID-19 contain nucleoside-modified mRNA encoding the viral spike glycoprotein of SARS-CoV-2, a recombinant spike protein, or a replication-incompetent adenovirus vector expressing spike protein.

CONJUGATES

Conjugates are proteins that chemically combine with polysaccharide antigens to increase immunogenicity and induce immunological memory. Conjugates improve immune response for children younger than 18 months who do not consistently respond to polysaccharide antigens. Conjugates also boost antibody response to multiple doses of a vaccine. Some vaccines (eg, *Haemophilus influenzae* type b [Hib] and certain pneumococcal and meningococcal vaccines) include polysaccharide antigens chemically conjugated to protein carriers with proven immunologic potential (eg, non-toxic mutant of diphtheria toxin [CRM₁₉₇], tetanus toxoid protein, and meningococcal outer membrane protein complex).

ADJUVANTS

Adjuvants are vaccine ingredients that improve the immune response to antigens but do not themselves provide immunity. Adjuvants stimulate an immune response via cytokine release. Not all vaccines use adjuvants. For example, live vaccines such as MMR, varicella (VAR), and RV vaccines do not include adjuvants. Because the purpose of adjuvants is to generate stronger immune response, adjuvanted vaccines may cause local and systemic reactions more frequently compared with nonadjuvanted vaccines. Adjuvants have been used in vaccines in the United States for decades. Aluminum salts, a class of adjuvants that has been used safely in the United States since the 1930s and remains widely in use, are often in vaccines that contain subunit antigens of a cell (eg, hepatitis B vaccine [HepB]) or toxoids (eg, diphtheria and tetanus toxoids). Newer adjuvants currently in use in the United States are generally limited to certain vaccines approved for use only in adults. They include oil-in-water emulsions (used in adjuvanted non-live influenza vaccine [IIV]), deacylated monophosphoryl lipid A and saponin in a liposomal formulation (used in recombinant zoster vaccine), and cytosine-phosphate-guanine enriched oligodeoxynucleotide motifs (used in HepB vaccine, which is a HepB formulation). Adjuvants can also allow for “antigen sparing,” in which a reduced amount of antigen can stimulate an equivalent immune

response because of the presence of an adjuvant. Adjuvants also permit the production of multifold numbers of vaccine doses from a limited antigen supply when large numbers of people need them, such as during an influenza pandemic.

STABILIZERS

Stabilizers are ingredients used in vaccines to help ensure that vaccine potency is not affected by adverse conditions such as heat and abnormal pH during the vaccine manufacturing process or during transport and storage. Stabilizers used in vaccines include sugars (eg, lactose or sucrose in Hib), amino acids (eg, arginine or monosodium salt of glutamic acid in live attenuated influenza vaccine), or proteins (eg, gelatin in VAR and MMR).

PRESERVATIVES

Preservatives are included in multidose vials of vaccines as a safety measure to prevent the growth of microorganisms that may be introduced into the vaccine when the vial is penetrated repeatedly to withdraw doses of the vaccine. Examples of preservatives include thimerosal, formaldehyde, and phenol derivatives. Thimerosal is an ethyl mercury-containing organic compound that has been widely used as a preservative in many vaccines since the 1930s to help prevent contamination. Although there are minor side effects associated with vaccines containing thimerosal, such as redness and swelling at the injection site, thimerosal in vaccines has a long and strong safety record. Regardless, all routinely recommended vaccines for infants and children in the United States are available thimerosal free. IIV for pediatric use is available in thimerosal-free or thimerosal-containing (for multidose vials) formulations. Additional information on thimerosal in vaccines is available from the FDA at www.fda.gov/vaccines-blood-biologics/safety-availability-biologics/thimerosal-and-vaccines. Formaldehyde is used in vaccines to detoxify bacterial toxins (eg, diphtheria and tetanus toxoids) and inactivate viruses (eg, several IIV formulations). Although almost all formaldehyde is removed during the production of vaccines that use formaldehyde, very low amounts may remain. Formaldehyde exposure at such a residual level is far less than what occurs naturally in the environment. Phenols are used as a preservative in the 23-valent pneumococcal polysaccharide vaccine.

ANTIBIOTICS

As a class of preservatives, antibiotics are sometimes used during the vaccine manufacturing process to inhibit bacterial growth, and trace amounts can remain in the final product. Antibiotics such as neomycin, gentamicin, and polymyxin B are used during production of several IIV formulations. Other vaccines that have trace amounts of antibiotics include MMR and HepA.

DILUENTS

Some vaccines are supplied as a lyophilized powder that must be reconstituted with their supplied liquid diluent prior to use. For some vaccines, the diluent is sterile water (eg, measles, mumps, rubella, and varicella [MMRV]) and for others it is sodium chloride (eg, Hib). Certain multicomponent vaccines include a lyophilized component with some vaccine antigens and a diluent with the other vaccine antigens in solution (eg,

diphtheria and tetanus toxoids and acellular pertussis, adsorbed; non-live poliovirus; Hib [Pentacel]; and serogroups A, C, W, and Y meningococcal conjugate vaccine [Menveo]). Certain adjuvanted vaccines include a lyophilized component with the vaccine antigen and a diluent with the adjuvant component (eg, recombinant zoster vaccine). Diluents are specifically formulated for each vaccine. Therefore, only the specific diluent supplied for each vaccine should be used.

Vaccine Handling and Storage

For vaccines to be optimally effective, they must be stored properly from the time of manufacturing until they are administered. Immunization providers are responsible for proper storage and handling from the time the vaccine arrives at their facility until the vaccine is administered. All staff should be knowledgeable about the importance of proper storage and handling of vaccines and the implications of improper storage and handling. The administration of improperly stored and handled vaccines is a frequent error reported to the Vaccine Adverse Event Reporting System (VAERS) (see Understanding Vaccine Evaluation and Safety as an Approach to Addressing Parental Concerns, p 27).

Recommendations for handling and storage of vaccines are summarized in the package insert for each product (www.fda.gov/vaccines-blood-biologics/vaccines/vaccines-licensed-use-united-states) and should be reviewed. Additional information can be obtained directly from manufacturers. Contact information for manufacturers is available online (www.cdc.gov/vaccines/hcp/admin/storage/downloads/manufact-dist-contact.pdf). The Centers for Disease Control and Prevention (CDC) has online training and other resources including:

- You Call the Shots: Vaccine Storage and Handling is a free, online training module focused on storage and handling requirements (www.cdc.gov/vaccines/ed/youcalltheshots.html).
- Vaccine Storage and Handling toolkit is a useful resource for quality-control systems for safe handling and storage of vaccines in an office or clinic setting (www.cdc.gov/vaccines/hcp/admin/storage/toolkit/storage-handling-toolkit.pdf).

A written detailed vaccine-specific storage and handling plan should be available for reference by all staff members and kept on or near the unit used for storing vaccines. The plan should be updated annually and when new vaccines are added to the inventory. It should outline standard operating procedures for both routine management of vaccines and emergency measures for vaccine retrieval and storage, and should include documentation of these activities.

Most, but not all vaccines are designated for optimal storage between +2°C and +8°C (+36°F and +46°F). For the most current information, check the manufacturer's package insert. It is imperative that great care be taken to avoid exposing refrigerated vaccines to freezing temperatures, even for brief periods. Such exposure can compromise the integrity of refrigerated vaccines even without generating ice crystals or other changes in physical appearance of the vaccine. Visual inspection cannot reliably detect a vaccine that has been compromised by freeze exposure; thus, only the careful monitoring of the temperatures used to store these vaccines will allow identification of potentially altered vaccines. Refrigerator or freezer thermostats should be set at the factory-set or midpoint temperature, which will decrease the likelihood of temperature excursions.

Vaccines exposed to temperatures outside their approved storage ranges are generally considered ineffective, especially when no records exist about the temperature excursion or light exposure. They should be segregated in a bag or container, marked **“Do Not Use,”** and kept under the appropriate storage conditions (vaccine refrigerator or freezer). If it is a frozen vaccine that has been thawed, store in the refrigerator between 2°C and 8°C (36°F and 46°F) until manufacturer guidance is received, as refreezing the vaccine may damage it. The affected vaccines should not be used until the specifics of the temperature excursion are reviewed and it has been determined the vaccines can be administered. Protocols after the event vary depending on individual state or agency policies. Providers should contact their state immunization program, vaccine manufacturer, or both for guidance. Advice regarding disposition of improperly handled or stored vaccines should be documented. In general, manufacturers analyze information about the magnitude of the temperature excursion and the total amount of time that temperatures were out of range, as well as information about the vaccine in question, to determine whether a vaccine is likely to still be viable. Ideally, a temperature excursion should be immediately identified and immunization using affected vaccine halted until a vaccine viability determination can be made. If vaccine exposed to a temperature excursion is administered and subsequently determined not to be viable, the doses administered using the nonviable vaccine should be considered invalid. Providers should refer to state or agency policy on management of patients in receipt of invalid doses because of temperature excursion and vaccine administration errors. Manufacturers can be asked about possible replacement of nonviable vaccine.

Many vaccines should be protected from light prior to preparation and administration. Protection from light exposure can be accomplished by keeping each vial or syringe in its original carton while in recommended storage and until immediate use.

The diluent component of vaccines that need reconstitution may require storage at a different temperature than the antigen component and generally cannot be frozen. For appropriate storage of the diluent component, the recommendations in the package insert should be followed.

PERSONNEL

A primary staff vaccine coordinator and an alternate vaccine coordinator should be trained and responsible for vaccine storage and handling. In addition, a physician or manager with understanding of the importance of appropriate vaccine storage should be engaged with the responsible vaccine coordinating staff. The CDC offers online training on vaccine storage and handling, and information can be found at **www2a.cdc.gov/nip/isd/ycts/mod1/courses/sh/ce.asp**. Vaccine coordinators and all staff handling vaccines should have training and education on vaccine storage and handling as part of new employee orientation, annually (refresher training), when new vaccines are added to the inventory, and when recommendations for storage and handling of vaccines are updated (**www.cdc.gov/vaccines/ed/courses.html**). Document staff training with dates and participant names. The vaccine coordinator should be responsible for:

- Ordering vaccines.
- Overseeing proper receipt and storage of vaccine deliveries.
- Documenting vaccine inventory information.

- Organizing vaccines in storage units.
- Setting up temperature-monitoring devices.
- Checking and recording storage unit temperatures on a log (at the start of each workday if using a device that displays minimum/maximum temperatures or the current temperature at the start and end of the workday if using a device that does not display minimum/maximum temperatures).
- Reviewing and analyzing temperature data at least weekly for any shifts in temperature trends.
- Daily physical inspection of the storage unit.
- Rotating stock at least weekly so that vaccines closest to expiration date are used first.
- Contacting the state Vaccines for Children (VFC) program vaccine coordinator if it appears that VFC vaccines will expire before they will be used in the practice.
- Monitoring expiration dates and ensuring expired vaccines are removed from the refrigerator/freezer.
- Responding to potential storage temperature excursions and calling the manufacturer, VFC program, or both to obtain guidance for temperature excursion events.
- Overseeing proper vaccine transport, either routine or in an emergency.
- Maintaining all appropriate vaccine storage and handling documentation, such as inventory and temperature logs, including temperature excursion responses.
- Maintaining storage equipment and records, including VFC program documentation.
- Informing all people who will be handling vaccines about specific storage requirements and stability limitations of the products they will encounter. The details of proper storage conditions should be posted on or near each refrigerator or freezer used for vaccine storage or should be readily available to staff. Receptionists, mail clerks, and other staff members who also may receive shipments should be educated in these matters as well.
- Overseeing emergency preparations, such as tracking inclement weather conditions and ensuring appropriate handling of vaccines during a disaster or power outage.

EQUIPMENT

STORAGE UNITS

- Store vaccines in refrigerator and freezer units that can maintain the appropriate temperature range and are large enough to maintain the largest anticipated inventory without crowding. Use purpose-built or pharmaceutical-grade units designed to either refrigerate or freeze. These units can be compact, under-the-counter style, or large.
- Household-grade units can be an acceptable alternative to pharmaceutical-grade or purpose-built vaccine storage units in some situations. However, these units should be replaced with stand-alone units as soon as is practical. Household-grade units are primarily designed for home use. The freezer compartment is not recommended to store vaccines, and certain areas of the refrigerator should be avoided as well, including directly under cooling vents, in deli, fruit, or vegetable drawers, or in door shelves, because of instability of temperatures and air flow in these areas. A separate freezer unit is necessary if the facility provides frozen vaccines.
- Dormitory-style or bar-style combined refrigerator/freezer units are not acceptable for vaccine storage under any circumstances and are not allowed for vaccine storage of VFC program products. These units have a single exterior door and an evaporator

plate/cooling coil, usually located in an icemaker/freezer compartment. These units pose a significant risk of freezing vaccine, even when used for temporary storage.

- Inspection of door seals, vacuuming coils, and other maintenance of refrigeration units should be performed at least annually.
- Use refrigerators with wire—not glass—shelving to improve air circulation in the unit, and do not place bins or boxes against rear or side walls of the refrigerator.

TEMPERATURE MONITORING DEVICE

- The CDC recommends that each vaccine storage unit and each transport unit (emergency or nonemergency) should be monitored by a digital data logger (DDL). At least one back-up DDL is recommended in case of breakage.
- Recommended DDL features include:
 - ♦ Accuracy of $\pm 0.5^{\circ}\text{C}$ (1°F)
 - ♦ The temperature-monitoring device should be capable of continuous frequent measurements (no less frequently than every 30 minutes)
 - ♦ Detachable probe that best reflects vaccine temperatures, such as those in a temperature buffer (eg, biosafe glycol, glass beads, sand, Teflon)
 - ♦ Display current minimum and maximum temperatures, and these should be readable without opening the unit door
 - ♦ An alarm for out-of-range temperatures and a low-battery indicator
- The buffered probe(s) should be located in the center of the vaccines, away from the walls, vents, and floor of the vaccine storage unit. Temperature data should be displayed graphically and should be able to be stored for 3 years.
- The temperature-monitoring device with buffered probe should have a Certificate of Calibration Testing (also known as Report of Calibration). Such temperature-monitoring devices have been individually tested for accuracy against a recognized reference standard by a laboratory with accreditation from an International Laboratory Accreditation Cooperation (ILAC) Mutual Recognition Arrangement (MRA) signatory body, or by a laboratory or manufacturer with documentation that calibration testing performed meets ISO/IEC 17025 international standards for calibration testing and traceability. These devices are sold with an individually numbered certificate documenting this testing. Providers who receive VFC vaccines or other vaccines purchased with public funds should consult their state's immunization program regarding the required methods and timeframe for temperature-monitoring device calibration testing. The National Institute of Standards and Technology maintains a website devoted to vaccine storage education (www.nist.gov/programs-projects/reliable-vaccine-storage). Calibration testing and traceability must be performed every 1 to 2 years from the last calibration testing date (date certificate issued) or suggested calibration timelines from the manufacturer of the device must be used. Temperature accuracy of temperature-monitoring devices can be checked using an ice melting point test (www.nist.gov/pml/div685/grp01/upload/Ice-Melting-Point-Validation-Method-for-Data-Loggers.pdf). Providers should check with their state VFC program for specific requirements related to calibration testing of temperature-monitoring devices. Do not drill through the refrigerator or freezer to route a temperature probe.
- Providers should use a remote alarm notification system that sends an alert if the temperature is out of range. These alarms usually have the capability to send

notifications via email, telephone, or text. Redundant, multiple alerts are recommended to ensure receipt. Provision should be made to ensure alerts are still sent if there is loss of power and/or internet.

PROCEDURES

- Maintain a vaccine inventory log, which should include vaccine name, number of doses, arrival condition of the vaccine, manufacturer and lot numbers, and expiration date. If the shipment includes lyophilized (freeze-dried) vaccines, ensure they came with the correct type and quantity of diluents.
- Formally accept vaccine on receipt of shipment:
 - ♦ Ensure that the expiration date of the delivered product has not passed and identify any soon-to-expire products.
 - ♦ Examine the merchandise and its shipping container for any evidence of damage during transport.
 - ♦ Determine whether the interval between shipment from the supplier and arrival of the product at its destination is within the allowable limit noted on the shipping insert or container and whether the product has been exposed to excessive heat or cold that might alter its integrity. Review vaccine time and temperature indicators, both chemical and electronic, if included in the vaccine shipment.
 - ♦ Find and inspect any temperature excursion devices (electronic or temperature-tape) in the shipment for evidence of temperature excursions. Do not accept the shipment if reasonable suspicion exists that the delivered product may have been damaged by environmental insult or improper handling during transport.
 - However, if you are a VFC provider, do not refuse vaccine shipments. In the case of vaccine shipment compromise or a problem with the temperature monitors, the VFC provider must contact the McKesson Specialty Contact Center and/or the VFC program immediately using the telephone number dedicated to receiving provider calls about vaccine usability: 1-877-TEMP123.
 - ♦ Contact the vaccine supplier or manufacturer when unusual circumstances raise questions about the stability of a delivered vaccine. Store suspect vaccine under proper conditions and label it **“Do Not Use”** until the usability has been determined.
- Inspect the refrigerator and freezer:
 - ♦ A **“Do Not Unplug”** sign should be affixed directly next to the refrigerator electrical outlet and to the circuit breaker controlling that circuit.
- Train and designate staff to respond immediately to temperature recordings outside the recommended range and to document response and outcome.
- Establish routine procedures:
 - ♦ Store vaccine where temperature remains constant.
 - ♦ Store vaccines according to temperatures specified in the package insert.
 - ♦ Check and record the minimum/maximum temperature at the beginning of each workday.
 - ♦ Rotate vaccine supplies so that the shortest-dated vaccines are in front to reduce wastage because of expiration.
 - ♦ Inspect the unit weekly for outdated vaccine and either dispose of or return expired products appropriately.

- ♦ Promptly remove expired (outdated) vaccines and diluents from inventory and dispose of them appropriately or return to manufacturer to avoid accidental use.
- ♦ Store both opened and unopened vials in the original packaging, which facilitates temperature stability, inventory management, and rotation of vaccine by expiration date and avoids light exposure. Mark the outside of boxes of opened vaccines with a large “X” to indicate that they have been opened.
- ♦ Keep opened vials of vaccine in a tray so that they are readily identifiable.
- ♦ Indicate on the label of each vaccine vial the date and time the vaccine was reconstituted or first opened.
- ♦ Prepare vaccine just prior to administration. Avoid reconstituting multiple doses of vaccine or drawing up multiple doses of vaccine in multiple syringes. Predrawing vaccine increases the possibility of medication errors and causes uncertainty of vaccine stability.
- ♦ Because different vaccines can share similar components/names (eg, diphtheria and tetanus and acellular pertussis vaccines [DTaP and Tdap], or pneumococcal, meningococcal, and influenza products), care should be taken during storage to ensure that the different products are stored separately in a manner to avoid confusion and possible medication errors. CDC vaccine storage labels (www.cdc.gov/vaccines/hcp/admin/storage/guide/vaccine-storage-labels.pdf) help to easily identify and organize vaccines within the storage unit.
- ♦ Each vaccine and diluent vial should be inspected carefully for damage or contamination prior to use.
- ♦ The expiration date should be checked prior to preparation and administration. For all licensed vaccines, the expiration date is printed on the carton. Additionally, the expiration date may be printed on the container (eg, vial or syringe) label or may be accessed by scanning a barcode. For vaccines authorized for use under emergency use authorization, the expiration date may not be printed on the carton or container labels; instead, the date of manufacture is printed on the carton. In such cases, the expiration date must be accessed elsewhere (eg, barcode scan, website). The Fact Sheet for Health Care Providers may also provide the calculated expiration date based on the date of manufacture. Ensure staff are knowledgeable regarding how to determine the expiration date of the vaccines and diluents in the facility’s inventory. Expired vaccine or diluent should never be used. When the expiration date has only a month and year, the product may be used up to and including the last day of that month. If a day is included with the month and year, the product may only be used through the end of that day. Regardless of expiration date, vaccine and diluent should only be used as long as their appearance is as described in the product package insert and they have been stored and handled properly.
- ♦ Beyond-use date/time (BUD): Some vaccines have a BUD, which is calculated based on the date the vial is first entered and the storage information in the package insert. If the vaccine has no BUD, use the expiration date provided by the manufacturer. The BUD replaces but never exceeds the product’s expiration date. Once calculated, the BUD should be noted on the label along with the initials of the person making the calculation. Examples of BUDs include some vaccines in multidose vials, a reconstituted vaccine, and manufacturer-shortened expiration dates. BUD information is available in the product package insert.

- ♦ All reconstituted vaccines should be administered as soon as possible after reconstitution and within the time interval specified in the package insert.
- ♦ Always store vaccines in the refrigerator or freezer as indicated until immediately prior to administration.
- ♦ Do not keep food or drink in refrigerators in which vaccine is stored. This will reduce frequent opening of the unit that leads to thermal instability.
- ♦ Do not store radioactive materials in the same refrigerator in which vaccines are stored.
- ♦ Discuss with all clinic or office personnel any violation of protocol for handling vaccines or any accidental temperature excursion. Determine the root cause and put strategies in place to prevent it from happening again. Follow temperature excursion procedures until the vaccine manufacturers can be contacted to determine the disposition of the affected vaccine.

SUMMARY

Best equipment and practices for storage of refrigerated vaccines are as follows:

1. Purpose-built or pharmaceutical-grade refrigerator is recommended for vaccine storage.
 - a. Wire shelving—not glass—and an interior circulating fan.
2. A digital data logger with a buffered probe should be placed in the center of the vaccines within each storage unit.
 - a. Displays with current temperature and resettable maximum and minimum temperatures visible on the outside of the unit.
 - b. Audible temperature alarm with capability for rapid user notification via phone/text message/email should temperature excursion be detected.
3. Household-grade units can be used to store vaccines. However, the freezer compartment of this type of unit is not recommended to store vaccines. If the facility provides vaccines that must be stored frozen, a separate freezer unit is necessary.
 - a. Extra space in a household-grade unit should be filled with water bottles to serve as a cold mass and to prolong safe storage in the event of refrigerator failure. Follow manufacturer's guidance for purpose-built and pharmaceutical-grade vaccine storage units because this practice may not be necessary or recommended in those units.

VACCINE TRANSPORT

Transport of vaccines is not routinely recommended but may be necessary in emergency situations (eg, entire stock is being relocated for its protection) and may be appropriate for off-site clinics or when relocation of stock is required (eg, another site needs your excess supply). Vaccines should only be transported, even for short distances, using appropriate packing materials that provide the maximum protections. Portable vaccine refrigerator or freezer units are preferred, but qualified containers and packouts may also be used for either emergency or other necessary vaccine transport. The conditioned water bottle transport system may only be used for emergency transport. The manufacturer's original shipping container may only be used in an emergency as a last resort. Soft-sided food and beverage coolers should never be used; however, soft-sided containers engineered specifically for vaccine transport may be

used. Phase change materials at +4°C to +5°C (+39°F to +41°F) can be purchased to maintain proper temperatures. Follow the manufacturer's instructions for use to reduce the risk of freezing vaccines during transport.

- Do not use frozen gel packs or coolant packs from original vaccine shipments to pack refrigerated vaccines. They can still freeze vaccines even if they are conditioned or appear to be “sweating.”
- Use a continuous temperature-monitoring device, preferably a digital data logger with a probe that best reflects vaccine temperatures such as a buffered probe, for monitoring and recording temperatures while transporting vaccines. Place the buffered probe directly with the vaccines.
 - ♦ Keep the temperature-monitoring device display outside of the transport unit so the temperature can be seen easily without opening the container.
 - ♦ Use a temperature log to record transport unit temperatures.
- Ensure staff are trained on emergency procedures, and roles and responsibilities are clearly detailed in a written plan that is easily accessible to all staff.

EMERGENCY VACCINE STORAGE AND HANDLING

In addition to emergency transport instructions, practices should develop a written plan for emergency management of vaccine in the event of a catastrophic event or malfunction of the storage unit, train personnel, and make the plan easily accessible. Refrigerators vary and may maintain their +2°C to +8°C temperature for only 2 to 3 hours without power. This plan should include establishing an agreement with at least one alternate storage facility even if you have a generator or battery-powered back-up equipment. Ensure 24-hour access to alternate facilities as well as after-hours access to your own facility. Refer to emergency transport plans in the event you need to move vaccine to an alternate facility.

After a power outage or mechanical failure, it should not be assumed that vaccine exposed to temperature above the recommended range is unusable without first contacting the vaccine manufacturer (or, for VFC vaccines, the McKesson Specialty Contact Center at 1-877-TEMP123 and/or VFC program) for guidance before discarding vaccine. Guidance on vaccine transport is available from CDC (www.cdc.gov/vaccines/hcp/admin/storage/toolkit/index.html).

Vaccine Administration

GENERAL CONSIDERATIONS

Proper vaccine administration is critical to ensure safe and effective delivery of the vaccine antigen to the recipient. Practices are advised to identify an individual(s) to serve as vaccine champion whose job description includes keeping vaccine operations and staff education current. Health care personnel who administer vaccines should be trained in proper vaccine preparation, administration, infection control practices, and care of patients before and after vaccine administration, including considerations for needle anxiety, needlestick pain, and potential injection site pain after vaccination. The complete Advisory Committee on Immunization Practices (ACIP) guidance for vaccine administration is available as a resource at www.cdc.gov/vaccines/hcp/acip-recs/general-recs/administration.html.

TRAINING AND EDUCATION. Competency-based training on vaccination, including a post-vaccine administration observation component, should be integrated into existing staff education programs such as new staff orientation and annual continuing education requirements. Numerous in-person and online vaccination training opportunities are available, including the web-based education and training modules available at www.aap.org/en-us/advocacy-and-policy/aap-health-initiatives/immunizations/Practice-Management/Pages/Vaccine-Administration.aspx and www.cdc.gov/vaccines/ed/index.html. Additionally, demonstration videos and other resources can be found at www.aap.org/en/patient-care/immunizations/implementing-immunization-administration-in-your-practice/vaccine-administration, www.cdc.gov/vaccines/hcp/admin/resource-library.html, and immunize.org/clinic/administering-vaccines.asp.

INFECTION CONTROL. Health care personnel who administer vaccines should take appropriate precautions to protect themselves and minimize the risk of disease spread. Proper hand hygiene is required before preparing and administering vaccines and with each new patient contact. The use of gloves is not required when administering vaccines unless the health care provider has an open lesion on the hand, if contact with body fluids is anticipated, or when gloves are required because of isolation precautions for the patient. Proper hand hygiene should be practiced whether or not gloves are used, and gloves should be changed between patients. Syringes and needles must be sterile and not reused. Discard used syringes and needles promptly in a proper puncture-proof, labeled container located in the room where the vaccine is administered. To prevent inadvertent needlesticks or reuse, needles should not be recapped after use; the use of safety needles is preferred.

VACCINE PREPARATION. Vaccines and diluents should be used only if they have been stored and handled properly. Vaccines should be prepared following the manufacturer's guidance and immediately before administration using aseptic technique. If the vaccine requires reconstitution or dilution, only the diluent supplied for that vaccine should be used. Each vaccine and diluent should be carefully inspected for damages on the container or vial and evidence of contamination (eg, unusual coloration or sediments). The expiration date for both the vaccine and diluent should be checked to ensure that the vaccine and diluent have not expired. Some vaccines in a multidose vial should be used within a certain timeframe after the initial puncture to the vial septum ("beyond use date/time," or BUD); the BUD on the package insert should be identified and noted on the vial. Vaccine should not be administered after the BUD. Changing needles between drawing vaccine into a syringe and its administration is not necessary unless the needle has been damaged.

PATIENT CARE BEFORE, DURING, AND AFTER VACCINE ADMINISTRATION. Before administering any vaccine, patients should be screened for contraindications and precautions, even if the patient has previously received that vaccine. The patient's health condition or recommendations regarding contraindications or precautions for vaccination may change from one visit to the next. To assess patients correctly and consistently, a standardized, comprehensive screening tool is recommended. An example of screening checklist for contraindications for vaccines can be found at

www.immunize.org/catg.d/p4060.pdf. Health care personnel are required to provide the vaccine information sheet (VIS) for the patient, and the VIS can also be used as a tool to inform and counsel the patient on the vaccine. Because of the rare possibility of a severe allergic reaction to a vaccine or its components, health care personnel who administer vaccines should be able to recognize, treat, and report allergic reactions, including anaphylaxis (see Hypersensitivity Reactions After Immunization, p 71).

A patient should be comfortably seated or lying down before an injection and, if necessary, safely restrained (see Managing Injection Pain, p 57). Syncope can occur following vaccine administration, particularly in adolescents and young adults. Health care personnel should take appropriate measures to prevent injuries if weakness, dizziness, or loss of consciousness occurs. However, syncope can occur without presyncopal symptoms, so patients should be seated or lying down during vaccination. A 15-minute observation period (with the patient sitting or lying down) is advised after all vaccine administration to avoid the risk of injury if syncope occurs. Syncope following vaccination is not a contraindication to that or any other vaccine in the future. Any clinically significant adverse event that occurs during or following vaccine administration should be reported to the Vaccine Adverse Event Reporting System (VAERS) (see Understanding Vaccine Evaluation and Safety as an Approach to Addressing Parental Concerns, p 27).

Patient education should include a discussion of comfort and care after vaccination. These instructions should include information for dealing with common side effects such as injection site pain, fever, and fussiness (especially in infants) and should provide guidance about when to seek medical attention and when to notify the health care provider about concerns that arise following vaccination.

SITES AND ROUTES OF VACCINE ADMINISTRATION

Each vaccine has a specific administration route: parenteral, oral, or intranasal. Parenteral routes include intramuscular (IM) and subcutaneous (SC) injections; intradermal (ID) vaccines are not routinely used in children in the United States. Additional information is available at **www.aap.org/en/patient-care/immunizations/implementing-immunization-administration-in-your-practice/vaccine-administration** and **www.cdc.gov/vaccines/hcp/admin/admin-protocols.html**.

PARENTERAL VACCINATION. Approved sites and routes of administration can be found in package inserts of vaccines and in Table 1.7 (p 40). When multiple parenteral vaccines are indicated, separate injection sites should be used. If the same limb must be used as the injection site for 2 or more vaccinations, separate injections by at least 1 inch so that local reactions can be differentiated if they develop. Multiple vaccines should not be mixed in a single syringe. In sequencing the vaccinations, vaccines that are more reactive/likely to cause an injection site reaction (eg, diphtheria and tetanus toxoids and acellular pertussis, pneumococcal conjugate vaccine) should be administered in different limbs if possible, and vaccines that are more painful (eg, human papillomavirus; measles, mumps, and rubella [MMR]) should be administered last (see Simultaneous Administration of Multiple Vaccines, p 63).

IM Administration. Most vaccines are administered intramuscularly. Vaccines administered intramuscularly should be injected in a 90° angle at a site that minimizes risks for neural, vascular, or tissue injury. Vaccinators should be familiar with the anatomy of the area of the identified site (vastus lateralis or deltoid muscles) to correctly identify where to inject vaccine. For IM injections, the site of choice between thigh and arm depends on the age of the vaccine recipient, degree of muscle development, and thickness of adipose tissue at the injection site. In children younger than 2 years, the anterolateral aspect of the upper thigh provides the largest muscle and is the preferred site. In older children, the deltoid muscle is usually large enough for IM injection. Decisions on needle length should be based on the size of the muscle and the thickness of adipose tissue at the injection site. Needles should be long enough to reach the muscle mass and prevent vaccine from seeping into subcutaneous tissue and causing local reactions but not so long as to reach underlying nerves, blood vessels, or bone. Aspiration after injection is not needed and can increase pain at the injection site. The use of a 22- to 25-gauge needle generally is recommended for IM injections. Suggested needle lengths are described in Table 1.8. Note that the upper, outer aspect of buttocks generally should not be used for vaccination, because the gluteal region is covered by a significant layer of subcutaneous fat. Because of diminished immunogenicity, hepatitis B and rabies vaccines should not be administered in the buttocks at any age. Localized swelling, redness, and pain can occur at the IM injection site, but serious complications are rare. Reported adverse events include infections, bleeding, nerve injury, and shoulder injury related to vaccine administration (SIRVA) from inadvertent injection into the joint space. In general, vaccines containing adjuvants (eg, aluminum) are recommended to be injected deep into the muscle mass. If administered subcutaneously or intradermally, these vaccines can cause local irritation, inflammation, granuloma formation, and tissue necrosis. For patients with a known bleeding disorder or receiving anticoagulant therapy, bleeding complications following IM injection can occur. Additional information on vaccinating patients with bleeding disorders and other special populations such as preterm infants and pregnant women are available at www.cdc.gov/vaccines/hcp/acip-recs/general-recs/special-situations.html.

SC Administration. Several routinely recommended vaccines are administered subcutaneously, including the PRIORIX MMR vaccine. In contrast, M-M-R-II; measles, mumps, rubella, and varicella (MMRV); and varicella (VAR) vaccines may be administered subcutaneously or intramuscularly. Non-live poliovirus and pneumococcal polysaccharide vaccines can be administered subcutaneously or intramuscularly (pneumococcal conjugate vaccines are administered intramuscularly). SC injections place the vaccine in the tissue between the dermal and muscle layers. SC administration is made at the anterolateral aspect of the thigh or the upper outer triceps area by inserting the needle in a pinched-up fold of skin at a 45° angle. A 23- to 25-gauge needle of ⅝ inch length is generally recommended. Like other vaccines that are administered parenterally, localized swelling, redness, and pain can occur at the injection site, but serious complications are rare.

ORAL VACCINATION. Only rotavirus vaccines and oral typhoid vaccine are approved for oral administration in children. For infants, oral vaccines should be administered slowly down one side of the inside of the cheek between the cheek and gum toward the back of the mouth, allowing the infant to swallow, but not so far as to trigger the gag reflex. Do not squirt the vaccine directly into the throat. Detailed information on oral delivery of vaccines is included in package inserts. Breastfeeding does not appear

Table 1.8. Site and Needle Length by Age for Intramuscular Immunization^a

Age Group	Needle Length, inches (mm)	Suggested Injection Site
Newborns (preterm and term) and infants <1 mo of age	$\frac{5}{8}$ (16) ^b	Anterolateral thigh muscle
Infants, 1–12 mo of age	1 (25)	Anterolateral thigh muscle
Toddlers, 1–2 years	1–1 $\frac{1}{4}$ (25–32)	Anterolateral thigh muscle (preferred)
		Deltoid muscle of the arm
	$\frac{5}{8}$ ^b –1 (16–25)	
Children, 3–10 years	$\frac{5}{8}$ ^b –1 (16–25)	Deltoid muscle of arm (preferred)
	1–1 $\frac{1}{4}$ (25–32)	Anterolateral thigh muscle
Children, 11–18 years	$\frac{5}{8}$ ^b –1 (16–25)	Deltoid muscle of arm (preferred)
	1–1 $\frac{1}{2}$ (25–38)	Anterolateral thigh muscle
Adults		
Weight <130 lb	1 (25) ^c	Deltoid muscle of the arm
Weight 130–152 lb	1 (25)	Deltoid muscle of the arm
Weight 153–200 lb	1–1 $\frac{1}{2}$ (25–38)	Deltoid muscle of the arm
Weight 201–260 lb	1–1 $\frac{1}{2}$ (25–38) ^d	Deltoid muscle of the arm
Weight >260 lb	1 $\frac{1}{2}$ (38)	Deltoid muscle of the arm

^aAdapted from General Best Practice Guidelines for Immunization: Best Practices Guidance of the Advisory Committee on Immunization Practices (ACIP), Vaccine Administration, Table 6-2 (www.cdc.gov/vaccines/hcp/acip-recs/general-recs/administration.html#t6_2).

^bIf the skin is stretched tightly and subcutaneous tissues are not bunched.

^cSome experts recommend a $\frac{3}{8}$ -inch needle for adults who weigh less than 130 lb. If used, skin must be stretched tightly (do not bunch subcutaneous tissue).

^dConsider individual body composition (eg, adiposity, muscle mass) in determining needle length.

to diminish response to rotavirus vaccines, and the infant can eat or drink immediately following oral vaccination. If a dose of rotavirus vaccine is regurgitated, spat out, or vomited out, do not readminister the vaccine. Currently, there are no data available on the benefits or risks of repeating the dose. The infant should receive the remaining recommended doses of rotavirus vaccine following the routine schedule.

INTRANASAL VACCINATION. Live attenuated influenza vaccine (LAIV) is the only vaccine currently approved for intranasal administration. LAIV is approved for use for healthy, nonpregnant people 2 years through 49 years of age. The vaccine is prepared inside a special sprayer device that divides the dose into equal parts for delivery into each nostril and should be delivered in single brisk movement on each side rather than slowly. Patients should be sitting upright, the vaccinator should put a hand behind the patient's head, and the patient should be asked to breathe normally. The dose does not need to be repeated if the patient sneezes after vaccination. LAIV can be administered during

minor illnesses, but if nasal congestion might impede delivery of LAIV then administer injectable influenza vaccine or defer LAIV until after the resolution of nasal congestion.

VACCINE ADMINISTRATION ERRORS

Vaccines, like other medications, can inadvertently be administered in error. Vaccine administration errors can have many consequences, including inadequate immunologic protection, possible injury to the patient, cost, inconvenience, and reduced confidence in the health care delivery system. Common vaccine administration errors include use of expired vaccine or diluent, doses administered too early, and the use of improperly stored vaccines. Guidance for handling common vaccine administration errors is included in ACIP's General Best Practice Guidelines for Immunization (www.cdc.gov/vaccines/hcp/acip-recs/general-recs/administration.html). When a vaccine administration error occurs, health care personnel should determine how it happened and put strategies in place to prevent it occurring again in the future. In addition, they are encouraged to report vaccine administration errors to VAERS (see Understanding Vaccine Evaluation and Safety as an Approach to Addressing Parental Concerns, p 27).

Managing Injection Pain

Children of all ages benefit from a planned approach to decrease pain and anxiety related to immunization. The Advisory Committee on Immunization Practices (ACIP),¹ the Canadian Medical Association,² and the World Health Organization³ provide guidance on a variety of pain mitigation interventions during vaccination. Parents, children 3 years and older, and health care providers administering vaccine injections should be educated about age-appropriate, evidence-based techniques for reducing injection pain or distress. Combination vaccines should be used when feasible to reduce the number of injections and their attendant pain.

PHYSICAL AND PSYCHOLOGICAL TECHNIQUES FOR MINIMIZING INJECTION PAIN AND ANXIETY

Strategies to reduce pain include tactile stimulation (rubbing the site near the injection before and after the vaccination) and holding the child, which is routinely recommended in children younger than 3 years (along with patting or rocking the child after the injection). Allowing children 3 years and older to sit up rather than lie down can also assist in decreasing child anxiety. If multiple vaccines are to be given, they should be administered in order from least to most painful (painful vaccines include measles, mumps, rubella; pneumococcal conjugate vaccine; human papillomavirus; and diphtheria, tetanus, and acellular pertussis). The appropriately sized needle should be plunged rapidly through the skin and removed rapidly without aspiration. Aspiration

² Taddio A, McMurtry M, Shah V, et al. Reducing pain during vaccine injections: clinical practice guideline. *CMAJ*. 2015;187(13):975-982

³ World Health Organization. Reducing pain at the time of vaccination: WHO position paper – September 2015. *Wkly Epidemiol Rec*. 2015;90(39):505-510

before injection is not necessary, because large blood vessels are not present at the recommended injection sites and pain may be increased with longer needle dwell time in the tissue. For children younger than 3 years, breastfeeding, feeding sweet-tasting solutions (eg, sucrose or glucose solution 1-2 minutes before the vaccine), and applying topical anesthetics (all ages) at the site of injection are other strategies that have been used before vaccine administration to decrease pain (www.cdc.gov/vaccines/hcp/acip-recs/general-recs/administration.html).

Distraction strategies, including pinwheels, deep breathing exercises, music, and videos or video games, have been used in older children to decrease anxiety and pain. Adolescents should be seated or lying down during vaccination to reduce the risk of injury should syncope develop. Warming a vaccine by rubbing it between the hands is not recommended because of concern for altering vaccine effectiveness.

PHARMACOLOGIC TECHNIQUES FOR MINIMIZING INJECTION PAIN

If topical anesthesia is used, planning ahead is necessary to ensure the anesthetic is applied sufficiently in advance to develop effective anesthesia. Strategies can include applying the anesthetic en route to the office visit or immediately on arrival. Lidocaine 4% (LMX4) is approved by the US Food and Drug Administration (FDA) for children older than 2 years, is available over the counter, and takes effect 30 minutes after application. Lidocaine 2.5%/prilocaine 2.5% (EMLA), available by prescription, is approved by the FDA for neonates >37 weeks' estimated gestational age, infants, and children and takes effect 60 minutes after application. These products should be applied under occlusion. Topical application of ethyl chloride, a coolant sprayed onto a cotton ball and placed over the injection site for 15 seconds prior to administering the injection, has been shown to decrease injection pain in school-aged children. Note that for some children, topical anesthesia may not penetrate deeply enough to alleviate pain from intramuscular injections. Administration of oral analgesics, such as acetaminophen, prior to vaccinations has not been shown to reduce pain and may have a detrimental effect on the immune response to the vaccine(s) being administered. Age-appropriate doses of acetaminophen can be used after immunization to treat pain and to reduce the discomfort of fever.

Immunization Schedule and Timing of Vaccines

The purpose of a vaccine is to prompt the development of immunity against a disease in a person without the person developing the disease. The balance between timely protection and optimal immunologic response is the basis of the immunization schedule. The immunization schedule—including dose, frequency, and timing, along with the age and health status of the person—considers available clinical and epidemiologic data on vaccine safety and efficacy as well as programmatic considerations (such as incorporating vaccinations into scheduled health maintenance visits; www.cdc.gov/vaccines/schedules/hcp/imz/child-adolescent.html). The schedule must be read with its accompanying notes and special considerations. For those who fall behind or start late, catch-up vaccination should occur at the earliest opportunity following the recommended catch-up immunization schedule for children and adolescents who start late or who are more than 1 month behind (www.cdc.gov/vaccines/schedules/hcp/imz/catchup.html).

RECOMMENDED IMMUNIZATION SCHEDULE

The “Recommended Child and Adolescent Immunization Schedule for Ages 18 Years or Younger, United States” represents the recommendation of the Advisory Committee on Immunization Practices (ACIP), a federal advisory committee administered by the Centers for Disease Control and Prevention (CDC), with approval by the CDC. The immunization schedule is also approved by the American Academy of Pediatrics (AAP), the American Academy of Family Physicians (AAFP), the American College of Obstetricians and Gynecologists (ACOG), the American College of Nurse-Midwives (ACNM), the American Academy of Physician Associates (AAPA), and the National Association of Pediatric Nurse Practitioners (NAPNAP). The immunization schedule is reviewed annually and published in February each year. Creating unique vaccination schedules outside of the aforementioned reviewed and recommended schedules is not advised and may not provide effective protection against vaccine-preventable diseases.

AGE INDICATIONS FOR VACCINES

The age at which a vaccine is indicated depends on the immunologic maturity and health status of the patient, risk of exposure to the pathogen for which the vaccine is effective, vaccine safety, and optimal booster effect if the vaccine is a part of a series. In general, a vaccine is recommended for the youngest age of patients who are at risk for disease for which the vaccine is safe and provides protection. With a parenterally administered live vaccine for infants, the inhibitory effect of residual maternal antibody determines the optimal age at which the infant should receive the vaccine. For example, a measles-containing vaccine provides suboptimal seroconversion during the first year of life of an infant because of an interference by maternal antibody acquired through transplacental passage as well as the infant’s own immature immune system.

MULTIPLE DOSES OF THE SAME VACCINE

Some vaccines are administered as a series of doses to provide optimal protection. For example, one dose of the measles, mumps, and rubella vaccine (MMR) is 93% effective against measles, 78% effective against mumps, and 97% effective against rubella. Two doses of MMR increases vaccine effectiveness to 97% for measles, 88% for mumps and >97% for rubella. The protection provided by some vaccines wanes over time, and booster doses are periodically indicated. For example, tetanus and diphtheria toxoids require booster doses to maintain protective antibody concentrations. For multidose primary vaccination series, administration of doses at recommended intervals optimizes the immunologic response and minimizes possible adverse reactions (eg, local and systemic reactions to diphtheria and tetanus toxoids administration).

MULTIPLE VACCINES ADMINISTERED AT THE SAME TIME

In general, it is safe to administer different vaccines at the same time. Administration of multiple vaccines at the same time, as recommended in the immunization schedule, promotes adherence to completion of vaccination series (ie, reduced medical visits) and ensures optimal protection. Simultaneous administration of vaccines is also important for scheduling immunizations for children with lapsed or missed immunizations, for children requiring early or rapid protection, and for people preparing for international travel (see Simultaneous Administration of Multiple Vaccines, p 63).

Table 1.9. Guidelines for Spacing of Live and Non-Live Vaccines

Antigen Combination	Recommended Minimum Interval Between Doses
2 or more non-live ^a	May be administered simultaneously or at any interval
Non-live plus live	May be administered simultaneously or at any interval
2 or more live ^b	28-day minimum interval if not administered simultaneously

^aSee text below for the 3 exceptions to this.
^bAn exception is made for live oral vaccines, which can be administered simultaneously or at any interval before or after non-live or live parenteral vaccines.

More than 1 live-virus vaccine (eg, MMR, varicella, and live attenuated influenza vaccines) may be administered at the same time. However, immune responses may be impaired when 2 or more parenterally or nasally administered live-virus vaccines are not administered simultaneously but within 28 days (4 weeks) of each other; therefore, live-virus vaccines not administered on the same day should be given at least 28 days apart whenever possible (Table 1.9). Live oral vaccines—Ty21a typhoid vaccine and rotavirus vaccine—may be administered simultaneously with or at any interval before or after non-live or live injectable vaccine or nasally administered vaccine (Table 1.9).

No minimum interval is required between administration of different non-live vaccines, with 3 exceptions:

1. When both pneumococcal conjugate vaccine (PCV) and 23-valent pneumococcal polysaccharide vaccine (PPSV23) are indicated, PCV should be administered first, followed by PPSV23 at least 8 weeks later, to optimize immune response (see *Streptococcus pneumoniae* (Pneumococcal) Infections, p 810).
2. When MenACWY-D (Menactra) is administered 30 days after diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP), it interferes with the immune response for all four meningococcal serogroups. Therefore, MenACWY-D (Menactra) should be administered either before or at the same time as DTaP; alternatively, Menveo or MenQuadfi (if ≥ 2 years of age) may be administered because they do not have any interference with DTaP (see Meningococcal Infections, p 585).
3. Because of their high risk for invasive pneumococcal disease, children with functional or anatomic asplenia or HIV infection should not be vaccinated with MenACWY-D (Menactra) before age 2 years to avoid interference with the immune response to PCV (see Meningococcal Infections, p 585). Only MenACWY-CRM (Menveo) should be used in this group; MenACWY-TT (MenQuadfi) should not be used in this situation because it is only approved in children ≥ 2 years of age.

COMBINATION VACCINES

Combination vaccine products may be administered when they are age appropriate and any of the component vaccine is indicated and other components are not contraindicated. The use of a combination vaccine generally is preferred over separate injections of its equivalent component vaccines (see Combination Vaccines, p 65).

Web-based childhood immunization schedulers using the current vaccine recommendations are available for parents, caregivers, and health care professionals to facilitate making schedules for children and adolescents at www.cdc.gov/vaccines, and associated vaccination recommendations by the AAP can be found at www.aap.org/en/patient-care/immunizations/vaccination-recommendations-by-the-aap/. State and certain city immunization information systems (also known as vaccine registries) will generally forecast immunizations that are due according to the immunization schedule.

Minimum Ages and Minimum Intervals Between Vaccine Doses

Immunizations generally are recommended for members of the youngest age group at risk of experiencing the disease for whom efficacy, effectiveness, immunogenicity, and safety of the vaccine have been demonstrated. Most vaccines in the childhood and adolescent immunization schedule require 2 or more doses for stimulation of an adequate and persisting immune response. The schedule is determined based on studies demonstrating safety and effectiveness of individual vaccines evaluated in the context of the existing childhood immunization schedule (www.cdc.gov/vaccines/schedules/index.html).

Vaccines generally should not be administered at intervals less than the recommended minimum or at an age earlier than the recommended minimum (ie, accelerated schedules). If intervals between doses are longer than recommended, the vaccine series can continue and does not need to be started over. Administering doses of a multidose vaccine at intervals shorter or at an age earlier than those recommended for routine vaccination might be necessary in circumstances in which an infant or child is behind schedule and needs to be brought up to date quickly or when international travel is anticipated. In these situations, the minimum intervals and ages for catch-up vaccinations can be used (www.cdc.gov/vaccines/schedules/hcp/imz/catchup.html#table-catchup). For example, during a measles outbreak or for international travel, measles vaccine may be administered as early as 6 months of age. However, if a measles-containing vaccine is administered before 12 months of age, the dose is not counted toward the 2-dose measles vaccine series, and the child should be reimmunized at 12 through 15 months of age with a measles-containing vaccine; a third dose of a measles-containing vaccine then is indicated at 4 through 6 years of age but can be administered as early as 4 weeks after the second dose (see Measles, p 570).

Certain circumstances, such as the need for an additional office visit or a patient or parent poorly adherent to scheduled visits, could lead to consideration of administering a vaccine up to 4 days before the minimum interval or age. In general, vaccine doses administered (intentionally or inadvertently) 4 days or fewer before the minimum interval or age can be counted as valid. Health care professionals should be aware that state and school guidelines may consider such doses invalid and require additional vaccinations. Doses administered 5 days or more before the minimum interval or age should not be counted as valid doses and should be repeated as age appropriate. The repeat dose should be spaced by the recommended

minimum interval after the invalid dose. Because of the unique schedule for rabies vaccine, consideration of days of a shortened interval between doses must be individualized.

The latest recommendations can be found in the annual immunization schedule (http://redbook.solutions.aap.org/SS/Immunization_Schedules.aspx).

Additional information from the Centers for Disease Control and Prevention (CDC) can be found on the CDC website (www.cdc.gov/vaccines/hcp/acip-recs/general-recs/index.html).

Interchangeability of Vaccine Products

Similar vaccines made by different manufacturers can vary in several ways: the type, number, and amount of antigenic components; the formulation of adjuvants and conjugating agents; and the choice of stabilizers and preservatives. These differences may lead to variation in the immune response elicited. When possible, effort should be made to complete a series with vaccine made by the same manufacturer. If different brands of a particular vaccine require a different number of doses for series completion (eg, *Haemophilus influenzae* type b [Hib] and rotavirus [RV] vaccines) and a provider mixes brands in the primary series, the higher number of doses is recommended for series completion. Although data documenting the effects of interchanging vaccines are limited, available results are reassuring for adequate immune responses, and most experts have considered vaccines interchangeable when administered according to their recommended schedule and dosing regimen. Approved vaccines that may be used interchangeably during a vaccine series from different manufacturers, according to recommendations from the AAP or ACIP, include Hib conjugate, hepatitis B (HepB), hepatitis A (HepA), RV, and quadrivalent meningococcal conjugate vaccines.

Adolescents 18 years or older who start their HepB series with Heplisav-B should complete it with the same product. Of note, data are limited on safety and immunogenicity when PreHevbrio is interchanged with HepB vaccines from other manufacturers.

Regarding the 2 serogroup meningococcal B vaccines (ie, Bexsero and Trumenba), because each use very different protein antigens and because there are no data on their interchangeability, the same vaccine must be used for all doses to complete the full meningococcal serogroup B series.

Approved rotavirus vaccines (RV5 [RotaTeq 3-dose series] and RV1 [Rotarix 2-dose series]) are considered interchangeable as long as recommendations concerning conversion from a 2-dose regimen (RV1) to a 3-dose regimen (RV5) are followed (see Rotavirus, p 730). If any dose in the series is either RotaTeq or unknown, default to a 3-dose series.

Similarly, approved Hib conjugate vaccines are considered interchangeable, as long as recommendations for a total of 3 doses in the first year of life are followed (ie, if 2 doses of Hib-OMP PedvaxHIB are not administered, 3 doses of a Hib-containing vaccine are required). The combination diphtheria and tetanus and acellular pertussis (DTaP)-non-live poliovirus (IPV)-Hib-HepB vaccine (Vaxelis) is not recommended for use as a booster dose; a different Hib-containing vaccine should be used for the booster dose at age 12 to 15 months.

When a vaccine with increased serotype content is recommended as an option (eg, 15-valent or 20-valent pneumococcal conjugate vaccine [PCV15 or PCV20] as an alternative for 13-valent pneumococcal conjugate vaccine [PCV13]) or replaces a previously recommended product (eg, 9-valent human papillomavirus vaccine [9vHPV] for quadrivalent human papillomavirus vaccine [4vHPV]), the vaccines are considered interchangeable, so the series can be completed with the broader serotype product.

Minimal data on safety and immunogenicity and no data on efficacy are available for interchangeability of DTaP vaccines from different manufacturers. When feasible, DTaP from the same manufacturer should be used for the primary series (see Pertussis, p 656). However, in circumstances in which the DTaP product received previously is not known or the previously administered product is not readily available, any of the DTaP vaccines may be used according to licensure for dose and age. Matching of booster doses of DTaP and adolescent tetanus and diphtheria toxoids and acellular pertussis vaccine (Tdap) by manufacturer is not necessary. Single-component vaccines from the same manufacturer of combination vaccines, including DTaP-IPV-Hib-HepB (Vaxelis), DTaP-HepB-IPV (Pediarix), and DTaP-IPV/Hib (Pentacel) are interchangeable (see Combination Vaccines, p 65).¹

In general, written documentation of immunizations received outside of the United States can be accepted as valid evidence of previous immunization if the vaccines, dates of administration, number of doses, intervals between doses, and age of the child at the time of immunization are comparable to current US or World Health Organization schedules (www.who.int/immunization/policy/immunization_tables/en/; see Immunizations Received Outside the United States, p 119).

Simultaneous Administration of Multiple Vaccines

Simultaneous administration of most vaccines according to the recommended immunization schedule is safe and effective. Infants and children have sufficient immunologic capacity to respond to multiple vaccine antigens administered at the same time. The immune response to one vaccine generally does not interfere with responses to other vaccines. For example, simultaneous administration of non-live poliovirus vaccine; measles, mumps, and rubella vaccine (MMR); varicella vaccine; or diphtheria and tetanus and acellular pertussis vaccine (DTaP) results in rates of seroconversion and of adverse events similar to those observed when these vaccines are administered at separate visits.

There is no contraindication to simultaneous administration of multiple vaccines routinely recommended for infants and children, with 2 exceptions:

1. When both pneumococcal conjugate vaccine (PCV) and 23-valent pneumococcal polysaccharide vaccine (PPSV23) are indicated, PCV should be administered first, followed by PPSV23 at least 8 weeks later, to optimize immune response (see *Streptococcus pneumoniae* (Pneumococcal) Infections, p 810).
2. In children for whom quadrivalent meningococcal conjugate vaccine is indicated,

¹ Kroger A, Bahta L, Long S, Sanchez P. General best practice guidelines for immunization. Best practices guidance of the Advisory Committee on Immunization Practices (ACIP). Available at: www.cdc.gov/vaccines/hcp/acip-recs/general-recs/downloads/general-recs.pdf.

MenACWY-D (Menactra) should not be administered concomitantly OR within 4 weeks of administration of PCV vaccine, to avoid potential interference with the immune response to PCV. Therefore, because of their high risk for invasive pneumococcal disease, children with functional or anatomic asplenia or HIV infection should not be vaccinated with MenACWY-D (Menactra) before age 2 years to avoid interference with the immune response to PCV (see Meningococcal Infections, p 585). Only MenACWY-CRM (Menveo) should be used in this group; MenACWY-TT (MenQuadfi) should not be used in this situation because it is only approved in children ≥ 2 years of age.

A slightly increased risk of febrile seizures is associated with the first dose of measles, mumps, rubella, and varicella vaccine (MMRV) compared with MMR and monovalent varicella vaccine administered simultaneously at separate sites among children 12 through 23 months of age; after dose 1 of MMRV, 1 additional febrile seizure is expected to occur per approximately 2300 to 2600 young children immunized, compared with MMR and monovalent varicella administered simultaneously at separate sites. Evidence from epidemiologic studies indicated that during the 2 influenza seasons spanning 2010–2012, there was an increased risk of febrile seizures in young children, mostly concentrated in children 6 through 23 months of age, when non-live influenza vaccine (IIV) was administered simultaneously with PCV13 or DTaP-containing vaccines. This risk occurred on the day of vaccination to the day after; there did not appear to be an increased risk when IIV was administered without PCV13 or DTaP-containing vaccines. The risk was small with, at most, 1 additional febrile seizure per 3333 children vaccinated with any combination of simultaneous administration of these vaccines. A Sentinel Program Center for Biologics Evaluation and Research (CBER)/Post-licensure Rapid Immunization Safety Monitoring (PRISM) surveillance report evaluating influenza vaccines and febrile seizures found no evidence of an elevated risk of febrile seizures in children 6 through 23 months of age following IIV administration during the 2013–2014 and 2014–2015 influenza seasons, noting that the risk of seizures after PCV13 or concomitant PCV13 and IIV was low compared with a child's lifetime risk of febrile seizures from other causes. Overall, simultaneous administration of IIV and PCV continues to be recommended when both vaccines are indicated because of the preponderance of benefit relative to the risk.

In adolescents or young adults whose sex assigned at birth is male, it is reasonable to consider waiting 4 weeks after orthopoxvirus (mpox) vaccination (either JYNNEOS or ACAM2000) before receiving a Moderna, Novavax, or Pfizer-BioNtech COVID-19 vaccine because of the known risk for myocarditis and/or pericarditis after both these COVID-19 vaccines and the unknown risk after orthopoxvirus vaccine.

Individual vaccines should never be mixed in the same syringe unless they are specifically approved and labeled for administration in 1 syringe. Separate sites should be used, and injections into the same extremity should be separated by at least 1 inch so that any local reactions can be differentiated. If a non-live vaccine and an immune globulin product are indicated concurrently (eg, hepatitis B vaccine and hepatitis B immune globulin, rabies vaccine and rabies immune globulin, tetanus-containing vaccine and tetanus immune globulin), they should be administered at separate anatomic sites (eg, different extremities).

Combination Vaccines

Combination vaccine products may be administered when they are age appropriate and any of the component vaccine is indicated and other components are not contraindicated. The use of a combination vaccine generally is preferred over separate injections of its equivalent component vaccines because they can decrease the number of injections during a single clinic visit. Table 1.10 lists combination vaccines approved for use and the age groups for which they are approved in the United States. Factors that could be clinically considered, in consultation with the parent, for their use include the routinely recommended schedule for vaccines based on age, health status, and other indications; vaccine safety and availability; cost; the number of injections needed; and whether the patient is likely to return for follow-up and complete the vaccine series. Not all providers stock all vaccines that are routinely recommended. In addition, the use of combination vaccines can involve complex economic and logistic considerations.

When patients have received the recommended series of immunizations for a particular antigen, administering an extra dose of this antigen as part of a combination vaccine is permissible and doing so will reduce the number of injections required, as long as the vaccines are age appropriate and there are no contraindications.

Table 1.10. Combination Vaccines Approved by the US Food and Drug Administration (FDA)^a

Vaccine ^b	Trade Name (Year Approved)	FDA Licensure	
		Age Group	Use in Immunization Schedule
HepA-HepB	Twinrix (2001)	≥18 y	Three doses on a 0-, 1-, and 6-mo schedule
DTaP-HepB-IPV	Pediarix (2002)	6 wk through 6 y	Three-dose series at 2, 4, and 6 mo of age
MMRV ^c	ProQuad (2005)	12 mo through 12 y	Two doses usually at 12–15 mo and 4–6 y of age (see Varicella-Zoster Infections, p 938); separate by at least 1 mo between measles-containing vaccine and ProQuad and at least 3 mo between varicella-containing vaccine and ProQuad
DTaP-IPV	Kinrix (2008)	4 y through 6 y	Booster for fifth dose of DTaP and fourth dose of IPV in children who have received 3 doses of Pediarix or Infanrix and a fourth dose of Infanrix
DTaP-IPV/Hib	Pentacel (2008)	6 wk through 4 y	Four-dose series administered at 2, 4, 6, and 15 mo through 18 mo of age

Table 1.10. Combination Vaccines Approved by the US Food and Drug Administration (FDA),^a continued

Vaccine ^b	FDA Licensure		
	Trade Name (Year Approved)	Age Group	Use in Immunization Schedule
DTaP-IPV	Quadracel (2015)	4 y through 6 y	Single dose approved for use in children 4 through 6 years of age as a fifth dose in DTaP series and as a fourth or fifth dose in IPV series, in children who have received Pentacel, Daptacel, or Vaxelis vaccine
DTaP-IPV-Hib-HepB	Vaxelis (2018)	6 wk through 4 y	Three dose series administered at 2, 4, and 6 months of age ^d

DTaP indicates diphtheria and tetanus toxoids and acellular pertussis vaccine; HepA, hepatitis A vaccine; HepB, hepatitis B vaccine; HepA-HepB, hepatitis A and hepatitis B combination vaccine; Hib, *Haemophilus influenzae* type b vaccine; IPV, non-live poliovirus vaccine; MMRV, measles, mumps, rubella, and varicella vaccine.

^aExcludes measles, mumps, rubella vaccine (MMR); DTaP; tetanus and diphtheria toxoids and acellular pertussis vaccine (Tdap), and tetanus and diphtheria toxoids (Td), for which individual component vaccines are not available. IPV is not available as a single-antigen vaccine.

^bDash (–) indicates products in which the active components are supplied in their final (combined) form by the manufacturer; slash (/) indicates products in which active components must be mixed by the user.

^cThe American Academy of Pediatrics expresses no preference between MMR plus monovalent varicella vaccine or MMRV for toddlers receiving their first immunization of this kind. Parents should be counseled about the rare possibility of their child developing a febrile seizure 1 to 2 weeks after immunization with MMRV for the first immunizing dose.

^dA fourth dose of acellular pertussis vaccine is needed to complete the pertussis primary series in infants who receive 3 doses of Vaxelis.

Confusing ambiguities in the names of vaccines and vaccine combinations benefit from development of electronic systems that automate bar code scanning, which reduce potential recording errors enhancing the convenience and accuracy of transferring vaccine-identifying information into health records and immunization information systems.

Lapsed Immunizations

A lapse in an immunization series does not require restarting the series or adding doses to the series. If a dose in a vaccine series is missed or delayed, it should be administered at the next opportunity, and the series should resume for completion as recommended from the time of the catch-up vaccination. The catch-up schedule for children who have fallen behind on immunizations can be found at **www.cdc.gov/vaccines/schedules/hcp/imz/catchup.html**. Not all childhood vaccine series are required to be completed if there is an extended gap between doses or a delay in series initiation. A summary of recommended intervals between doses in vaccine series can be found at **www.cdc.gov/vaccines/hcp/acip-recs/general-recs/timing.html#t-02**. Although this summary discusses typically straightforward recommendations for several catch-up vaccinations, 2 distinct recommendations are described below.

1. For rotavirus vaccination, the doses in the series are age limited, and catch-up vaccination may not be indicated (see Rotavirus Infections, p 730). The rotavirus vaccination series should not start at or after age 15 weeks, 0 days, and the final dose in the series should not be administered after age 8 months, 0 days.
2. Children 6 months through 8 years of age who are receiving influenza vaccine for the first time or have received only 1 dose before the current influenza season should receive 2 doses of influenza vaccine separated by at least 4 weeks. Detailed influenza vaccination recommendations can be found in the Influenza chapter (p 511) and in the annual influenza policy statement of the American Academy of Pediatrics, which can be accessed through <https://redbook.solutions.aap.org/ss/influenza-resources.aspx>.

Health records of children for whom immunizations have been missed or delayed should be flagged as a reminder to resume their immunization series at the next opportunity and to implement reminder/recall communications to the family. An interactive app developed by the Centers for Disease Control and Prevention is available for downloading and has up-to-date information on the childhood immunization schedule, including catch-up timing of missed vaccines (www.cdc.gov/vaccines/schedules/hcp/schedule-app.html).

Unknown or Uncertain Immunization Status

Many children, adolescents, and young adults do not have adequate documentation of their vaccinations, which reinforces the need to record all vaccinations in state-based immunization information systems (IISs). Parent, guardian, or child recollection of immunization history may not be accurate. Additionally, many immigrant children have missing or unavailable vaccination records at the time of arrival in the United States. Health care providers should only accept written/electronic, dated, and authentic records as evidence of immunization, as long as the vaccines, dates of administration, number of doses, intervals between doses, and age of the child at the time of immunization are comparable to current US or World Health Organization schedules (www.who.int/immunization/policy/immunization_tables/en/). The 2 exceptions to this are influenza vaccine and pneumococcal polysaccharide vaccine (PPSV23); self-reported doses of these vaccines are acceptable.

When vaccine history is uncertain, there should be an immediate attempt to locate missing records by contacting previous health care providers, reviewing state or local IISs, and asking parents and guardians to search personally held records. In general, when in doubt, a person with unknown or uncertain immunization status should be considered disease susceptible, and recommended immunizations should be initiated without delay on a schedule appropriate for the person's current age. If the primary series has been started but not completed, the series should be completed if it is age appropriate, but there is no need to repeat doses or restart the full course.

Health care providers may use one of multiple approaches if the immunogenicity of vaccines or the completeness of series, especially those administered outside of the United States, is in question. Repeating the vaccinations is a safe, acceptable option that prevents the need to obtain and interpret serologic tests. If avoiding unnecessary

injections is desired, judicious use of serologic testing may help determine which vaccinations are needed for certain antigens (eg, measles, rubella, hepatitis A, and tetanus) (see Serologic Testing to Document Immunization Status, p 121, and Table 1.19, p 122). Curtailing the number of excess doses administered to patients controls costs incurred by patients, providers, insurers, vaccination programs, and other stakeholders and could potentially decrease adverse reactions to vaccines. However, commercial serologic testing takes time, can lead to a failed immunization opportunity, and may not always be sufficiently sensitive to indicate protection. Importantly, no evidence suggests that administration of vaccines to already immune recipients is harmful. In addition, serologic testing may not satisfy some school immunization requirements.

Vaccine Dose

Recommended vaccine doses are those that have been determined to be both safe and effective for their specified indication in prelicensure clinical trials; variations from the recommended route or site of administration or volume or number of doses of any vaccine are ill-advised, because they may not be safe or effective. Reducing or exceeding a recommended dose volume or collecting residual volumes to make up a dose is never recommended. Reducing or dividing doses of any vaccine, including vaccines administered to preterm or low birth weight infants, can result in inadequate immune responses. A previous immunization with a dose that was less than the standard dose or one administered by a nonstandard route should not be counted as valid, and the person should be reimmunized as recommended for age.

A special situation is a child who transitions between doses recommended for age groups for primary series doses of COVID-19 vaccine (www.cdc.gov/vaccines/covid-19/clinical-considerations/interim-considerations-us.html#transitioning-younger-older). For example, if a child turns 12 years of age between their first and second dose of Pfizer-BioNTech COVID-19 vaccine and they received the second vaccine in a dose appropriate for 5- to 11-year old children, the vaccine dose does not need to be repeated. Another special situation is with influenza vaccine, where recommendations for 2 versus 1 dose depend on age of the child and whether they had received influenza vaccine at any time in the past. Children who receive the first dose before their ninth birthday should receive 2 doses, even if they turn 9 years of age during the same influenza season.

Active Immunization After Receipt of Antibody-Containing Products

Donor-derived antibodies contained in polyclonal immune globulin (IG) preparations, including hyperimmune globulins like hepatitis B immune globulin (HBIG), can inactivate certain live-virus vaccines and reduce their immunogenicity. As such, these vaccines should be deferred for varying periods of time when IG preparations have been administered. Other blood products, such as plasma or packed red blood cells, also may contain antibodies capable of inactivating live vaccines. However, because the concentration of antibodies in these blood products is generally low, the length of vaccine deferral is less.

In the United States, the issue of interference by passively administered antibodies is most relevant for measles, mumps, and rubella vaccine (MMR); varicella vaccine (VAR); and measles, mumps, rubella, and varicella vaccine (MMRV). Table 1.11 shows the suggested intervals between receipt of blood products, including IG, and vaccine administration. This varies depending on the product type, the calculated amount of immunoglobulin G (IgG) in the product, and the dose of the product. Although there is some evidence that passive antibodies can interfere with the response to certain non-live vaccines, these vaccines may be administered at any time in relation to receipt of antibody-containing blood products. When both IG and vaccine are indicated to provide short- and long-term protection, respectively (eg, HBIG and hepatitis B vaccine [HepB] for an infant whose birthing parent is a carrier of hepatitis B virus), the products should always be administered in different anatomic sites (eg, different extremities used for HBIG and HepB). For additional information, see chapters on specific diseases in Section 3. The respiratory syncytial virus monoclonal antibodies palivizumab and nirsevimab do not interfere with the immunogenicity of any vaccine.

Live intranasal (live attenuated influenza vaccine [LAIV]) and oral (rotavirus vaccine [RV], and Ty21A typhoid vaccine) vaccines do not need to be deferred, because parenterally administered antibodies are unlikely to achieve significant concentrations at mucosal surfaces. Also, donor blood in the United States is unlikely to have neutralizing antibodies to *Salmonella* Typhi, yellow fever, and currently circulating strains of influenza. Immunogenicity and safety of recombinant live attenuated dengue vaccine after administration of immune globulin intravenous (IGIV) and other immunoglobulin-containing products has not been studied. Clinicians considering dengue vaccine for persons who recently received blood products (including IGIV) or other immunoglobulin containing products should delay prevaccination testing and administration of vaccine doses by 12 months.

Table 1.11. Recommended Intervals Between Receipt of Blood Products and Administration of MMR, Varicella, or MMRV Vaccines^a

Indications or Blood Product	Route	Usual Dose	Interval, mo ^{b,c}
Blood transfusion			
Washed RBCs	IV	10 mL/kg (negligible IgG/kg) ^d	0
RBCs, adenine-saline added	IV	10 mL/kg (10 mg IgG/kg) ^d	3
Packed RBCs	IV	10 mL/kg (60 mg IgG/kg) ^d	6
Whole blood	IV	10 mL/kg (80–100 mg IgG/kg) ^d	6

Rabies immune globulin	IM	20 IU/kg (22 mg IgG/kg)	4
Tetanus immune globulin	IM	250 U (10 mg IgG/kg)	3
Varicella immune globulin	IM	125 U/10 kg (60–200 mg IgG/kg) (max 625 U)	5

Table 1.11. Recommended Intervals Between Receipt of Blood Products and Administration of MMR, Varicella, or MMRV Vaccines,^a continued

Indications or Blood Product	Route	Usual Dose	Interval, mo ^{b,c}
Immune globulin			
Hepatitis A prophylaxis			
Contact prophylaxis	IM	0.1 mL/kg (16.5 mg IgG/kg)	6
International travel (short-term <1 month stay)	IM	0.1 mL/kg (16.5 mg IgG/kg)	6
International travel (long-term ≥1 month stay)	IM	0.2 mL/kg (33 mg IgG/kg)	6
Measles prophylaxis			
Not pregnant or immunocompromised ^e	IM	0.5 mL/kg (80 mg IgG/kg; maximum 15 mL)	6
Pregnant or immunocompromised ^f	IV	400 mg/kg	8
Varicella prophylaxis	IV	400 mg/kg	8
Replacement for immunodeficiency ^g	IV	300–400 mg/kg	8
Treatment of immune thrombocytopenic purpura	IV	400 mg/kg OR 1000 mg/kg	8 10
Treatment of Kawasaki disease	IV	2000 mg/kg	11

Adapted from General Best Practice Guidelines for Immunization: Best Practices Guidance of the Advisory Committee on Immunization Practices (ACIP), Vaccine Administration, Table 3–6 (www.cdc.gov/vaccines/hcp/acip-recs/general-recs/timing.html#t-06).

IM indicates intramuscular; IV, intravenous; MMR, measles, mumps, and rubella; MMRV, measles, mumps, rubella, and varicella; RBCs, red blood cells.

^aLive vaccines may be contraindicated in patients receiving certain blood products because of immunosuppression caused by their underlying disease.

^bThese intervals should provide sufficient time for decreases in passive antibodies that would allow for an adequate immune response to measles vaccine. Physicians should not assume that children are protected fully against measles during these intervals, and if measles virus is circulating in the community or if the child is traveling to an area where measles may be circulating, a measles-containing vaccine should be administered but not counted as a valid dose (measles vaccine should be readministered after the appropriate interval has passed from the receipt of blood product in accordance with the routine immunization schedule). If a blood product must be given within 14 days after administration of a measles- or varicella-containing vaccine, these vaccine doses are considered invalid and the vaccines should be readministered after the appropriate interval.

^cThe interval between dengue vaccine and blood/passive antibody products should be 12 months.

^dThe given intervals are applicable for neonates, even though transfusion volume may be 15 mL/kg of washed, adenine-saline added, or packed RBCs. Whole blood transfusions of >10 mL/kg may be used for cardiopulmonary surgery, exchange transfusions, or responding to trauma.

^eThis table is not intended for determining the correct indications and dosages for using antibody-containing products.

Unvaccinated people might not be protected fully against measles during the entire recommended interval, and additional doses of IG or measles vaccine might be indicated after measles exposure. Concentrations of measles antibody in an IG preparation can vary by manufacturer's lot. Rates of antibody clearance after receipt of an IG preparation also might vary. Recommended intervals are extrapolated from an estimated half-life of 30 days for passively acquired antibody and an observed interference with the immune response to measles vaccine for 5 months after a dose of 80 mg IgG/kg.

^fImmune globulin intravenous is recommended for pregnant people without evidence of measles immunity and for severely immunocompromised hosts regardless of immunologic or vaccination status, including patients with severe primary immunodeficiency; patients who have received a bone marrow transplant until at least 12 months after finishing all immunosuppressive treatment, or longer in patients who have developed graft-versus-host disease; patients on treatment for acute lymphocytic leukemia within and until at least 6 months after completion of immunosuppressive chemotherapy; individuals who have received a solid organ transplant; and people with HIV infection who have severe immunosuppression, defined as CD4+ T-lymphocyte percentage <15% for children ≤5 years of age and a CD4+ T-lymphocyte percentage <15% or a CD4+ T-lymphocyte count <200/mm³ for children >5 years, and those who have not received MMR vaccine since receiving effective antiretroviral therapy.

^gPatients who receive immune globulin subcutaneous (IGSC) at regular (eg, 1–4 week) intervals should not be vaccinated with MMR, varicella, MMRV, or dengue vaccines (see footnote c) while on therapy. If IGSC therapy is discontinued and vaccination is not otherwise contraindicated, vaccination with MMR, varicella, or MMRV may occur ≥8 months later.

Hypersensitivity Reactions After Immunization

Anaphylactic reactions to vaccines are rare. However, medications, equipment, and competent staff necessary to respond to these medical emergencies, to maintain patency of the airway, and to manage cardiovascular collapse should be available to treat anaphylaxis in all settings in which vaccines are administered (see Treatment of Anaphylactic Reactions, p 84). This recommendation includes administration of vaccines in schools, pharmacies, or other nontraditional vaccination settings.

In general, children who have experienced an immediate-type hypersensitivity reaction to a vaccine should be evaluated by an allergist before receiving subsequent doses of the suspect vaccine or other vaccines containing an ingredient in common. This evaluation may help determine whether an adverse event following immunization (AEFI) was allergic, or perhaps attributable to other mimics such as a vasovagal reaction or immunization stress-related response. Even when the child truly is allergic and no alternative vaccines are available, in almost all cases the risk of remaining unimmunized or inadequately immunized exceeds the risk of careful, graded increase in vaccine dose that is administration under observation where personnel, medications, and equipment are available and prepared to treat anaphylaxis, should it occur.

IMMEDIATE-TYPE ALLERGIC REACTIONS

Immediate allergic reactions may be caused by the immunizing agent (vaccine antigen) itself or, more often, by other vaccine components, particularly protein excipients. Almost all anaphylactic reactions to vaccines occur within minutes to 1 to 2 hours after vaccination.

ALLERGIC REACTIONS TO EGG PROTEIN (OVALBUMIN). Current measles and mumps vaccines (and some rabies vaccines) are derived from chicken embryo fibroblast tissue cultures and do not contain significant amounts of egg proteins. Studies indicate that children with egg allergy, even those with a history of severe reactions to egg ingestion, have no increased risk of anaphylaxis to these vaccines (eg, measles, mumps, and rubella [MMR] or measles, mumps, rubella, and varicella [MMRV]) compared with children without egg allergy. Most immediate hypersensitivity reactions after MMR or MMRV vaccination are attributable to other vaccine components, such as gelatin. Therefore, children with egg allergy may receive MMR or MMRV vaccines without special precautions.

Most non-live influenza vaccines (IIVs) and the live attenuated influenza vaccine (LAIV) also are produced in eggs and contain residual amounts of egg protein (ovalbumin). However, data have shown that these vaccines are well tolerated by recipients who have egg allergy, including patients with severe egg allergy, likely because the concentration of ovalbumin in the vaccines is below the threshold required to induce an allergic reaction. All children with egg allergy of any severity can receive any influenza vaccine without any additional precautions beyond those recommended for all vaccines.¹

The yellow fever vaccine may contain a larger amount of egg protein than influenza vaccines, but there are fewer reports on administering the vaccine to patients with egg allergy. A history of egg allergy should be sought prior to administration, and

¹ American Academy of Pediatrics, Committee on Infectious Diseases. Recommendations for prevention and control of influenza in children, 2022-2023. *Pediatrics*. 2022;150(4):e2022059274

consultation with an allergist is recommended if there is such a history. The vaccine package insert describes a protocol involving skin testing the patient with the vaccine and, if positive, administering the vaccine in graded doses.

ALLERGIC REACTIONS TO GELATIN. Some vaccines, such as MMR, MMRV, varicella, yellow fever, LAIV, and some rabies vaccines, contain gelatin of porcine or bovine origin as a stabilizer. Children who are allergic to gelatin (which is very rare) should receive IIV (or recombinant influenza vaccine if age-appropriate) instead of LAIV. The Vero cell culture-derived Japanese encephalitis (JE-VC) vaccine and the recombinant zoster vaccine do not contain gelatin stabilizers. People with a history of food allergy to gelatin may develop anaphylaxis after receipt of gelatin-containing vaccines. In addition, people without any apparent clinical allergy to oral ingestion of gelatin may experience an immediate hypersensitivity reaction following injection of a vaccine containing gelatin. In those very rare situations in which a patient is believed to be allergic to gelatin, evaluation by an allergist should occur, with immediate-type allergy skin testing before receiving gelatin-containing vaccines. If gelatin allergy is confirmed, gelatin-containing vaccines should be administered in graded doses under observation, with competent personnel, medications, and equipment available to manage anaphylaxis.

ALLERGIC REACTIONS TO YEAST. Hepatitis B and human papillomavirus vaccines are manufactured using recombinant technology in *Saccharomyces cerevisiae* (baker's or brewer's yeast). Allergy to yeast is rare; however, patients claiming such an allergy should be evaluated by an allergist before receiving yeast-containing vaccines to confirm the yeast allergy. If the history and testing suggest immediate hypersensitivity, the vaccine should be administered, in graded doses, under observation, with competent personnel, medications, and equipment available to manage anaphylaxis.

ALLERGIC REACTIONS TO LATEX. Dry natural rubber latex contains naturally occurring proteins that may be responsible for allergic reactions, although such reactions to dry natural rubber latex are much less common than reactions to natural rubber latex. Some vaccine vial stoppers and syringe plungers contain dry natural rubber latex. However, allergic reactions to such vaccines in recipients with latex allergy are exceedingly rare, likely because little, if any, latex allergen from the vial or syringe is present in the liquid vaccine being administered. Other vaccine vials and syringes contain synthetic rubber, which does not pose risk to the child with latex allergy. Information about latex used in vaccine packaging is available in the manufacturer's package inserts or on the Centers for Disease Control and Prevention website (www.cdc.gov/vaccines/pubs/pinkbook/downloads/appendices/B/latex-table.pdf). Patients with latex allergy should receive vaccines with natural rubber latex in the packaging in the normal manner, but under observation, with competent personnel, medications, and equipment available to manage the rare allergic reaction, should it occur.

DELAYED-TYPE ALLERGIC REACTIONS

With most cell-mediated, delayed-type hypersensitivity (DTH) allergic reactions, the allergens are small molecules. The molecules present in vaccines capable of producing such reactions include preservatives like thimerosal, adjuvants like aluminum, and antimicrobial agents.

ALLERGIC REACTIONS TO THIMEROSAL. Most patients with DTH reactions to thimerosal tolerate injection of vaccines containing thimerosal uneventfully or with only a temporary nodule or swelling at the injection site. This is not a contraindication to receive a vaccine that contains thimerosal. Thimerosal was removed from childhood vaccines in 2001. Only multidose vials of influenza vaccines currently contain thimerosal, and many thimerosal-free influenza vaccines in prefilled syringes are available.

ALLERGIC REACTIONS TO ALUMINUM SALTS. Sterile abscesses or persistent nodules have occurred at the site of injection of certain adjuvanted vaccines. These abscesses may result from a DTH response to the aluminum salts used as vaccine adjuvants such as aluminum hydroxide, aluminum phosphate, alum (potassium aluminum sulfate), or mixed aluminum salts. In some instances, these reactions may be caused by inadvertent subcutaneous inoculation of a vaccine intended for intramuscular use (Table 1.7, p 40). Aluminum-related abscesses recur frequently with subsequent dose(s) of vaccines containing aluminum. Only if such reactions were severe would they constitute a contraindication to further vaccination with aluminum-containing vaccines.

ALLERGIC REACTIONS TO ANTIMICROBIAL AGENTS. Many vaccines contain trace amounts of streptomycin, neomycin, or polymyxin B. Some people have DTH reactions to these agents and may develop an injection site papule 2- to 4 days after vaccine administration. This minor reaction is not a contraindication to future doses of vaccines containing these agents. The rare patients with a history of an anaphylactic reaction to one of these antimicrobial agents should be evaluated by an allergist before receiving vaccines containing them. No vaccine currently approved for use in the United States contains penicillin or its derivatives, cephalosporins, or fluoroquinolones.

OTHER VACCINE REACTIONS

Large local injection site swelling after administration of tetanus-containing vaccines had been believed to be common if such vaccines were given at short intervals between doses. However, recent studies indicate that the reactions are uncommon, even with short intervals between immunizations. These reactions are self-limited and do not contraindicate future doses of vaccines at appropriate intervals. Therefore, when indicated, a tetanus-containing vaccine should be administered regardless of interval since the last tetanus-containing vaccine.

..... PASSIVE IMMUNIZATION

Passive immunization entails administration of preformed antibody to a recipient and, unlike active immunization, confers immediate protection but for only a limited period of time. Passive immunization is indicated in the following general circumstances for prevention or amelioration of infectious diseases:

- For prophylaxis, when a person susceptible to a disease is exposed to or has a high likelihood of exposure to a specific infectious agent. This is especially important when that person has a high risk of complications from the disease or when time does not permit adequate protection by active immunization alone (eg, rabies immune globulin, varicella zoster immune globulin, hepatitis B immune globulin, tetanus immune globulin).

- As replacement, when people are deficient in synthesis of antibody as a result of primary immune deficiency (eg, severe combined immunodeficiency) or secondary immune deficiency in which antibody production is defective, alone or in combination with other immunodeficiencies (eg, immunosuppressive therapy or human immunodeficiency virus [HIV] infection).
- Therapeutically, when a disease is already present, whereby administration of preformed antibodies (ie, passive immunization) may ameliorate or aid in suppressing the effects of a toxin (eg, foodborne, wound, or infant botulism; diphtheria; or tetanus), ameliorate or suppress clinical disease (eg, anthrax, vaccinia, post-transplantation hepatitis B, post-transplantation cytomegalovirus [CMV]), or suppress certain inflammatory responses (eg, Kawasaki disease or multisystem inflammatory syndrome in children [MIS-C]).

Passive immunization can be accomplished with several types of products. The choice is dictated by the types of products available, the type of antibody desired, the route of administration, timing, and other considerations. These products include standard immune globulin intramuscular (IGIM); standard immune globulin intravenous (IGIV); hyperimmune globulins, some of which are for intramuscular use (eg, hepatitis B, rabies, tetanus, varicella) and some of which are for intravenous use (eg, botulism, CMV, vaccinia); antibodies of animal origin (eg, foodborne botulism, black widow spider, coral snake, rattlesnake, and scorpion antitoxins); and monoclonal antibodies (eg, respiratory syncytial virus [RSV], and SARS-CoV-2). Although the use of immune globulin subcutaneous (IGSC) for replacement has become increasingly common, IGSC usually is not preferred for initial prophylactic or therapeutic use because of the slower absorption and diminished bioavailability compared with IGIV. For patients requiring replacement therapy, bioavailability differences can be compensated for by giving a 1.3 to 1.37 times higher dose of IGSC (product-specific calculation) and monitoring trough levels to ensure equivalence with the prior IGIV dose.

Indications for administration of IG preparations other than those relevant to infections, Kawasaki disease, or MIS-C are not reviewed in the *Red Book*.

Immune Globulin Intramuscular (IGIM)

Immune globulin intramuscular (IGIM) is derived from pooled plasma of adults by a cold ethanol fractionation procedure (Cohn fraction II). IGIM consists of at least 90% immunoglobulin (Ig) G with trace amounts of IgA and IgM. It is treated with solvent/detergent to inactivate lipid-enveloped viruses, is sterile, and is not known to transmit any virus or other infectious agent. IGIM is a concentrated protein solution (approximately 16.5%, or 165 mg/mL) containing specific antibodies that reflect the infection prevalence and immunization status of the population from whose plasma the IGIM was prepared. Many donors (1000 to 60 000 donors per lot of final product) are used to include a broad spectrum of antibodies. Products sold in the United States are derived from plasma collected exclusively in US-licensed facilities. See www.fda.gov/vaccines-blood-biologics/approved-blood-products/immune-globulins for more information on products licensed in the United States.

IGIM is licensed and recommended for intramuscular administration. Therefore, IGIM should be administered deep into a large muscle mass (see Sites and Routes of Vaccine Administration, p 54). Ordinarily, no more than 5 mL should be administered

at one site in an adult, adolescent, or large child; a lesser volume per site (1–3 mL) should be given to small children and infants. Health care professionals should refer to the package insert for total maximal dose at one time. Peak serum concentrations usually are achieved 2 to 3 days after administration.

Standard human IGIM should never be administered intravenously. Intradermal use of IGIM is not recommended. For information on hyperimmune globulins for intramuscular use (eg, hepatitis B, rabies, tetanus, varicella), see chapters on specific diseases in Section 3.

INDICATIONS FOR THE USE OF IGIM

HEPATITIS A PROPHYLAXIS. IGIM is indicated for **postexposure prophylaxis (PEP)** to provide short-term protection against hepatitis A infection in previously unvaccinated patients. PEP with IGIM alone should be used for infants younger than 12 months and for people who have serious allergy to the hepatitis A (HepA) vaccine or its components. For patients older than 40 years, depending on the clinician's risk assessment (stacks.cdc.gov/view/cdc/59777), IGIM may be administered in addition to HepA vaccine. For patients 12 months through 40 years of age, HepA vaccine alone is preferred for PEP against hepatitis A infection (see Table 3.17, p 432).

For unvaccinated patients traveling to areas with high or intermediate hepatitis A endemicity, IGIM alone can be used for **preexposure prophylaxis (PrEP)** in infants younger than 6 months and people who have serious allergy to HepA vaccine or its components. For protection of infant travelers 6 through 11 months of age, preexposure HepA vaccine is preferred to IGIM because IGIM would interfere with the measles vaccine that also is required for international travel; this HepA dose does not count toward completing the immunization requirement. For healthy travelers 12 months through 40 years of age, HepA vaccine alone is recommended. For people older than 40 years, immunocompromised people of all ages, and people with chronic liver disease or other chronic medical condition, HepA vaccine should be administered, and in addition, IGIM can be considered (see Table 3.19, p 435).

IGIM is not indicated for people with clinical manifestations of hepatitis A infection or for people exposed to hepatitis A virus more than 14 days earlier.

MEASLES PROPHYLAXIS. IGIM administered to exposed, measles-susceptible (immunocompromised or not previously vaccinated) people can prevent or attenuate infection if administered within 6 days of exposure (see Measles, p 570). The effectiveness of IGIM is titer dependent. Vaccine-eligible people 12 months or older exposed to measles should preferably receive measles, mumps, and rubella vaccine (MMR), if it can be administered within 72 hours of initial exposure (see Table 3.32, p 575). Measles vaccine and IGIM should not be administered at the same time. Subsequent vaccination with MMR is recommended in nonimmune people exposed to measles who received IGIM for PEP. The appropriate interval between IGIM administration and measles immunization varies with the dose of IGIM and the specific product (see Table 1.11, p 69).

RUBELLA PROPHYLAXIS. Administration of IGIM to susceptible people experimentally exposed to rubella virus can prevent clinical rubella. However, there have also been many reports of the failure of IGIM to prevent the anomalies of congenital

rubella. For this reason, the routine use of IGIM for the prevention of rubella in an exposed pregnant patient is not recommended.

REPLACEMENT THERAPY IN ANTIBODY DEFICIENCY DISORDERS. Most experts no longer consider IGIM appropriate for replacement therapy in immunodeficiency because of the pain of administration and the inability to achieve therapeutic blood concentrations of IgG. If IGIM is used for this indication, the usual dose (limited by muscle mass and the volume that should be administered) is 100 mg/kg (equivalent to 0.66 mL/kg) every 3 weeks. Customary practice is to administer twice this dose initially and to adjust the interval between administration of the doses (2–4 weeks) on the basis of trough IgG concentrations and clinical response (absence of or decrease in infections).

ADVERSE REACTIONS TO IGIM

- Almost all recipients experience local discomfort and many experience pain at the site of IGIM administration that is related to the volume administered per injection site. Discomfort is lessened if the preparation is at room temperature at the time of injection. Less common reactions include nausea, flushing, chills, headache, and aseptic meningitis.
- Serious reactions are uncommon; these reactions can be anaphylactic or anaphylactoid in nature and manifest as chest pain or constriction, dyspnea, or hypotension and shock.
- Both IGIM and immune globulin subcutaneous have been associated with thrombosis, particularly for individuals at increased risk. To minimize risk of thrombosis, recipients should be adequately hydrated before IGIM administration.
- An increased risk of systemic reactions, including renal dysfunction, hemolysis, and transfusion-related acute lung injury (TRALI), may result from inadvertent intravenous administration. Standard IGIM should not be administered intravenously.
- People requiring repeated doses of IGIM have been reported to experience systemic reactions, such as fever, chills, sweating, and shock.
- IGIM should not be administered to people with known selective IgA deficiency (serum IgA concentration <7 mg/dL; IgG and IgM concentrations normal). Because IGIM contains trace amounts of IgA, people who have selective IgA deficiency may develop anti-IgA antibodies on rare occasions and on a subsequent dose of IGIM may experience an anaphylactic reaction with systemic symptoms such as fever, chills, and shock. In rare cases in which reactions related to anti-IgA antibodies have occurred, subsequent use of a licensed immune globulin intravenous (IGIV) preparation with the lowest IgA concentration may decrease the likelihood of further reactions. Because these reactions are rare, routine screening for anti-IgA antibodies is not recommended.

PRECAUTIONS FOR THE USE OF IGIM

- Caution should be used when administering IGIM to a patient with a history of adverse reactions to IGIM. In this circumstance, some experts recommend administering a test dose (1%–10% of the intended dose) before the full dose.
- Although systemic reactions to IGIM are rare (see Adverse Reactions to IGIM), epinephrine and other means of treating serious, acute reactions should be immediately available. Health care professionals administering IGIM should have training in the management of anaphylaxis and shock.

- Unless the benefit will outweigh the risk, IGIM should not be used in patients with severe thrombocytopenia or any coagulation disorder that would preclude IM injection. In such cases, use of IGIV is recommended.

Immune Globulin Intravenous (IGIV)

Immune globulin intravenous (IGIV) is a highly purified preparation of immunoglobulin (Ig) G antibodies extracted from the pooled plasma of 1000 to 60 000 qualified adult donors using methods that vary by manufacturer. IGIV contains more than 95% IgG, with trace amounts of IgA and IgM. IGIV is available as a lyophilized powder or as a formulated liquid solution, with final concentrations of IgG of 5% or 10% depending on the product. IGIV does not contain thimerosal or any other preservative. IGIV products vary in their sodium content, type of stabilizing excipients (eg, sugars, amino acids), osmolality/osmolality, pH, IgA content, isoagglutinins, trace amounts of other plasma proteins, and recommended infusion rate. Each of these factors may contribute to tolerability and the risk of serious adverse events. All IGIV preparations must have a minimum concentration of antibodies to measles virus, *Corynebacterium diphtheriae* toxoid, poliovirus, and hepatitis B virus. Antibody concentrations against other pathogens, such as *Streptococcus pneumoniae*, cytomegalovirus, and respiratory syncytial virus (RSV), vary widely among products and even between lots from the same manufacturer. One product, Asceniv, is produced from donors with high anti-RSV titers and has a specification for amount of anti-RSV antibody; it is approved for treatment of primary immunodeficiency in patients 12 years and older, but the clinical impact of the high anti-RSV titers on this or other patient populations is unknown.

INDICATIONS FOR THE USE OF IGIV

IGIV preparations available in the United States currently are licensed by the US Food and Drug Administration (FDA) for use in 8 conditions for either immune prophylaxis for primary and secondary immune deficiency or for immune modulation, as in Kawasaki disease and immune-mediated thrombocytopenia (Table 1.12). IGIV

Table 1.12. Uses of Immune Globulin Intravenous (IGIV) Approved by the US Food and Drug Administration^a

Primary immunodeficiency disorders such as common variable immunodeficiency, X-linked agammaglobulinemia, Wiskott-Aldrich syndrome
Kawasaki disease, for prevention of coronary aneurysms
Immune-mediated thrombocytopenia, to increase platelet count
Secondary immunodeficiency attributable to therapy for B-cell chronic lymphocytic leukemia or autoimmunity
Chronic inflammatory demyelinating polyneuropathy, to improve neuromuscular disability
Multifocal motor neuron neuropathy, to improve muscle strength
Reduction of serious bacterial infection in children with HIV infection
Dermatomyositis in adults

^aNot all IGIV products are approved by the FDA for all indications and not all products are approved for children or for all ages of the pediatric population.

products may be useful for other conditions, including multisystem inflammatory syndrome in children (MIS-C), although demonstrated efficacy from controlled trials is often not available. Blood sample(s) needed for diagnostic serologic tests for infectious diseases or to evaluate for immunologic disorders must be obtained before IGIV administration, because IgG antibodies present in IGIV may confound test interpretation over many months. Administration of IGIV can increase the erythrocyte sedimentation rate (ESR).

All IGIV products are licensed to prevent serious bacterial infections in primary humoral immunodeficiency, but not all licensed products are approved for the other indications listed in Table 1.12. Not all products are licensed for the entire pediatric age spectrum, and in some cases only a single product has certain indications. Therapeutic differences among IGIV products from different manufacturers may exist, but there are no comparative clinical trials of currently available products. Most experts believe that licensed IGIV and immune globulin subcutaneous (IGSC) products are equally efficacious except for Kawasaki disease, which should be treated with IGIV. IGIV (but not IGSC) is among the recommended therapies for MIS-C (see Coronavirus Disease-2019 [COVID-19], p 324). However, IGSC has slower absorption and diminished bioavailability compared with IGIV. Hyperimmune globulins (eg, BabyBIG, varicella-zoster immune globulin) as well as animal-derived immune globulin products are not discussed in this chapter. Among the licensed IGIV products, but not necessarily for each product individually, indications for prevention or treatment of infectious diseases in children and adolescents include the following:

- **Replacement therapy in antibody-deficiency disorders.** The typical dose of IGIV in primary immune deficiency is 400 to 600 mg/kg but may be as high as 800 mg/kg or higher, administered by IV infusion approximately every 21 to 28 days. Because of the half-life of administered IgG, dosing intervals greater than 28 days are not recommended. Dose and frequency of infusions should be based on clinical effectiveness in an individual patient and in conjunction with an expert on primary immune deficiency disorders. When possible, the same brand of IGIV should be administered longitudinally, because changing products is associated with an increased risk of adverse reactions.
- **Kawasaki disease.** Administration of IGIV at a dose of 2 g/kg as a single dose within the first 10 days of onset of fever, when combined with salicylate therapy, decreases the frequency of coronary artery abnormalities and shortens the duration of symptoms. IGIV treatment for children with symptoms of Kawasaki disease for more than 10 days is recommended, although data on efficacy are not available (see Kawasaki Disease, p 522). Repeat doses of IGIV may be indicated for refractory Kawasaki disease.
- **Pediatric human immunodeficiency virus (HIV) infection.** In children with HIV infection and hypogammaglobulinemia, IGIV may be used to prevent serious bacterial infection.¹

¹ Guidelines for the Prevention and Treatment of Opportunistic Infections in Children With and Exposed to HIV. Department of Health and Human Services. Available at: <https://clinicalinfo.hiv.gov/en/guidelines/hiv-clinical-guidelines-pediatric-opportunistic-infections/bacterial-infections>. Accessed May 20, 2023

- **Immune thrombocytopenia (ITP).**¹ Several IGIV products are licensed for the treatment of ITP and are considered first line therapy by some experts. Studies have demonstrated a more rapid rise in platelet count with IGIV therapy compared with other treatments.
- **MIS-C.** Although optimal treatment for MIS-C is unknown, most experts recommend administration of IGIV at a dose of 2 g/kg, with infusion length/frequency based on cardiac function, weight, and fluid status of the patient. Steroids and immunomodulatory biologic therapies (ie, anakinra) can be administered concurrently. A recent study found that initial treatment with both IGIV and steroids led to earlier resolution of fever compared with IGIV alone. See Coronavirus Disease 2019 (COVID-19), p 324, for additional information.
- **Guillain-Barré syndrome (GBS), chronic inflammatory demyelinating polyneuropathy (CIDP), and multifocal motor neuropathy (MMN).** In GBS, IGIV treatment has been demonstrated to have efficacy equivalent to that of plasmapheresis and is easier to administer. IGIV has been licensed by the US Food and Drug Administration for treatment of CIDP and MMN in adults. IGIV is equivalent to steroids and plasmapheresis in treatment of CIDP, although individual patients may respond better to one treatment than another. MMN, unlike GBS and CIDP, responds only to IGIV, not steroids or plasmapheresis.
- **Toxic shock syndrome.** IGIV has been administered to patients with severe staphylococcal or streptococcal toxic shock syndrome and necrotizing fasciitis, although its use is controversial. Therapy appears most likely to be beneficial when used early in the course of illness.
- **Low birth weight infants.** Results of most clinical trials have indicated that IGIV does not decrease the incidence or mortality rate of late-onset infections in infants who weigh less than 1500 g at birth. IGIV is not recommended for routine use in preterm infants to prevent early-onset or late-onset infection.
- **Other potential uses.** IGIV may be useful for sustained hypogammaglobulinemia secondary to anti-B cell therapy for autoimmunity or malignancy, severe anemia caused by parvovirus B19 infection, neonatal alloimmune thrombocytopenia that is unresponsive to other treatments, neonatal enteroviral sepsis syndrome, immune-mediated neutropenia, decompensation in myasthenia gravis, dermatomyositis, polymyositis, stiff person syndrome, transplant rejection, and severe thrombocytopenia that is unresponsive to other treatments.

TRANSMISSION OF INFECTION BY IGIV

Following an outbreak of hepatitis C virus infection associated with IGIV in the United States in 1993, changes in the preparation of IGIV, including additional viral clearance steps (such as solvent/detergent exposure, pH 4 incubation, trace enzyme exposure, nanofiltration, and heat treatment), have been instituted to prevent transmission of hepatitis C virus and other enveloped viruses, nonenveloped viruses, and prions via immune globulin (IG) preparations. Most manufacturers use 3 or 4 different pathogen removal/inactivation procedures. All products currently available in the United States are believed to be free of known pathogens,

¹ Neunert C, Terrell DR, Arnold DM, et al. American Society of Hematology 2019 guidelines for immune thrombocytopenia. *Blood Adv.* 2019;3(23):3829-3866

and the risk of transmission of infection with IGIV administration is extremely low. Transmission of HIV by any IGIV product licensed in the United States has never been reported.

ADVERSE REACTIONS TO IGIV

INFUSION REACTIONS. Reactions such as fever, headache, myalgia, chills, nausea, and vomiting often are related to the rate of IGIV infusion and may occur in as many as 25% of patients. These systemic adverse events usually are mild to moderate and self-limited (Table 1.13). There have been numerous documented cutaneous reactions to IGIV, including urticaria, eczematous or lichenoid eruptions, petechiae, erythroderma, nonspecific macular or maculopapular rashes, and pruritus. Serum sickness reactions with arthritis have also been reported. The cause of most acute reactions is uncertain. Product-to-product variations in adverse effects occur among individual patients, but it is not possible at this time to predict the reactogenicity of one product relative to others.

SERIOUS ADVERSE REACTIONS. Acute, severe reactions including hypersensitivity and anaphylactoid reactions occur infrequently and are marked by flushing, changes in blood pressure, tachycardia, and shock. Anaphylactic reactions induced by anti-IgA are very rare and only occur in some patients with selective IgA deficiency (ie, total absence of circulating IgA, IgA <7 mg/dL, with normal anti-protein antibody forming ability) who have been previously sensitized to IgA, rarely in patients with common variable immunodeficiency who develop IgE antibodies to IgA, and in a small number of patients with primary humoral immunodeficiency. Infusion of licensed IGIV

Table 1.13. Managing IGIV Reactions^a

Timing	Symptoms	Management
During infusion	Anaphylactic/ anaphylactoid	Stop the infusion. Administer epinephrine and fluid support, diphenhydramine, and glucocorticoid.
	Headache, fever, chills, myalgias, cough, mild hypotension	Slow the infusion until symptoms resolve. Administer diphenhydramine, NSAID; consider glucocorticoid. When symptoms resolve, the infusion rate may be increased. Pretreatment with an NSAID, antihistamine, or glucocorticoid or a combination may lessen or prevent a reaction.
After infusion	Headache	Administer NSAID, triptan, glucocorticoid. Consider additional hydration with normal saline before/after infusion, using an alternative product or changing to IGSC if there are repeated reactions.
	Myalgia/malaise	Administer NSAID, glucocorticoid. Consider an alternative product or change to IGSC if there are repeated reactions.

NSAID indicates nonsteroidal anti-inflammatory drug.
^aThere are no studies of the management of IGIV adverse effects, only expert opinion.

products with a low concentration of IgA may reduce the likelihood of further reactions but rarely is needed. Because of the extreme rarity of these reactions, screening for anti-IgA antibodies is not recommended.

Other potentially life-threatening adverse reactions include thrombosis, isoimmune hemolysis, renal insufficiency and failure, aseptic meningitis, noncardiogenic pulmonary edema, and transfusion-related acute lung injury (TRALI). Products are screened for antibody to A and B blood group antigens (hemolysis risk) and coagulation factor 11 (FXIa) contamination (thrombosis risk). Although products now are tested for presence of thrombogenic substances, occasional events still may occur, particularly in patients with underlying thrombosis risk factors. Renal failure is rare and occurs mainly in patients with preexisting renal dysfunction and diabetes mellitus. It has been mostly, but not exclusively, associated with products containing sucrose excipient. Acute renal failure also may occur secondary to acute hemolysis mediated by isoagglutinins.

Hemolytic events are observed mainly in patients with A, B, or AB blood types receiving high doses of IGIV (approximately 80% of patients received ≥ 1.5 g/kg). Patients receiving high doses of IGIV should be monitored for hemolysis, which can be acute or can evolve over 5 to 10 days. Complications of severe hemolysis include need for transfusion, renal failure, and rarely, disseminated intravascular coagulation. If transfusion is needed, type O blood cells are recommended.

Aseptic meningitis syndrome beginning several hours to days following IGIV treatment is rare and may be associated with severe headache, nuchal rigidity, fever, nausea, and vomiting. Pleocytosis frequently is present in the cerebrospinal fluid. Aseptic meningitis is more common with high-dose IGIV (ie, 2 g/kg) and in those with a history of migraines.

Reactions are more likely to occur during the first infusion, when infusion rates are fast, if there was a long interval since previous infusion, when patients are switched to a new product, and in the setting of active infection. Risk factors for these adverse reactions include hypertension, coronary artery disease, diabetes mellitus, history of thrombosis, other thrombotic risk factors, oral contraception use, prior renal compromise, and underlying hyperviscosity. The risk of some reactions can be mitigated by limiting the dose and infusion rate or by subcutaneous administration using IGSC (see Immune Globulin Subcutaneous, p 82). The infusion rate and type of adverse events are factors that should be considered when deciding on a route of IG administration.

PRECAUTIONS FOR THE USE OF IGIV

- Patients receiving IGIV should be adequately hydrated before and during the infusion to reduce the risk of renal dysfunction, which can occur in volume depleted patients.
- Caution should be used when administering IGIV to a patient with a history of adverse reactions to IG.
- Because acute anaphylactic or anaphylactoid reactions to IGIV can occur (see Adverse Reactions to IGIV, p 80), experienced personnel, medications, and equipment to manage anaphylaxis should be immediately available. If an anaphylactic or anaphylactoid reaction occurs, the risk versus benefit of further infusions should be evaluated. If IG therapy is continued, IGSC or enzyme-facilitated subcutaneous infusion (see Immune Globulin Subcutaneous, p 82) is recommended because of

the decreased incidence of systemic adverse events compared with IGIV. Whichever modality of administration is used, the product that elicited the reaction should not be used again.

- As practitioners have gained experience with IGSC (see Immune Globulin Subcutaneous, p 82), many experts recommend a change to subcutaneous administration instead of manipulating methods of IV infusion or administering premedications to patients who have had reactions to IGIV.
- Most of the infusion-related adverse events associated with IGIV are associated with the rate of infusion. The initial infusion rate for most products is 4 mg/kg/min with a maximum infusion rate of 8 mg/kg/min, although some patients can tolerate up to 12 mg/kg/min. Reducing either the rate of infusion or the IGIV dose often can alleviate mild to moderate infusion-related nonallergic adverse reactions (excluding life-threatening subacute adverse events). Patients sensitive to one product often tolerate alternative products. Patients who experience aseptic meningitis with IGIV often tolerate IGSC. Although there are no studies to support the practice, most experts pretreat patients who have experienced significant reactions with a nonsteroidal anti-inflammatory agent such as ibuprofen or aspirin, acetaminophen, antihistamines, or a glucocorticoid to modify or relieve symptoms. Clinicians should balance the benefits of routine, long-term glucocorticoid premedication with the known accumulating risks of ongoing exposure. Significant adverse effects of IGIV administration should prompt consultation with an immunologist or other specialist experienced in managing this problem.
- Seriously ill patients with compromised cardiac function who are receiving large volumes of IGIV may be at increased risk of vasomotor or cardiac complications manifested as elevated blood pressure, cardiac failure, or both. In this setting, a low-sodium, high-IgG concentration product should be used if available. In hospitalized patients, these and other IGIV adverse event risks can be mitigated by using very slow infusion rates (approximately 30 mL/hour of a 10% IGIV product).

Immune Globulin Subcutaneous (IGSC)

Subcutaneous (SC) administration of immune globulin (IG) using manual syringe push or mechanical or battery-driven pumps has been shown to be safe and effective immune globulin prophylaxis in the treatment of adults and children with primary immunodeficiencies. Because the SC delivery method does not require intravenous or implanted venous access devices, most parents or patients can be taught to infuse immune globulin subcutaneous (IGSC) at home. Compared with immune globulin intravenous (IGIV), IGSC uses smaller doses administered more frequently (ie, daily to biweekly), providing a slow release of IG into systemic circulation. This leads to a more consistent steady state IgG concentration. When transitioning patients from IGIV to IGSC, the majority of clinicians use 1:1 dosing and monitor serum immunoglobulin (Ig) G concentrations and frequency of clinical infections to adjust the IGSC dose. Immunoglobulin replacement therapy doses are generally started around 400 to 600 mg/kg/month. Patients with chronic lung disease or bronchiectasis may benefit from higher doses (750–800 mg/kg/month).

Both mild and severe systemic reactions are substantially less frequent with IGSC than with IGIV therapy, and premedication is rarely required for IGSC. The most common adverse effects of IGSC are infusion-site reactions, including local swelling,

Table 1.14. Comparison of Routes for Immune Globulin Administration

Attribute	IGIV	Conventional IGSC	IGHY
Infusion frequency	Typically every 3–4 weeks	Most often daily to every 2 weeks	Every 2–4 weeks
Administration requirements	IV access, usually by a health care provider	No IV access, self-administered	No IV access, self-administered or by a health care provider
Sites/month	1	4–30	1–2
Systemic adverse events	Higher than with IGSC	Lower than with either IGIV or IGHY	Lower than with IGIV
Local adverse events	Infrequent	Common	Similar to conventional IGSC

IGIV indicates immune globulin intravenous; IGHY recombinant human hyaluronidase plus IGSC; IGSC, immune globulin subcutaneous; IV, intravenous.

redness, itching, soreness, induration, and local heat. These most often occur during or soon after completion of infusion and generally resolve over 1 to 2 days. Such reactions occur more frequently during the first months of treatment. Many local site reactions are associated with infusion needle length. Selection of 6-mm, 9-mm, or 12-mm needles is based on an individual's subcutaneous tissue composition. The most common systemic reaction is headache. Systemic reactions should be treated as discussed for IGIV (p 80). Infusing daily to several times a week decreases or eliminates systemic adverse effects in most patients.

Factors involved in selection of IGSC versus IGIV are listed in Table 1.14. Several products, with concentrations of 10%, 16.5%, and up to 20%, are licensed in the United States for conventional SC use (www.fda.gov/vaccines-blood-biologics/approved-blood-products/immune-globulins). IGSC is well tolerated in patients with thrombocytopenia and those receiving anticoagulant therapy. High-dose IGSC has been shown to be effective for immunomodulation in autoimmune neurologic conditions, and a 20% IGSC product has been licensed for the treatment of chronic inflammatory demyelinated polyneuropathy. Because there are limited data on the efficacy of IGSC for conditions requiring high-dose IG, only IGIV should be used for the treatment of Kawasaki disease or multisystem inflammatory syndrome in children (MIS-C).

Because the subcutaneous space limits infusion volume, multiple infusion sites and frequent infusions are needed to achieve an adequate steady state IgG level using conventional IGSC. Dosing volumes/site are product-dependent. The prescribing information for each product should be consulted to determine the starting volumes for new patients and the maximum volume/site that can be given. Pretreatment with recombinant human hyaluronidase (a spreading factor) permits the subcutaneous infusion of larger volumes (up to 600 mL) of IG at a single site, although many clinicians prefer to limit infusions to 300 mL/site. Products have been developed that include both the hyaluronidase for pre-infusion and the IGSC and are known as IGHY. The efficacy of IGHY products is comparable with that of standard IGSC and of IGIV. The infusion frequency and number

of needlesticks required for IGHY are similar to those for IGIV, and IGHY has less than half the frequency of systemic adverse events compared with IGIV. The peak serum IgG concentration achieved following IGHY administration occurs several days following infusion and is far lower than that of IGIV. Unlike the consistent steady-state serum concentration achieved following conventional IGSC, trough concentrations associated with IGHY are comparable to those following administration of IGIV.

TRANSMISSION OF INFECTION BY IGSC

The transmission of infections by IGSC products is considered to be the same as with IGIV and is exceedingly low.

PRECAUTIONS FOR THE USE OF IGSC AND IGHY

- Caution should be used when administering IGSC to a patient with a history of adverse reactions to any form of immunoglobulin replacement. In this circumstance, most experts recommend use of an alternative product. Some suggest administering a fraction (1/30) of the monthly dose daily.
- Immediate, systemic reactions to IGSC are substantially less common and usually less severe than those with IGIV (see Adverse Reactions to IGIV, p 80). Epinephrine should be immediately available (ie, epinephrine autoinjector) where the IGSC is administered. Health care professionals administering IGSC should have training in the management of emergencies (particularly anaphylactic shock). Parents and patients should be trained in the use of epinephrine autoinjector in case of anaphylaxis outside of a medical setting.
- Life-threatening, subacute systemic adverse reactions (eg, thrombosis, hemolysis, renal injury) appear to be less common following IGSC than with IGIV but may occur (see Adverse Reactions to IGIV, p 80).

Treatment of Anaphylactic Reactions

Health care professionals administering vaccines or other biologic products must be able to recognize and treat systemic anaphylaxis. Medications, equipment, and competent staff necessary to maintain the patency of the airway and to manage cardiovascular collapse must be available.^{1,2} In the event of a severe reaction requiring interventions beyond the capacity of the initial treatment team, emergency medical services should be requested to initiate additional emergency care prior to and during transport to a site for higher level of care.

The emergency treatment of anaphylactic reactions is epinephrine administered intramuscularly in the anterolateral thigh. Delayed administration of epinephrine is believed to be the major contributor to fatalities. Mild symptoms such as skin reactions alone (eg, pruritus, erythema, localized urticaria, or angioedema) may be the first signs of an anaphylactic reaction but in isolation are not dangerous and can be treated with antihistamines. However, using clinical judgment, an injection of epinephrine may be administered, depending on the clinical situation (Table 1.15). Epinephrine should be

² Sicherer SH; American Academy of Pediatrics, Section on Allergy and Immunology. Epinephrine for first-aid management of anaphylaxis. *Pediatrics*. 2017;139(3):e20164006

Table 1.15. Epinephrine in the Treatment of Anaphylaxis^a

Epinephrine autoinjector (0.1 mg per dose for children weighing <10 kg; 0.15 mg per dose for children weighing 10 through 25 kg; or 0.3 mg per dose for children weighing 26 kg through 50 kg), IM (anterolateral thigh), repeated every as often as every 5 min if necessary

OR

Epinephrine 1 mg/mL (1:1000) (aqueous): IM (anterolateral thigh), 0.01 mg/kg (0.01 mL/kg) per dose, up to 0.5 mg (0.5 mL), repeated every as often as every 5 min if necessary

A continuous infusion should be started if inadequate response to repeated intramuscular doses. 1 mg (1 mL) of 1 mg/mL (1:1000) dilution of epinephrine added to 250 mL of 5% dextrose in water, resulting in a concentration of 4 µg/mL, is infused initially at a rate of 0.1 µg/kg per minute and increased gradually to 1 µg/kg per minute to maintain blood pressure.

^aIn addition to epinephrine, maintenance of the airway and administration of oxygen are critical.

injected promptly for anaphylaxis, which is likely (although not exclusively) occurring when 1 of the following 3 criteria are fulfilled:

1. Acute onset of an illness (minutes to hours) with involvement of the skin, mucosal tissue, or both with either respiratory involvement or reduced blood pressure and/or associated symptoms of end-organ dysfunction; or
2. Two or more of the following that occur rapidly after exposure to a likely allergen for the patient, including (i) involvement of skin-mucosal tissue, (ii) respiratory involvement, (iii) reduced blood pressure or associated symptoms, or (iv) gastrointestinal symptoms; or
3. Reduced blood pressure as a result of exposure to a known allergen trigger.¹

If a patient is known to have had a previous severe allergic reaction to the biologic product/serum, onset of skin, cardiovascular, or respiratory symptoms alone may warrant treatment with epinephrine. Epinephrine should be administered via the intramuscular (IM) route, because higher in vivo concentrations are achieved more rapidly compared with subcutaneous administration. Use of readily available commercial epinephrine autoinjectors (available in 3 dosages based on patient weight: 0.1, 0.15, and 0.3 mg/dose; see Table 1.15) are preferred and have been shown to reduce time to drug administration and dosing errors.

Aqueous epinephrine (1 mg/mL [1:1000], 0.01 mg/kg; maximum dose, 0.5 mg) or autoinjector can be administered as often as every 5 minutes, as necessary, to control symptoms and maintain blood pressure. Repeat doses of epinephrine are required in up to 35% of cases of anaphylaxis cases. Most patients being treated for anaphylaxis should be placed in a supine position. Patients having difficulty breathing may be asked to sit up, and patients who are vomiting may be asked to lie on their side. When the patient's condition improves and remains stable, an oral antihistamine can be given for an additional 24 to 48 hours but is not always necessary. Corticosteroids have no proven role in the treatment of acute anaphylaxis.

¹ Shaker MS, Wallace DV, Golden DBK, et al. Anaphylaxis—a 2020 practice parameter update, systematic review, and Grading of Recommendations, Assessment, Development and Evaluation (GRADE) analysis. *J Allergy Clin Immunol*. 2020;145(4):1082-1123

Maintenance of the airway and administration of oxygen should be instituted promptly. Severe or potentially life-threatening systemic anaphylaxis involving severe bronchospasm, laryngeal edema, other airway compromise, shock, and cardiovascular collapse necessitates additional therapy. Rapid intravenous (IV) bolus infusion of isotonic fluids adequate to maintain blood pressure may be required to compensate for the loss of circulating intravascular volume.

Epinephrine is administered intramuscularly in the anterolateral thigh immediately while IV access is being established. IV epinephrine may be indicated for continuous infusion but should be used with extreme caution and only after failure of symptoms to respond to multiple intramuscular doses (see Table 1.15). Administration of epinephrine intravenously can lead to lethal arrhythmia, and cardiac monitoring is recommended. A slow, continuous, low-dose epinephrine infusion is preferable to repeated bolus administration, because the dose can be titrated to the desired effect, and accidental administration of large boluses of epinephrine can be avoided.

Nebulized albuterol is indicated for bronchospasm. In some cases, the use of other inotropic agents, such as dopamine, may be necessary for blood pressure support. H₁ antihistamines may be used as adjunctive therapy. These and other secondary drugs used for anaphylaxis are detailed in Table 1.16.

All patients showing signs and symptoms of systemic anaphylaxis, regardless of severity, should be observed in an appropriate facility, even after remission of immediate symptoms. Anaphylactic reactions are monophasic in 90% of cases, but can be biphasic or persistent over 24 to 36 hours despite early and aggressive management. Although a specific period of observation has not been established, a reasonable period of observation would be 1 hour for a mild episode in a person with no risk factors for biphasic anaphylaxis (eg, severe initial reaction, drug or unknown trigger) and as long as 24 hours for a severe episode.

Table 1.16. Dosages of Commonly Used Secondary Drugs in the Treatment of Anaphylaxis

Drug	Dose
H1 receptor-blocking agents (antihistamines)	
Diphenhydramine	Oral, IM, IV: 1 mg/kg, every 4–6 h (40 mg, maximum single dose <12 y; 50 mg, maximum single dose for 12 y and older)
Cetirizine	Oral: 2.5 mg, 6–23 mo; 5 mg, 2–5 y; 10 mg, ≥6 y (single dose daily)
B₂-agonist	
Albuterol	Nebulizer solution: 0.5% (5 mg/mL), 0.05–0.15 mg/kg per dose in 2–3 mL isotonic sodium chloride solution, maximum 5 mg/dose every 20 min over a 1-h to 2-h period, or 0.5 mg/kg/h by continuous nebulization (15 mg/h, maximum dose)
Vasopressor	
Dopamine	5–20 µg/kg/min, IV drip

IM indicates intramuscular; IV, intravenous.

Anaphylaxis occurring in people who are taking beta-adrenergic–blocking agents or angiotensin-converting enzyme inhibitors can be more profound and significantly less responsive to epinephrine and other beta-adrenergic agonist drugs. More aggressive therapy with epinephrine may override receptor blockade in some patients. In a patient who is taking a beta-blocker who has not responded to at least 2 doses of intramuscular epinephrine, glucagon can be administered via the IM or IV route at a dose of 0.5 mg for children weighing less than 25 kg and 1 mg for children weighing more than 25 kg.

At the time of discharge, all patients should be provided with an epinephrine auto-injector, a written emergency plan to treat future reactions, and follow-up appointment with an allergist. The patient and/or parent(s) should be trained on the use of the specific autoinjector provided.

..... IMMUNIZATION IN SPECIAL CLINICAL CIRCUMSTANCES

Immunization in Preterm and Low Birth Weight Infants

Infants born preterm (at less than 37 weeks of gestation) or low birth weight (less than 2500 g) who are clinically stable should, with few exceptions, receive all routinely recommended childhood vaccines at the same chronologic age as term and normal birth weight infants. Although studies have shown decreased immune responses to several vaccines administered to neonates with very low birth weight (less than 1500 g) and neonates of very early gestational age (less than 29 weeks of gestation), most preterm infants, including infants who receive corticosteroids for bronchopulmonary dysplasia, produce sufficient vaccine-induced immunity to prevent disease. Vaccine dosages administered to term infants should not be reduced or divided when administered to preterm or low birth weight infants.

Preterm and low birth weight infants tolerate most childhood vaccines as well as term infants do. Some studies show that cardiorespiratory events may increase in extremely (less than 1000 g) and very (less than 1500 g) low birth weight infants who receive selected vaccines. Apnea within 24 hours prior to immunization, younger age, or weight less than 2000 g at the time of immunization and 12-hour Score for Neonatal Acute Physiology II¹ greater than 10 have been associated with development of postimmunization apnea, and it may be prudent to monitor infants with these characteristics for 48 hours after immunization if they are still in the hospital.

Medically stable preterm infants who remain in the hospital at 2 months of chronologic age should receive all inactivated vaccines recommended at that age (see Recommended Child and Adolescent Immunization Schedule for Ages 18 Years or Younger [http://redbook.solutions.aap.org/SS/Immunization_Schedules.aspx]). A medically stable infant is defined as one who does not require ongoing management for serious infection; metabolic disease; or acute renal, cardiovascular, neurologic, or respiratory tract illness and who demonstrates a clinical course of sustained recovery and a pattern of steady growth. All immunizations required at 2 months of

¹ Zupancic JAF, Richardson DK, Horbar JD, Carpenter JH, Lee SK, Escobar GJ. Vermont Oxford Network SNAP Pilot Project Participants. Revalidation of the Score for Neonatal Acute Physiology in the Vermont Oxford Network. *Pediatrics*. 2007;119(1):e156-e163

age can be administered simultaneously to preterm or low birth weight infants, with the possible exception of live oral rotavirus vaccine in hospitalized infants (see below and Rotavirus, p 730). The number of vaccine injections at 2 months of age can be minimized by using combination vaccines. When limited injection sites preclude simultaneous administration, vaccines recommended at 2 months of age may be administered at different times with any interval between doses of different inactivated parenteral vaccines. The choice of needle lengths used for intramuscular (IM) vaccine administration is determined by available muscle mass of the preterm or low birth weight infant (see Table 1.8, p 56).

Hepatitis B vaccine administered to preterm or low birth weight infants weighing 2000 g or more at birth produces an immune response comparable to that in term infants. Medically stable infants weighing less than 2000 g demonstrate a lower hepatitis B antibody response. Hepatitis B vaccine schedules for infants weighing <2000 g and infants weighing ≥ 2000 g whose birthing parent's hepatitis B surface antigen (HBsAg) status is positive, negative, or unknown are provided in Hepatitis B, Special Considerations, including Table 3.22 (p 451). Only monovalent hepatitis B vaccine should be used for preterm or term infants younger than 6 weeks. Administration of a total of 4 doses of hepatitis B vaccine is permitted when a combination vaccine containing hepatitis B vaccine is administered after the birth dose.

Because all preterm infants are considered at increased risk of complications of influenza, 2 doses of inactivated influenza vaccine, administered 1 month apart, should be offered for all preterm infants beginning at 6 months of chronologic age (see Influenza, p 511). Influenza vaccine should be given to all pregnant people during pregnancy (may be administered at any time during pregnancy) to protect the pregnant person and to provide passive protection of young infants. Because preterm infants younger than 6 months and infants of any age with chronic complications of preterm birth are extremely vulnerable to influenza virus infection, it is very important that household contacts, child care providers, and hospital nursery personnel caring for preterm infants receive influenza vaccine annually (see Influenza, p 511).

Preterm infants younger than 6 months, who are too young to have completed the primary immunization series, are at increased risk of pertussis infection and pertussis-related complications. Tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis (Tdap) vaccine should be administered to all pregnant people (ideally between weeks 27 and 36 of gestation, to maximize passive antibody transfer to the infant) during every pregnancy. Tdap should be administered immediately postpartum for birthing parents who were not immunized during pregnancy. Health care personnel caring for pregnant people and infants, as well as household contacts and child care providers of all infants who have not previously received Tdap, also should be vaccinated with Tdap (see Pertussis, p 656). Preterm infants, infants born with certain congenital heart defects, and certain infants with chronic lung disease of prematurity or hemodynamically significant heart disease may benefit from immunoprophylaxis with a monoclonal antibody product (respiratory syncytial virus monoclonal antibody) during respiratory syncytial virus season (see Respiratory Syncytial Virus, p 713). Routine childhood immunizations should be administered on schedule in infants receiving palivizumab or nirsevimab.

Rotavirus vaccine virus is shed by some infants in the weeks after vaccination. There are limited published studies on the transmission of vaccine virus in hospital settings, including neonatal intensive care units, that have not documented nosocomial

transmission. Individual institutions may consider administering rotavirus vaccine at the recommended chronologic age to otherwise eligible infants during hospitalization, including in the neonatal intensive care unit. Otherwise, the first dose of rotavirus vaccine should be administered at the time of discharge to eligible infants.

Preterm or very low birth weight infants are at increased risk for respiratory illness from SARS-CoV-2 infection (see Coronavirus Disease-2019 [COVID-19], p 324). Extra efforts should be made to provide COVID-19 vaccines to all caregivers of preterm and very low birth weight infants to decrease the risk to infants and to the infants themselves beginning at 6 months of age.

Immunization in Pregnancy¹

Immunization is an essential component of care in pregnancy. Several vaccine-preventable diseases, such as influenza and COVID-19, are associated with increased morbidity and mortality during pregnancy, and others, like pertussis, can affect newborn infants who are too young to begin active vaccination until months after birth. The benefits of vaccinating the pregnant individual and providing protection for the infant through transplacentally acquired antibodies have led to recommendations for select vaccinations during pregnancy.² Vaccines routinely recommended during pregnancy are safe for the pregnant person and the fetus. Obstetric care providers play a critical role in reviewing pregnant patients' vaccination history and ensuring that they receive recommended vaccines. Pediatric care providers are also frequently asked about vaccines during pregnancy by expectant parents and play an important role in reinforcing the importance of vaccines. This chapter covers active immunization during pregnancy. Immunity passively transferred to the infant via human milk is discussed in the chapter Breastfeeding and Human Milk (p 135).

Four vaccines are specifically recommended for routine administration during pregnancy—tetanus and diphtheria toxoids and acellular pertussis vaccine (Tdap), non-live influenza vaccine (IIV), COVID-19 vaccine, and respiratory syncytial virus (RSV) vaccine.

- **Tdap With Each Pregnancy.** Tdap administered during the third trimester of pregnancy reduces pertussis infection in infants. The Centers for Disease Control and Prevention (CDC), the American Academy of Pediatrics (AAP), the American College of Obstetricians and Gynecologists (ACOG), and the American Academy of Family Physicians (AAFP) recommend administration of Tdap during every pregnancy to ensure that infants have high concentrations of pertussis-specific antibodies at the time of birth. The recommended timing for administration of Tdap is as early as possible during the interval between 27 and 36 weeks' gestation, to maximize the pregnant individual's antibody response and passive antibody transfer to the infant. Tdap may be safely administered at any time during pregnancy if needed for wound management, pertussis outbreaks, or other extenuating circumstances. If Tdap was not administered during the current pregnancy, previously unimmunized individuals should be receive Tdap immediately postpartum (see Pertussis, p 656). Tdap, COVID-19, and IIV can be administered together safely, and Tdap can be safely administered after a recent dose of Td regardless of interval.

¹ See adult immunization schedule available at www.cdc.gov/vaccines/schedules/hcp/adult.html.

² www.cdc.gov/vaccines/pregnancy/index.html

- **Influenza Vaccine Each Influenza Season.** Pregnancy increases risks of severe influenza infection even among those who do not have underlying medical conditions. Influenza vaccination is recommended for everyone 6 months of age or older who does not have a contraindication, and pregnancy is a specific indication for vaccination with IIV or recombinant influenza vaccine (RIV). In addition to protecting the pregnant person, influenza vaccination in pregnancy also protects infants younger than 6 months of age who are too young to be vaccinated with IIV. IIV or RIV may be administered at any time during pregnancy (see Influenza, p 511). Pregnancy is a contraindication for live attenuated influenza vaccine (LAIV).
- **COVID-19 vaccine.** The CDC, ACOG, and Society for Maternal-Fetal Medicine recommend COVID-19 vaccines (primary series and boosters) for persons who are pregnant, breastfeeding, trying to get pregnant now, or might become pregnant in the future. There is an increased risk of severe COVID-19 infection and death during pregnancy as well as an increased risk for adverse pregnancy and neonatal outcomes. Accumulating data have supported the safety and effectiveness of COVID-19 vaccination in persons who are pregnant. COVID-19 vaccination can be administered in any trimester. The latest guidance on the use of COVID-19 vaccines currently approved or authorized in the United States is available at www.cdc.gov/vaccines/covid-19/clinical-considerations/interim-considerations-us.html.
- **RSV vaccine.** On December 21, 2022, Pfizer Inc submitted a biologics license application (BLA) to the US Food and Drug Administration (FDA) to support licensure of its RSVpreF vaccine (Abrysvo) in pregnant people for prevention of RSV in their infants. Vaccine efficacy for prevention of severe RSV-associated lower respiratory tract disease within 90 days after birth was 81.8% (99.5% confidence interval [CI]: 40.6, 96.3), and within 180 days after birth was 69.4% (97.6% CI: 44.3, 84.1). Safety assessments for both the pregnant and infant populations were similar for vaccine and placebo recipients. A slightly higher percentage of preterm births occurred in the vaccine recipients compared with placebo recipients (5.6% [95% CI: 4.9%, 6.4%] versus 4.7% [95% CI: 4.1%, 5.5%]), but this did not reach statistical significance. On August 21, 2023, the FDA approved RSVpreF vaccine for use in pregnant people as a single dose to be given at 32 through 36 weeks' gestation, and in September 2023, the CDC recommended its use for pregnant people during 32 through 36 weeks' gestation, using seasonal administration, to prevent RSV lower respiratory tract infection in infants.

LIVE ATTENUATED VACCINES

Pregnancy is generally a contraindication for most live-virus vaccines, given the theoretical risks to the developing fetus. The background rate of major and minor structural fetal malformations in otherwise uncomplicated pregnancies, commonly accepted as 3% to 5%, needs to be considered when discussing concerns regarding a birth defect diagnosed before or after birth that could be inappropriately attributed to a vaccine. This consideration is particularly important when vaccination with a live or live-attenuated vaccine has occurred after completion of embryogenesis in the first trimester. Inadvertent administration of live-virus vaccines in early pregnancy has not been shown to result in specific embryopathy and is not an indication to consider pregnancy termination. However, pregnancy should be avoided for 4 weeks after receiving a live-virus vaccine because of the theoretical risk to the fetus.

- **Measles, Mumps, and Rubella Vaccine.** Measles, mumps, and rubella (MMR), varicella (VAR), and measles, mumps, rubella, and varicella (MMRV) vaccines are contraindicated for pregnant people. Efforts should be made to immunize individuals without evidence of immunity against these viruses before they become pregnant or in the immediate postpartum period. Following receipt of MMR, individuals should avoid pregnancy for at least 4 weeks. No case of embryopathy caused by live rubella vaccine has been reported; however, a rare theoretical risk of embryopathy from inadvertent administration cannot be excluded. Because pregnancy might result in a higher risk for severe measles disease and complications, immune globulin intravenous (IGIV) should be administered to pregnant people who do not have evidence of measles immunity and have been exposed to measles (see Measles, p 570, and Table 3.33, p 576). IGIV does not prevent rubella or mumps infection after exposure and is not recommended for that purpose.
- **Varicella Vaccine.** Like MMR, varicella-containing vaccines (VAR, MMRV) are live vaccines and are contraindicated in pregnancy. This contraindication is based on a theoretical risk for congenital varicella syndrome, although there is no association between inadvertent administration of VAR or MMRV and adverse pregnancy outcome based on available safety surveillance. A pregnant person living in a household is not a contraindication for another household member to be vaccinated against varicella. Pregnant individuals who do not have evidence of immunity to varicella are at risk for severe disease and related complications. Varicella-zoster immune globulin is recommended for pregnant people without evidence of immunity who have been exposed and should ideally be administered within 96 hours of exposure for greatest effectiveness but can be administered up to 10 days after exposure (see Varicella-Zoster Virus Infections, p 938, and Fig 3.22, p 945). The purpose of using varicella-zoster immune globulin during pregnancy is to prevent complications in the pregnant person rather than to protect the fetus/infant. If varicella-zoster immune globulin is not available, some experts suggest use of IGIV. Published data on the benefit of acyclovir as postexposure prophylaxis among immunocompromised individuals are limited, although the use of acyclovir during pregnancy is not contraindicated if clinically indicated.
- **Live Attenuated Influenza Vaccine (LAIV).** Although influenza vaccination is recommended during pregnancy, LAIV, as a live vaccine, is contraindicated even though there have been no demonstrated harms because of inadvertent LAIV administration during pregnancy. Any licensed non-live influenza vaccine (IIV, RIV) that is otherwise appropriate for age should be used instead.
- **Yellow Fever Vaccine.** Unlike most other live vaccines, the yellow fever vaccine is not contraindicated in pregnancy. It nevertheless poses a theoretical risk, and pregnancy is a precaution to yellow fever vaccine administration because of rare cases of transmission of the vaccine virus in utero, albeit without adverse effects in the infant. Whenever possible, pregnant people should defer travel to areas where yellow fever is endemic. If travel to an area with endemic disease is unavoidable and risks for yellow fever virus exposure are believed to outweigh the vaccination risks, a pregnant individual should be vaccinated. Breastfeeding also is a precaution for yellow fever vaccine administration (see Breastfeeding and Human Milk, p 135).
- **Typhoid Vaccine.** There are 2 types of typhoid vaccine currently available in the United States—a live attenuated vaccine for oral administration and a

polysaccharide vaccine for parenteral administration. No information is available on the safety of either typhoid vaccine in pregnancy. Generally, live vaccines should be avoided in pregnancy. If travel to an endemic area is unavoidable in pregnancy, inactivated typhoid vaccine may be considered.

- **Cholera Vaccine.** Pregnant people are at increased risk for poor outcomes from cholera infection. No information is available on the safety of live attenuated cholera vaccine in pregnancy. The vaccine is not absorbed from the recipient's gastrointestinal tract. Thus, administration of the vaccine to a pregnant person is not expected to result in fetal vaccine virus exposure. When considering cholera vaccination during pregnancy, for travel to areas of cholera transmission, the benefit of protection offered by the vaccine should be weighed against the risk of possible adverse events.
- **Smallpox-Mpox Vaccine.** The use of live replicating smallpox virus (vaccinia) vaccine (ACAM2000) is limited to laboratory workers who work with the virus or other orthopoxviruses that infect humans (eg, mpox) and is contraindicated in pregnant or breastfeeding people. Smallpox causes more severe disease in pregnant than nonpregnant individuals, but it is unknown whether mpox is more severe during pregnancy. The live, nonreplicating smallpox/mpox vaccine (JYNNEOS) can be offered to people who are pregnant or breastfeeding who are otherwise eligible, although data on safety are limited.

NON-LIVE VACCINES

- **Pneumococcal Vaccines.** Generally, pneumococcal vaccines should be deferred during pregnancy; however, pregnant people with underlying conditions that warrant pneumococcal immunization may be vaccinated when the benefit of the vaccination is considered to outweigh any potential risks.
- **Meningococcal Vaccines.** Serogroups A, C, W, and Y meningococcal conjugate vaccine (MenACWY) should be administered to pregnant people if indicated. Because limited data are available for MenB vaccination during pregnancy, vaccination with MenB should be deferred unless the pregnant individual is at increased risk and, after consultation with the pregnant person's health care provider, the benefits of vaccination are considered to outweigh the potential risks.
- **Hepatitis A and Hepatitis B Vaccines.** Infection with hepatitis A virus or hepatitis B virus can result in severe disease in the pregnant person and, in the case of hepatitis B, chronic infection in the infant. If not already vaccinated with hepatitis A vaccine (HepA), the vaccine should be administered in pregnancy if the patient is at risk for hepatitis A infection during pregnancy. No adverse effect on the developing fetus has been observed after immunization with hepatitis B vaccine (HepB) during pregnancy. Pregnancy and lactation are not contraindications to HepB immunization, and if not already vaccinated with HepB, the vaccine should be administered in pregnancy. Data about safety during pregnancy are not yet available for Heplisav B or PreHevbrio; until such data are available, other HepB vaccines are recommended for immunization during pregnancy.
- **Non-live Poliovirus Vaccine.** Although data on safety of inactivated poliovirus (IPV) vaccine for a pregnant person or developing fetus are limited, no adverse effect has been found. IPV vaccine can be administered to pregnant people who never have received poliovirus vaccine, are immunized partially, or are immunized completely but require a booster dose (see Poliovirus Infections, p 682).

- **Human Papillomavirus Vaccine.** The HPV vaccine is not recommended for use during pregnancy because of limited information about safety. The health care professional should inquire about pregnancy in patients who are known to be sexually active, but a pregnancy test is not required before starting the HPV vaccination series. If a vaccine recipient becomes pregnant, subsequent doses should be postponed until the person is no longer pregnant. If a dose has been administered inadvertently during pregnancy, no intervention is needed. Data to date show no evidence of adverse effect of any HPV vaccine on outcomes of pregnancy. Health care professionals can report inadvertent administrations of 9vHPV to pregnant people by calling the vaccine manufacturer at 1-800-986-8999.
- **Rabies Vaccine.** The serious consequences of rabies dictate prompt postexposure prophylaxis and the rabies vaccine should be administered regardless of pregnancy status. Studies have shown that there is no association between rabies vaccination and increases in spontaneous abortions, preterm births, or other adverse pregnancy outcomes. If the risk of exposure to rabies during pregnancy is substantial, preexposure vaccine may be indicated.
- **Japanese Encephalitis Vaccine.** No studies in humans have assessed the safety of Japanese encephalitis virus vaccine for pregnant people. Individuals at risk for Japanese encephalitis exposure should be immunized before pregnancy, if possible. Immunization during pregnancy may be considered if travel to an area with endemic infection is unavoidable and the risk of disease outweighs the risk of adverse events in pregnancy (see Arboviruses, p 237).
- **Tick-borne Encephalitis Vaccine.** No studies in humans have assessed the safety of tick-borne encephalitis virus vaccine for pregnant people. Individuals at risk of tick-borne encephalitis exposure should be immunized before pregnancy, if possible. Immunization during pregnancy may be considered if travel to an area with endemic infection is unavoidable and the risk of disease outweighs the risk of adverse events in pregnancy (see Arboviruses, p 237).
- **Anthrax Vaccine.** Anthrax vaccine is not licensed for use in pregnant people; however, in a postevent setting that poses a high risk of exposure to aerosolized *Bacillus anthracis* spores, pregnancy is neither a precaution nor a contraindication to its use in postexposure vaccine (see Anthrax, p 232).
- **Ebola Vaccine.** Limited human data from clinical trials with Ebola vaccines have not identified vaccine-associated risks during pregnancy. The decision regarding whether to vaccinate a pregnant person should consider the risk for exposure to Ebola virus (see Hemorrhagic Fevers Caused by Filoviruses: Ebola and Marburg, p 423).

Immunization and Other Considerations in Immunocompromised Children

The safety and effectiveness of vaccines in people with immunodeficiency depends on the nature and extent of their immunosuppression. Even though these individuals represent a heterogeneous population, their immunodeficiency can be classified into primary and secondary disorders. Primary disorders of the immune system generally are inherited and can involve any part of the immune defenses. Secondary disorders of the immune system are acquired, including conditions related to infection, malignancies, and chronic diseases and their treatments (see Table 1.17). The Infectious Diseases Society of

Table 1.17. Immunization of Children and Adolescents With Primary and Secondary Immune Deficiencies

Category	Example of Specific Immunodeficiency	Vaccine Contraindications ^a	Comments
Primary			
B lymphocyte (humoral)	Severe antibody deficiencies (eg, X-linked agammaglobulinemia and common variable immunodeficiency)	OPV, ^b BCG, smallpox vaccine, LAIV, YF vaccine, dengue vaccine, and live-bacteria vaccines ^c ; no data for rotavirus vaccines	Effectiveness of any vaccine is uncertain if dependent only on humoral response (eg, PPSV23). Replacement IG therapy interferes with response to live vaccines MMR and VAR. Annual IIV is the only vaccine administered routinely to patients with profound hypogammaglobulinemia receiving IG replacement therapy. All non-live vaccines are safe to administer as part of immune response assessment prior to instituting IG therapy.
	Less severe antibody deficiencies (eg, selective IgA deficiency and IgG subclass deficiencies)	OPV, ^b BCG, dengue vaccine, YF vaccine	All non-live and, with the exception of dengue vaccine, all live vaccines ^d on the standard annual schedule are safe, likely are effective (although responses may be attenuated), and should be administered. ^e PPSV23 should be administered beginning at 2 years of age. ^f
T lymphocyte (cell-mediated and humoral)	Complete defects (eg, severe combined immunodeficiency, complete DiGeorge syndrome)	All live-bacteria and live-virus vaccines (including rotavirus vaccine) ^{e,d,g}	All non-live vaccines probably are ineffective. Annual IIV is the only vaccine administered routinely to patients receiving IG replacement therapy, if there is some residual antibody-producing capacity.

Table 1.17. Immunization of Children and Adolescents With Primary and Secondary Immune Deficiencies, continued

Category	Example of Specific Immunodeficiency	Vaccine Contraindications ^a	Comments
T lymphocyte (cell-mediated and humoral)	Partial defects (eg, most patients with DiGeorge syndrome, hyper-IgM syndrome, Wiskott-Aldrich syndrome, ataxia telangiectasia)	All live-bacteria and live-virus vaccines ^{c,d,g}	All non-live vaccines on the standard annual schedule are safe, may be effective depending on the degree of the immune defect, and should be administered. ^e Those with ≥ 500 CD3+ T lymphocytes/mm ³ , ≥ 200 CD8+ T lymphocytes/mm ³ , and normal mitogen response could be considered to receive MMR and VAR vaccine (but not MMRV). PPSV23 should be administered beginning at 2 years of age. ^f Consider MenACWY-CRM series beginning in infancy ^h and the MenB series beginning at 10 years of age depending on splenic dysfunction.
	Interferon-alpha; interferon-gamma; interleukin 12 axis deficiencies; STAT1 deficiencies	All live-bacteria vaccines ^e and YF vaccine; other live-virus vaccines ^d if severely lymphopenic	All non-live vaccines on the standard annual schedule are safe, likely are effective, and should be administered. ^e Based on experience in HIV-infected children with the measles vaccine, MMR and VAR (but not MMRV) probably are safe and may be preferable to the risk of disease. Non-live typhoid vaccine (Typhoid Vi) should be used for people living in areas with endemic typhoid.
Complement	Persistent complement component, properdin, mannan-binding lectin, or factor B deficiency; secondary deficiency because receiving eculizumab	None	All non-live and live vaccines on the standard annual schedule are safe, likely are effective, and should be administered. ^e PPSV23 should be given beginning at 2 years of age ^f ; MenACWY-CRM series beginning in infancy ^h ; and the MenB series beginning at 10 years of age. Meningococcal vaccination may be ineffective in patients receiving eculizumab; prophylactic antimicrobial therapy such as amoxicillin or penicillin can be considered for duration of treatment and until immune competence has returned.

Category	Example of Specific Immunodeficiency	Vaccine Contraindications ^a	Comments
Phagocytic function	Chronic granulomatous disease	Live-bacteria vaccines ^e	All non-live and live-virus vaccines ^d on the standard annual schedule are safe, likely are effective, and should be administered. ^{e,i}
	Phagocytic deficiencies that are ill-defined or accompanied by defects in T-lymphocyte and natural killer cell dysfunction (such as Chediak-Higashi syndrome, leukocyte adhesion defects, and myeloperoxidase deficiency)	All live-bacteria ^e and live-virus vaccines ^d	All non-live vaccines on the standard annual schedule are safe, likely are effective, and should be administered. PPSV23 should be administered beginning at 2 years of age. ^f Consider MenACWY-CRM series beginning in infancy ^h and the MenB series beginning at 10 years of age depending on splenic dysfunction.
Secondary	HIV/AIDS	OPV, ^b smallpox vaccine, BCG, LAIV, MMRV, MMR, VAR, dengue, YF vaccine in highly immunocompromised children	All non-live vaccines on the standard annual schedule are safe, may be effective, and should be administered. ^e Rotavirus vaccine should be administered on the standard schedule. MMR and VAR are recommended for children with HIV infection who are asymptomatic or have only low-level immunocompromise. ^j PPSV23 should be administered beginning at 2 years of age. ^f MenACWY-CRM series should be administered beginning in infancy. ^h Hib is indicated for under- or unimmunized children ≥5 years of age. ^k

Table 1.17. Immunization of Children and Adolescents With Primary and Secondary Immune Deficiencies, continued

Category	Example of Specific Immunodeficiency	Vaccine Contraindications ^a	Comments
	Malignancy, transplantation, autoimmune disease, immunosuppressive or radiation therapy	All live-virus and live-bacteria vaccines, depending on immune status ^{c,d}	Refer to text for guidance. All non-live vaccines on the standard annual schedule are safe and may be effective depending on degree of immunocompromise ^e . Annual IIV is recommended unless receiving intensive chemotherapy or anti-B cell antibodies. PPSV23 should be administered beginning at 2 years of age. ^f Hib vaccine is indicated in under- or unimmunized children <5 years of age only. ^e
	Asplenia (functional, congenital anatomic, surgical)	LAIV	All non-live and live-virus vaccines on the standard annual schedule are safe, likely are effective, and should be administered. ^e PPSV23 should be administered beginning at 2 years of age ^f ; MenACWY-CRM series beginning in infancy ^h ; and the MenB series beginning at 10 years of age. Hib is indicated for under- or unimmunized children ≥5 years of age. ^k
	Chronic renal failure	None	All non-live and live-virus vaccines, except LAIV, on the standard annual immunization schedule are safe, likely are effective, and should be administered. ^e PPSV23 should be administered beginning at 2 years of age. ^f HepB is indicated if not previously immunized.
	CNS anatomic barrier defect (cochlear implant, congenital dysplasia of the inner ear, persistent CSF communication with naso-oropharynx)	LAIV	All non-live and live-virus vaccines on the standard annual immunization schedule are safe and effective and should be administered. ^e PPSV23 should be administered beginning at 2 years of age. ^f

Table 1.17. Immunization of Children and Adolescents With Primary and Secondary Immune Deficiencies, continued

Category	Example of Specific Immunodeficiency	Vaccine Contraindications ^a	Comments
AIDS indicates acquired immunodeficiency syndrome; BCG, bacille Calmette-Guérin; CNS, central nervous system; CSF, cerebrospinal fluid; HepB, hepatitis B vaccine; Hib, <i>Haemophilus influenzae</i> type b vaccine; HIV, human immunodeficiency virus; IG, immune globulin; IgA, immunoglobulin A; IgG, immunoglobulin G; IIV, non-live influenza vaccine; LAIV, live attenuated influenza vaccine; MenACWY, serogroups A, C, W, and Y meningococcal conjugate vaccine; MenACWY-CRM, MenACWY (Menveo); MenB, serogroup B meningococcal conjugate vaccine; MMR, measles, mumps, and rubella vaccine; MMRV, measles, mumps, rubella, and varicella vaccine; OPV, oral poliovirus vaccine; PPSV23, 23-valent pneumococcal polysaccharide vaccine; STAT1, signal transducer and activator of transcription 1; VAR, varicella vaccine; YF, yellow fever. ^aThis table refers to contraindications for nonemergency vaccination as recommended by the Advisory Committee on Immunization Practices, Centers for Disease Control and Prevention). ^bOPV vaccine not available in the United States. ^cLive-bacteria vaccines: BCG, Ty21a <i>Salmonella</i> Typhi vaccine, cholera vaccine. ^dLive-virus vaccines: MMR, VAR, MMRV, OPV, YF vaccine, dengue vaccine, vaccinia (smallpox vaccine), and rotavirus vaccine. Except for severe T-lymphocyte deficiency, data to contraindicate rotavirus vaccine are lacking; the immunocompromised state generally is considered a precaution for rotavirus vaccine. LAIV is not indicated for any person with a potentially immunocompromising condition. ^eChildren who are under- or unimmunized for age should receive routinely recommended vaccines, according to age and the catch-up schedule, with urgency to administer needed Hib and pneumococcal conjugate vaccine (PCV). ^fPPSV23 is begun at ≥2 years of age for patients with complement deficiency other than those with a deficiency limited to terminal complement components. If PCV is required (ie, for children <6 years who have not received all required doses, and for those ≥6 years of age who never received PCV), PCV dose(s) should be administered first, followed by PPSV23 at least 8 weeks later; a second dose of PPSV23 is given 5 years after the first. If one or more of the PCV doses is with PCV20, however, PPSV23 is not needed and should not be administered (see <i>Streptococcus pneumoniae</i> [Pneumococcal] Infections, p 810). ^gRegarding T-lymphocyte immunodeficiency as a contraindication to rotavirus vaccine, data only exist for severe combined immunodeficiency syndrome. ^hAge and schedule of doses depend on the product; repeated doses are required (see Meningococcal Infections, p 585). ⁱAdditional pneumococcal vaccine is not indicated for children with chronic granulomatous disease beyond age-based standard recommendations for PCV, because these children are not at increased risk of pneumococcal disease. ^jHIV-infected children should be considered for varicella vaccine if CD4+ T-lymphocyte count is ≥15% and should receive MMR vaccine if they are aged ≥12 months and do not have: 1) evidence of current severe immunosuppression (ie, to not have severe immunosuppression, individuals aged ≤5 years must have CD4+ T-lymphocyte percentages ≥15% for ≥6 months; and individuals aged >5 years must have both CD4+ T-lymphocyte percentages ≥15% and CD4+ T-lymphocyte counts ≥200 lymphocytes/mm³ for ≥6 months); and 2) other current evidence of measles, rubella, and mumps immunity. In cases when only CD4+ T-lymphocyte counts or only CD4+ T-lymphocyte percentages are available for those older than age 5 years, the assessment of severe immunosuppression can be based on the CD4+ T-lymphocyte values (count or percentage) that are available. In cases when CD4+ T-lymphocyte percentages are not available for those aged ≤5 years, the assessment of severe immunosuppression can be based on age-specific CD4+ T-lymphocyte counts at the time CD4+ T-lymphocyte counts were measured; i.e., absence of severe immunosuppression is defined as ≥6 months above age-specific CD4+ T-lymphocyte count criteria: CD4+ T-lymphocyte count >750 lymphocytes/mm³ while aged ≤12 months, and CD4+ T-lymphocyte count ≥500 lymphocytes/mm³ while aged 1 through 5 years. MMRV should not be administered to children with HIV infection, regardless of degree of immunosuppression, because of lack of safety data in this population. ^kA single dose of Hib is indicated for unimmunized children and adolescents ≥5 years of age (children and adolescents who have not received a primary series and booster dose or at least 1 dose of Hib after 14 months of age are considered unimmunized) who have anatomic or functional asplenia (including sickle cell disease), who will undergo splenectomy, or who have HIV infection.			

America (IDSA), in collaboration with the Centers for Disease Control and Prevention (CDC), the American Academy of Pediatrics (AAP), and other professional societies and organizations, has developed immunization guidelines for children and adults with primary and secondary immune deficiencies.¹ Health care providers should consult these guidelines for vaccinating children and adults with specific health conditions (eg, hematopoietic cell or solid organ transplant recipients) and life circumstances (eg, international travel or providing care for people with immune deficiencies). This chapter includes general principles and specific recommendations when the primary care physician is more likely to deliver care without the patient's continuous management by a subspecialist. Subspecialists who care for immunocompromised patients share responsibility with the primary care physician for ensuring appropriate vaccinations for immunocompromised patients and members of their households and other close contacts.

GENERAL PRINCIPLES

Certain generalizations regarding degree of immune suppression in patients with a primary or secondary immunodeficiency are useful for the health care provider and were adopted in the IDSA guideline.

High-level immunosuppression includes patients who:

- Have combined B- and T-lymphocyte primary immunodeficiency (eg, severe combined immunodeficiency [SCID])
- Receive cancer chemotherapy
- Receive chemotherapeutic agents (eg, cyclophosphamide, methotrexate, mycophenolate) or combination immunosuppressive drugs for rheumatologic conditions
- Have human immunodeficiency virus (HIV) infection and a CD4+ T-lymphocyte percentage <15% for children ≤5 years of age; for children >5 years of age, have either a CD4+ T-lymphocyte count <200 lymphocytes/mm³ or a CD4+ lymphocyte percentage <15%
- Receive daily corticosteroid therapy at a dose ≥20 mg/day (or ≥2 mg/kg/day for patients weighing <10 kg) of prednisone or equivalent for ≥14 days
- Receive certain biologic immune modulators (eg, tumor necrosis factor-α [TNF-α] antagonists, anti-B-lymphocyte monoclonal antibodies, anti-T-lymphocyte monoclonal antibodies, or checkpoint inhibitors)
- Are within 2 months of solid organ transplantation (SOT)
- Are within 2 to 3 months of receiving hematopoietic cell transplant (HCT) at a minimum and frequently for a much longer period (HCT recipients can have prolonged high degrees of immunosuppression depending on type of transplant [allogeneic > autologous], type of donor and cell source, and post-transplant complications [eg, graft versus host disease {GVHD}] and their treatments)

Low-level immunosuppression includes patients who:

- Have HIV infection and a CD4+ T-lymphocyte percentage ≥15% for children ≤5 years of age; for children >5 years of age, have both a CD4+ T-lymphocyte count ≥200 lymphocytes/mm³ and a CD4+ lymphocyte percentage ≥15%
- Receive a lower daily dose of systemic corticosteroids than for high-level immunosuppression for ≥14 days or receive alternate-day corticosteroid therapy

¹ Rubin LG, Levin MJ, Ljungman P, et al. 2013 IDSA clinical practice guideline for vaccination of the immunocompromised host. *Clin Infect Dis*. 2014;58(3):309-318. Available at: <https://academic.oup.com/cid/article/58/3/e44/336537>

- Receive methotrexate at a dosage of ≤ 0.4 mg/kg/week, azathioprine at a dosage of ≤ 3 mg/kg/day, or 6-mercaptopurine at a dosage of ≤ 1.5 mg/kg/day

TIMING OF VACCINES. For patients in whom initiation of immunosuppressive medication is planned, vaccinations should be administered before immunosuppression, when feasible. Live vaccines should be administered as indicated no closer than 4 weeks before initiation of immunosuppression or transplantation. If administration is not possible within this time restriction, immunization should be deferred until after recovery and/or reduction of profound immunosuppression. Non-live vaccines should be administered at least 2 weeks before immunosuppression or transplantation, if feasible.

Certain vaccines may be administered to children while they are modestly immunosuppressed, especially when the immunosuppressed state is likely to be lengthy or lifelong. Examples include some children with HIV infection and those having received solid organ transplants. Currently, there is no universally approved revaccination guidelines for nontransplanted childhood cancer survivors, and therefore the exact timing of when to revaccinate and/or catch-up children with cancer remains unclear. The IDSA recommends catch-up vaccination at 3 months following cessation of chemotherapy, but other societies recommend waiting 6 months. Patients who have received chemotherapies associated with longer-term immunocompromise, such as blinatumomab, rituximab, obinutuzumab, or alemtuzumab, may require longer delays. Some non-live vaccines have been administered during maintenance chemotherapy for children with acute leukemia, including non-live influenza vaccine (IIV) and COVID-19 vaccine. However, as described later in this chapter, live vaccines are generally contraindicated in immunocompromised people. Expert consultation is warranted if a live vaccine is being considered for immunocompromised people, including certain children after SOT, with HIV infection, and after HCT.

The interval between cessation of immunosuppressive therapy and immune reconstitution varies. Therefore, it is often not possible to make a definitive recommendation for an interval after cessation of immunosuppressive therapy when non-live vaccines can be administered effectively or when or whether live vaccines can be administered safely and effectively. Immunodeficiency that follows use of certain recombinant human proteins with anti-inflammatory properties, such as the anti-B-lymphocyte monoclonal antibody rituximab and the anti-leukemic monoclonal antibody blinatumomab, is prolonged and patients who receive such treatment are unlikely to respond to vaccines for at least 6 months and often much longer (see Biologic Response-Modifying Drugs Used to Decrease Inflammation, p 104).

Vaccinations after reduction or cessation of immunosuppression following transplantation vary depending on the vaccine, underlying disorder, specific immunosuppressive therapy, and presence or absence of GVHD.¹ Timing for non-live and live vaccines could vary from as early as 3 months after cessation of chemotherapy for acute leukemia to 24 months or longer for measles, mumps, and rubella vaccine (MMR) or varicella vaccine (VAR) after HCT in a patient without ongoing immunosuppression or GVHD. Timing also may be delayed for SOT recipients with graft rejection.

¹ Rubin LG, Levin MJ, Ljungman P, et al. 2013 IDSA clinical practice guideline for vaccination of the immunocompromised host. *Clin Infect Dis*. 2014;58(3):309-318. Available at: <https://academic.oup.com/cid/article/58/3/e44/336537>

LIVE VACCINES. In general, people who are severely immunocompromised or in whom immune function is uncertain should not receive live vaccines because of the risk of disease caused by the vaccine strains. However, there are particular immune deficiency disorders in which some live vaccines are safe and, for certain immunocompromised children and adolescents, the benefits may outweigh risks for use of particular live vaccines (see Table 1.17, p 94).

NON-LIVE VACCINES. Non-live vaccines do not convey substantial increased risk to an immunocompromised child compared with an immunocompetent child and, therefore, the decision to administer a non-live vaccine to children with immunodeficiency is based on an assessment of the likelihood of benefit. Non-live vaccines administered during certain immunosuppressive therapies (eg, receipt of anti-CD20 biologics, induction or consolidation chemotherapies) generally are not counted as valid in the recommended immunization schedule. Annual vaccination with non-live influenza vaccine (IIV) is recommended for immunocompromised patients 6 months of age and older. Other than IIV, non-live vaccines are generally not routinely administered to patients receiving immunoglobulin therapy for major antibody deficiency disorders or severe combined immunodeficiencies because of lack of added benefit.

Non-live vaccines not administered universally or at specific ages sometimes may be specifically indicated for children with inherited and acquired immunodeficient conditions because of their high risk for infection. These might include pneumococcal conjugate vaccine (PCV), followed by 23-valent pneumococcal polysaccharide vaccine (PPSV23) after the age of 6 years if not previously vaccinated with PCV; serogroups A, C, W, and Y meningococcal conjugate vaccine (MenACWY) beginning in infancy; serogroup B meningococcal conjugate vaccine (MenB) beginning at 10 years of age; and *Haemophilus influenzae* type b vaccine (Hib) after the age of 5 years. Some immunocompromised children and adolescents are at high risk of serious infection with SARS-CoV-2 and should receive booster doses of COVID-19 vaccine. Depending on the age of the person, the type of vaccine, and severity of immunocompromise, recommendations for primary series, additional doses, and use of boosters may vary. Clinicians should review the latest information available from the CDC and the Advisory Committee on Immunization Practices (ACIP).

Table 1.17 (p 94) provides guidance for some immunocompromising conditions. Additional information can be found in the IDSA clinical practice guideline for vaccination of the immunocompromised person (<https://academic.oup.com/cid/article/58/3/e44/336537>) and in the annually updated child and adolescent immunization schedule (https://redbook.solutions.aap.org/SS/Immunization_Schedules.aspx).

Because patients with congenital or acquired immunodeficiencies may not have an adequate response to vaccines, they may remain susceptible to infections despite having been immunized. Positive serologic test results are not always reliable markers of protection. Health care providers should generally assume susceptibility to infections when considering postexposure intervention strategies for these patients.

PRIMARY IMMUNODEFICIENCIES

Vaccine recommendations for primary immunodeficiency disorders depend on the specific immunologic abnormality and degree of impairment (Table 1.17, p 94). For B-lymphocyte primary immunodeficiency, vaccines to be avoided include oral

poliovirus, yellow fever, live attenuated influenza, and live bacterial vaccines; safety and efficacy of rotavirus vaccine is unknown in this population. All live-virus and non-live vaccines can be administered to children with isolated immunoglobulin (Ig) A and IgG subclass deficiencies. Non-live vaccines other than IIV are not routinely administered to patients with major antibody deficiencies or SCID during immune globulin therapy. For these patients, non-live vaccines can be administered as part of immunologic assessment prior to immune globulin intravenous (IGIV) therapy without safety concerns. For patients with common variable immunodeficiency, MenACWY should be administered beginning at 2 months of age because of their splenic dysfunction and lack of substantial meningococcal antibodies in IGIV.

Live-virus vaccines such as MMR and VAR should not be administered to patients with major antibody deficiencies, SCID, and T-lymphocyte immunodeficiencies, including any of the following conditions: DiGeorge syndrome with CD3+ T-lymphocyte count <500 cells/mm³,¹ other combined immunodeficiencies with similar CD3+ T-lymphocyte counts,¹ Wiskott-Aldrich syndrome, or X-linked lymphoproliferative disease or familial disorders that predispose to hemophagocytic lymphohistiocytosis.

Patients with primary complement deficiencies of early classic pathway, alternate pathway, or severe mannose-binding lectin deficiency should receive all routine non-live and live vaccines on the immunization schedule. For patients with complement deficiencies other than isolated terminal complement component deficiencies, PPSV23 should be administered at 2 years of age (and ≥ 8 weeks after last dose of PCV) and again 5 years after the initial dose. The MenACWY series should be initiated at age 2 months or older and the MenB series should be administered starting at age 10 years. MenACWY and MenB booster doses are indicated for those at chronic, increased risk for meningococcal disease (eg, functional [eg, sickle cell disease] and anatomical [eg, splenectomy] asplenia, HIV infection, persistent complement component deficiency) (see Meningococcal Infections, p 585). Both meningococcal vaccines are recommended for patients receiving eculizumab, which inhibits the complement cascade by binding to complement component 5 (C5).

Patients with phagocytic cell deficiencies (eg, chronic granulomatous disease [CGD], leukocyte adhesion deficiency [LAD], Chediak-Higashi syndrome, cyclic neutropenia) and patients with innate immune defects that result in defects of cytokine generation or response or cellular activation (eg, defects of interferon-gamma/interleukin [IL]-12 axis) should receive all non-live vaccines on the annual immunization schedule. Live-virus vaccines (eg, MMR) should be administered to patients with CGD and cyclic neutropenia, but live-bacterial vaccines (eg, oral typhoid vaccine [Ty21a]) should not be administered to these patients. Live-bacterial vaccines should not be administered to patients with interferon-gamma/IL-12 axis deficiencies. Live-bacterial and live-virus vaccines should not be administered to patients with LAD, Chediak-Higashi syndrome, or defects within the interferon-gamma or IL-12 pathway.

¹ Rubin LG, Levin MJ, Ljungman P, et al. 2013 IDSA clinical practice guideline for vaccination of the immunocompromised host. *Clin Infect Dis*. 2014;58(3):309-318. Available at: <https://academic.oup.com/cid/article/58/3/e44/336537>

SECONDARY (ACQUIRED) IMMUNODEFICIENCIES

Several factors should be considered in immunization of children with secondary immunodeficiencies (Table 1.17, p 94), including the underlying disease, the specific immunosuppressive regimen (dose and schedule), and the patient's infectious disease and immunization history. Live vaccines generally are contraindicated because of a proven or theoretical increased risk of vaccine virus disease. For example, in children with an immunocompromising condition or HIV infection and CD4+ T-lymphocyte percentage <15% or count <200/mm³, MMR and VAR are contraindicated. LAIV should not be administered to children with HIV infection. Rotavirus vaccine should be administered to HIV-exposed and HIV-infected infants, irrespective of CD4+ T-lymphocyte percentage or count, according to the schedule for uninfected infants (see Human Immunodeficiency Virus Infection, p 489). Rotavirus vaccine may be indicated for infants with acquired immunocompromising conditions if the potential benefit of protection outweighs the risk of adverse reaction.

HOUSEHOLD MEMBERS OF IMMUNOCOMPROMISED PATIENTS

Household contacts of immunocompromised patients should receive all age- and exposure-appropriate vaccines, with the exception of smallpox vaccine, to minimize the exposure of the immunocompromised patient to vaccine-preventable infections. LAIV may be administered to healthy household and other close contacts of people with altered immunocompetence. However, if the person with altered immunocompetence is in a protected environment, then LAIV recipients should avoid close contact with the immunocompromised person for 7 days.

Live vaccines, when indicated for travel (eg, yellow fever and oral typhoid vaccines), should also be administered to household contacts, with the exception of oral poliovirus vaccine (OPV), which still is available in many countries outside of the United States. Although the risk of transmission is low, immunocompromised patients should avoid contact with people who develop skin lesions after receipt of VAR until the lesions clear. When transmission of vaccine-strain varicella virus has occurred, the virus is expected to maintain its attenuated characteristics and susceptibility to acyclovir. Therefore, administration of varicella-zoster immune globulin or IGIV to an immunocompromised person after exposure to a person with skin lesions that developed after varicella vaccination is not indicated. All members of the household should wash their hands after changing the diaper of an infant who received rotavirus vaccine to minimize rotavirus transmission, as shedding of the virus may occur up to 1 month after the last dose; immunocompromised patients ideally should not change diapers of infants at all for several weeks after rotavirus vaccine.

SPECIAL SITUATIONS/HOSTS

CORTICOSTEROIDS. Before starting corticosteroid therapy for inflammatory or autoimmune diseases, patients should be current in their vaccinations based on their age and other indications. Non-live vaccines should ideally be administered at least 2 weeks before and live vaccines should be administered at least 4 weeks before initiating corticosteroid therapy.

Guidance for Administration of Non-live Vaccines During Corticosteroid Therapy. Non-live vaccines can still be administered to patients while they are receiving steroid therapy long-term. Non-live vaccine administration can be deferred temporarily until corticosteroids

are discontinued if the hiatus is expected to be brief and adherence to return appointment is likely. Non-live vaccines need not be avoided because of concern for exacerbation of an inflammatory or immune-mediated condition.

Guidance for Administration of Live Vaccines During Corticosteroid Therapy. Recommendations depend on potency, route of administration, and duration of corticosteroid therapy:

- **High doses of systemic corticosteroids given daily for 14 days or more.** Children receiving ≥ 2 mg/kg per day of prednisone or its equivalent, or ≥ 20 mg/day if they weigh 10 kg or more, for 14 days or more should not receive live vaccines until 4 weeks after discontinuation of treatment.
- **High doses of systemic corticosteroids given daily or on alternate days for fewer than 14 days.** Children receiving ≥ 2 mg/kg per day of prednisone or its equivalent, or ≥ 20 mg/day if they weigh 10 kg or more, can receive live-virus vaccines immediately after discontinuation of treatment.
- **Low or moderate doses of systemic corticosteroids or locally administered corticosteroids in children who have a disease (eg, systemic lupus erythematosus) that itself is immunosuppressive, or who are receiving immunosuppressive medication other than corticosteroids,** should not receive live vaccines during therapy, except in special circumstances during which the potential benefit of protection and the risk of adverse reaction are weighed.
- **Low or moderate doses of systemic corticosteroids given daily or on alternate days.** Children receiving < 2 mg/kg per day of prednisone or its equivalent, or < 20 mg/day if they weigh 10 kg or more, can receive live vaccines during corticosteroid treatment.
- **Physiologic maintenance doses of corticosteroids.** Children who are receiving only maintenance physiologic doses of corticosteroids can receive live vaccines.
- **Topical therapy, local injections, or aerosol use of corticosteroids.** Application of low-potency topical corticosteroids to localized areas on the skin; administration by aerosolization; application on conjunctiva; or intra-articular, bursal, or tendon injections of corticosteroids usually do not result in immunosuppression that limits the use of live vaccines.

BIOLOGIC RESPONSE-MODIFYING DRUGS USED TO DECREASE INFLAMMATION.

Biologic response modifiers (BRMs) are drugs used to treat immune-mediated conditions, including juvenile idiopathic arthritis, rheumatoid arthritis, and inflammatory bowel disease. Their immune-modulating effects can last for weeks to months after discontinuation. These BRMs are often used in combination with other immunosuppressive drugs, such as methotrexate or corticosteroids.

Vaccination status of patients who need BRMs should be assessed and recommended vaccines should be administered in advance where feasible (Table 1.18). Recommended vaccines include PPSV23 for patients 2 years or older unless they have received one or more doses of PCV20 already; if PCV is required (ie, for children < 6 years of age who have not received all required doses, and for those ≥ 6 years of age who never received PCV), PCV dose(s) should be administered first, followed by PPSV23 at least 8 weeks later if indicated (eg, if the child has not received any doses of PCV20).

Most BRMs are considered highly immunosuppressive, and live vaccines are contraindicated during therapy; non-live vaccines, including IIV, should be administered as per the immunization schedule and should not be withheld because of concern for an exaggerated inflammatory response. The interval following therapy

Table 1.18. Recommendations for Evaluation Prior to Initiation of Biologic Response-Modifying Drugs

- Perform tuberculin skin test (TST) or interferon-gamma release assay (IGRA) (see Tuberculosis, p 888)
- Consider chest radiograph on the basis of clinical and epidemiologic findings
- Document vaccination status and, if required, administer:
 - Non-live vaccines (including annual IIV) a minimum of 2 weeks before initiation of biologic response-modifying drug
 - Live-virus vaccines a minimum 4 weeks before initiation of biologic response modifier therapy, unless contraindicated by condition or other therapies
- Counsel household members regarding risk of infection and ensure vaccination (see Household Members of Immunocompromised Patients, p 103)
- Consider serologic testing for *Histoplasma* species, *Toxoplasma* species, and other intracellular pathogens depending on risk of past exposure
- Perform serologic testing for hepatitis B virus and vaccinate/revaccinate if HBsAb is <10 mIU/mL
- Consider serologic testing for varicella-zoster virus and Epstein-Barr virus
- Counsel regarding:
 - Food safety (www.cdc.gov/foodsafety)
 - Maintenance of dental hygiene
 - Risks of exposure to garden soil, pets, and other animals
 - Avoiding high-risk activities (eg, excavation sites or spelunking because of risk of *Histoplasma capsulatum*)
 - Avoiding travel to areas with endemic pathogenic fungi (eg, certain areas of southwestern United States for risk of *Coccidioides* species) or to areas where tuberculosis is endemic

IIV indicates non-live influenza vaccine; HBsAb, hepatitis B surface antibody.

Modified from Le Saux N; Canadian Paediatric Society, Infectious Diseases and Immunization Committee. *Paediatr Child Health*. 2012;17(3):147-150 and Davies HD; American Academy of Pediatrics, Committee on Infectious Diseases. Infectious complications with the use of biologic response modifiers in infants and children. *Pediatrics*. 2016;138(2):e20161209 (Reaffirmed March 2021).

until live vaccines can be administered safely has not been established and is likely to vary by agent.

Infants exposed in utero to maternally administered BRMs can have detectable drug concentrations for many months following delivery, resulting in concern for immunosuppression among infants in the 12 months after the last maternal dose during pregnancy. Data are sparse on the safety of rotavirus vaccines in infants who were exposed in utero to BRMs administered to the expectant parent during pregnancy. Considering that rotavirus disease is rarely life-threatening in the United States, rotavirus vaccines should be avoided in infants for the first 12 months after the last in utero exposure to most BRMs. Exceptions include certolizumab, which is not transferred across the placenta because of its structure as a pegylated Fab fragment, and likely infliximab, although the data are sparser; rotavirus vaccination of infants can be considered when either of these BRMs were administered during pregnancy. As more data become available for the other BRMs, recommendations are likely to change,¹

¹ Fitzpatrick T, Alsager K, Sadarangani M, et al; Special Immunization Clinic Network investigators. Immunological effects and safety of live rotavirus vaccination after antenatal exposure to immunomodulatory biologic agents: a prospective cohort study from the Canadian Immunization Research Network. *Lancet Child Adolesc Health*. 2023;7(9):648-656

so consultation with an immunologist or a pediatric infectious diseases physician is recommended. Because MMR, VAR, and measles, mumps, rubella, and varicella vaccine (MMRV) are recommended routinely at 12 months of age, previous receipt of BRMs during pregnancy does not preclude the infant from receiving these live vaccines at the recommended time. For measles prevention in infants younger than 12 months following exposure during outbreak settings or for travel, MMR or immune globulin intramuscular should be used. The choice depends on several factors (eg, age, time elapsed since exposure, which BRM was administered during pregnancy). International travel for infants who were exposed to BRMs in utero (other than certolizumab) should be discouraged for the 12 months following the last dose administered during pregnancy. These recommendations may not apply to management of infants born in other countries, where risks of wild-type infection may differ from the United States and where additional live vaccines may be administered in early infancy (eg, bacille Calmette-Guérin [BCG], OPV).

HEMATOPOIETIC CELL TRANSPLANTATION. Patients for whom HCT is planned should receive all routinely recommended non-live vaccines (including IIV) at least 2 weeks before the start of the conditioning period, when possible. Routinely recommended live vaccines should be administered if the patient is not already immunosuppressed and the interval to the start of the conditioning period is at least 4 weeks. By vaccinating the nonimmune patient before HCT, some protection likely will persist in the months after transplant. The HCT donor, if known and feasible, should be current with routinely recommended vaccines, but vaccination of the donor solely for benefit of the recipient is not recommended. Administration of MMR, MMRV, and VAR should be avoided within 4 weeks of hematopoietic stem cell harvest but may be contraindicated even prior to that because of pre-existing immunocompromise.

Household members of HCT recipients should be fully immunized (see Household Members of Immunocompromised Patients, p 103). Timing of immune reconstitution of HCT recipients varies greatly depending on type of transplantation, interval since transplantation, receipt of immunosuppressive medications, and presence or absence of GVHD and other complications. Routine and additional vaccinations are an important part of patient management in collaboration with the patient's specialty care providers. Revaccination for certain non-live vaccines, such as pneumococcal vaccines and IIV, can be given starting 3 to 6 months after transplantation. Live vaccines can be given as early as 2 years following transplantation but may be delayed if HCT recipients still have active GVHD and/or high degree of immunosuppression.

Following CD19-targeted chimeric antigen receptor T-cell (CAR-T) therapy, patients may have prolonged B-lymphocyte aplasia. The safety and immunogenicity of vaccinations after CAR-T therapy is not known, and currently no guidelines exist. On the basis of expert opinion, for patients in remission and who do not require additional chemotherapy or HCT, non-live vaccines may be administered if 6 months or longer has transpired following CAR-T therapy and it has been 2 months or more since last IG treatment; live vaccines may be administered if 1 year or longer has transpired following CAR-T therapy. Current mRNA COVID-19 vaccines should be offered beginning at 3 months after CAR-T therapy; refer to the most updated recommendations of primary and booster doses of COVID-19 vaccines from the CDC and ACIP (www.cdc.gov/coronavirus/2019-ncov/vaccines/recommendations/immuno.html).

SOLID ORGAN TRANSPLANTATION. Children and adolescents with chronic heart, lung, liver, or kidney disease should receive all vaccinations as appropriate for age and health condition. Similarly, SOT candidates should be current with their vaccination status and, if feasible, should receive non-live vaccines at least 2 weeks prior and live vaccines 4 weeks prior to SOT. SOT candidates younger than 2 years should receive pneumococcal vaccination with PCV as described in the annual immunization schedule. If PCV is required (ie, for children <6 years of age who have not received all required doses, and for those ≥ 6 years of age who never received PCV), PCV dose(s) should be administered first, followed by PPSV23 at least 8 weeks later; a second dose of PPSV23 is given 5 years after the first. SOT candidates who have negative hepatitis B surface antigen (HBsAg) and hepatitis B surface antibody (anti-HBsAb) test results should complete the hepatitis B vaccine (HepB) series, followed by serologic testing to confirm immunity. Additional doses of HepB may be indicated if serologic test results are negative. Patients 12 months or older who have not completed the hepatitis A vaccine (HepA) series or have negative hepatitis A serologic test results should complete the HepA series. MMR can be administered to infants 6 through 11 months of age who are SOT candidates and who are not immunocompromised, with a second dose provided 4 weeks later. MMR doses given before 12 months of age cannot be counted toward the standard 2-dose series. As such, if an infant ≥ 12 months of age has received MMR and is still awaiting a transplant that will not occur within 4 weeks, 2 doses of MMR should be administered at least 4 weeks apart. Living SOT donors should be current on their vaccination status, with considerations for required vaccines the same as for HCT donors (see Hematopoietic Cell Transplantation, p 106). Donors should avoid receiving live vaccines within 4 weeks before donation. Household members of SOT recipients should be current on their vaccination status.¹

HIV INFECTION (ALSO SEE HUMAN IMMUNODEFICIENCY VIRUS INFECTION, P 489).

HIV-infected children and adolescents should receive all non-live vaccines as indicated on the annual immunization schedule. PPSV23 should be administered to people with HIV 2 years or older, at least 8 weeks after the last required PCV dose. Meningococcal conjugate vaccine (MenACWY) should be administered beginning at 8 weeks of age. Depending on age of the patient and the vaccine manufacturer, the number of doses and the intervals between doses can vary. A booster dose of MenACWY is recommended 3 to 5 years after the primary series, depending on age at vaccination. Children with HIV should not receive Menactra before the age of 2 years to avoid interference with the immunologic response to the infant series of pneumococcal conjugate vaccine; only MenACWY-CRM (Menveo) should be used in this group (see Meningococcal Infections, p 585, Table 3.39, p 592, and Table 3.40, p 594). Currently, MenB is not specifically recommended for people with HIV infection. Rotavirus vaccine should be administered to HIV-exposed and HIV-infected infants, irrespective of CD4+ T-lymphocyte percentage or count, according to the schedule for uninfected infants (see Human Immunodeficiency Virus Infection, p 489). MMR and VAR should be administered to children 12 months or older who are clinically stable and who have a CD4+ T-lymphocyte percentage $\geq 15\%$ for children ≤ 5 years of age, or have both a CD4+ T-lymphocyte count ≥ 200 lymphocytes/mm³ and a CD4+ lymphocyte percentage $\geq 15\%$ for children >5 years of age (see General Principles, p 99).

¹ Suresh S, Upton J, Green M, et al. Live vaccines after pediatric solid organ transplant: proceedings of a consensus meeting, 2018. *Pediatr Transplant*. 2019;23(7):e13571

Children with HIV infection should not receive MMRV or LAIV. Mpox vaccination may be indicated for at-risk individuals with HIV and other immunocompromising conditions (www.cdc.gov/poxvirus/mpox/clinicians/people-with-HIV.html). JYNNEOS is the only mpox vaccine authorized for pre- and postexposure prophylaxis in eligible immunocompromised individuals.

In the United States, BCG is usually contraindicated for people with HIV. In areas of the world with a high incidence of tuberculosis, the World Health Organization (WHO) recommends administering BCG vaccine to children with HIV infection who are asymptomatic.

ASPLENIA AND FUNCTIONAL ASPLENIA. An asplenic state can result from the following: (1) surgical removal of the spleen (eg, after trauma, for treatment of hemolytic conditions); (2) functional asplenia (eg, from sickle cell disease or thalassemia); or (3) congenital asplenia or polysplenia. Special recommendations for patients with asplenia apply to all 3 categories. All infants, children, adolescents, and adults with asplenia have an increased risk of fulminant septicemia, especially associated with encapsulated bacteria, which is associated with a high mortality rate. In comparison with immunocompetent children who have not undergone splenectomy, the incidence of and mortality rate from septicemia are increased in children who have had splenectomy after trauma and in children with sickle cell disease by as much as 350-fold, and the rate may be even higher in children who have had splenectomy for thalassemia. The risk of invasive bacterial infection is higher in younger children than in older children, and the risk may be greater during the years immediately after surgical splenectomy. Fulminant septicemia, however, has been reported in adults as long as 25 years after splenectomy.

Streptococcus pneumoniae is the most common pathogen causing septicemia in children with asplenia. Less common vaccine-preventable causes include *Haemophilus influenzae* type b and *Neisseria meningitidis*.

Pneumococcal vaccination is vital for children with asplenia (see *Streptococcus pneumoniae* [Pneumococcal] Infections, p 810). Following administration of an appropriate number of primary series or catch-up doses of PCV, PPSV23 should be administered to children 24 months or older at least 8 weeks after the last PCV dose unless one or more of the PCV doses was with PCV20. If PPSV23 is used, a second dose of PPSV23 should be administered 5 years later (see *Streptococcus pneumoniae* [Pneumococcal] Infections, p 810).

Previously unimmunized children with asplenia younger than 5 years should receive appropriate number of doses of and intervals for Hib according to the catch-up schedule as described in the annual immunization schedule. Unimmunized children 5 years or older should receive a single dose of Hib.

MenACWY and Men B should be administered to children with asplenia, as recommended for those with primary complement component deficiencies (see Primary Immunodeficiencies, p 101), with one important caveat. MenACWY-D (Menactra) may interfere with antibody response to some serotypes contained in PCV when the vaccines are administered concurrently or closely together. Therefore, because of their high risk for invasive pneumococcal disease, children with functional or anatomic asplenia should not be vaccinated with MenACWY-D (Menactra) before age 2 years to avoid interference with the immune response to PCV (see Meningococcal Infections, p 585). Only MenACWY-CRM (Menveo) should be used in this group; MenACWY-TT (MenQuadfi) should not be used in this situation because it is only approved in children ≥ 2 years of age. For children 2 years of age and older, any of the

MenACWY vaccines (Menveo, MenQuadfi, or Menactra) can be used. For patients with asplenia who are younger than 7 years, an additional dose of meningococcal conjugate vaccine is recommended 3 years after the primary series and then every 5 years; for patients with asplenia who received the last dose of the primary series at 7 years and older, the initial booster dose following the primary series should be at 5 years instead of 3 years, and then every 5 years thereafter. Use of MenACWY vaccine (beginning in infancy) and MenB vaccine (beginning at 10 years of age) can be considered on a case-by-case basis for children with other primary or secondary splenic dysfunction.

When surgical splenectomy is planned, Hib, pneumococcal, and meningococcal vaccine history should be reviewed, and needed vaccines should be administered at least 2 weeks before surgery. If the patient is 2 years or older and is PPSV23 naïve, PPSV23 should be administered at least 8 weeks after indicated dose(s) of PCV and at least 2 weeks before surgery. If splenectomy is performed on an emergency basis or if needed vaccines were not administered before splenectomy, they should be administered as soon as possible when the patient's condition is stable.

In addition to immunization, antibiotic prophylaxis against pneumococcal infections is recommended for many children with asplenia (see *Streptococcus pneumoniae* [Pneumococcal] Infections, p 810).

CENTRAL NERVOUS SYSTEM ANATOMIC BARRIER DEFECTS. Patients of all ages scheduled to receive a cochlear implant as well as patients with congenital dysplasias of the inner ear or persistent cerebrospinal fluid (CSF) communication with the naso-oropharynx should receive vaccines recommended routinely on the annual immunization schedule. In addition, they should receive PCV as recommended for children with asplenia and at 24 months or older should receive PPSV23 (≥ 8 weeks after receipt of PCV). Indicated doses of PCV and PPSV23 should ideally be administered at least 2 weeks before cochlear implant surgery, when feasible.

There is no well-established evidence for use of antimicrobial prophylaxis for patients with CSF communication with the naso-oropharynx or middle ear. Risk of bacterial meningitis is highest in the first 7 to 10 days following acute traumatic breach. Some physicians recommend empiric parenteral antimicrobial therapy in the immediate post-traumatic period. Parenteral antimicrobial therapy also is given in the peri-operative period for cochlear implantation and reparative neurosurgical procedures. Routine chronic antimicrobial prophylaxis is not indicated for persistent CSF communications or following cochlear implantation.

Immunization in Children With a Personal or Family History of Seizures

Studies have demonstrated a short-term increased risk of a febrile seizure (ie, generalized, brief, self-limited) following receipt of several vaccines (eg, diphtheria, tetanus, and whole-cell pertussis vaccine [DTwP]; measles, mumps, and rubella vaccine [MMR]; measles, mumps, rubella, and varicella vaccine [MMRV]; 13-valent pneumococcal conjugate vaccine [PCV13], and non-live influenza vaccine [IIV]). An increased incidence of febrile seizures has not been found with the currently recommended diphtheria, tetanus, and acellular pertussis (DTaP) vaccines. Children 6 months to 2 years of age may experience a small increased risk for febrile seizure when IIV is given simultaneously with PCV13 or DTaP. However, children this age

should still continue to receive IIV, PCV13, and DTaP when these vaccines are due. Infants and children with a personal or family history of seizures of any etiology might be at greater risk of having a febrile seizure after receipt of these vaccines compared with children without such histories. Children who develop epilepsy soon after they receive immunization should be considered for genetic testing, because many genetic causes of early-life epilepsies present around the age at which vaccines are routinely given. No evidence indicates that febrile seizures cause permanent brain damage or epilepsy, aggravate neurologic disorders, or affect the prognosis for children with underlying disorders.

Parents of children with a personal history of febrile seizures should be informed that some vaccines could be associated with an increased risk of febrile seizures. However, vaccination generally should not be deferred in these children. Postimmunization seizures in these children are uncommon, and if they occur, they usually are febrile in origin, have a benign outcome, and are not likely to be confused with manifestations of a previously unrecognized neurologic disorder. In the case of pertussis immunization during infancy, vaccine administration could coincide with or hasten the recognition of a disorder associated with seizures, such as infantile spasms or Dravet syndrome, which could cause confusion about the role of pertussis immunization. Hence, pertussis immunization in infants with an *evolving* neurologic condition generally is deferred until the condition is stabilized. DTaP should be administered to infants and children with a *stable* neurologic condition, including well-controlled seizures, and to most children with a history of seizures (febrile or afebrile) occurring <3 days after a previous dose of DTwP or DTaP. However, a history of encephalopathy (eg, coma, decreased level of consciousness, prolonged seizures) not attributable to another cause occurring <7 days after a previous dose of DTwP or DTaP remains a contraindication to receiving DTaP.

Immunization in Children With Chronic Diseases

Chronic disease is defined as a medical condition that currently is not curable and that has been present for at least 3 months, will likely last longer than 3 months, or has occurred at least 3 times in the past year and likely will recur. Chronic diseases may increase children's susceptibility to infections or increase the severity of infection-related manifestations. Unless specifically contraindicated, immunizations recommended for healthy children should generally be administered to children with chronic diseases.

The importance of COVID-19 and annual influenza vaccinations, when indicated, should be particularly emphasized in children with chronic diseases and their household contacts. Children with hemophilia or other bleeding disorders should be immunized following the Centers for Disease Control and Prevention (CDC) guidelines for vaccinating persons with increased bleeding risk.¹ For children with chronic and immunocompromising conditions or therapies, see Immunization and Other Considerations in Immunocompromised Children (p 93) and the "Recommended Child and Adolescent Immunization Schedule for Ages 18 Years or Younger, United States," which is updated annually (www.cdc.gov/vaccines/schedules/hcp/imz/child-adolescent.html and https://redbook.solutions.aap.org/SS/Immunization_Schedules.aspx).

¹ www.cdc.gov/vaccines/hcp/acip-recs/general-recs/special-situations.html

Children with certain chronic diseases such as allergic, respiratory, cardiovascular, hematologic, metabolic, and renal disorders are at increased risk of complications from pneumococcal infection and may need to receive pneumococcal conjugate vaccine and 23-valent pneumococcal polysaccharide vaccine (PPSV23), or both, as recommended for age and condition (see *Streptococcus pneumoniae* [Pneumococcal] Infections, p 810). Children with certain immunocompromising conditions, such as asplenia or persistent complement component deficiencies, are particularly susceptible to severe infections by encapsulated bacteria and are routinely recommended to receive *Haemophilus influenzae* type b vaccine (Hib), serogroups A, C, W, and Y meningococcal vaccine (MenACWY), serogroup B meningococcal vaccine (MenB), and pneumococcal conjugate vaccine and PPSV23. See Table 3 in the Recommended Child and Adolescent Immunization Schedule by Medical Condition, United States, at https://redbook.solutions.aap.org/SS/Immunization_Schedules.aspx, and Immunization and Other Considerations in Immunocompromised Children, p 93.

All children with chronic liver disease are at risk of severe clinical manifestations of acute hepatitis virus infections and should receive hepatitis A (HepA) and hepatitis B (HepB) vaccines if not previously vaccinated (see Hepatitis A, p 430, and Hepatitis B, p 437). Household members of children with chronic diseases also should be up-to-date on recommended vaccines based on their age and health conditions (https://redbook.solutions.aap.org/SS/Immunization_Schedules.aspx).

In 2012, the National Academy of Medicine (NAM) assessed whether vaccines (measles, mumps, and rubella; acellular pertussis-containing diphtheria and tetanus; tetanus toxoid; influenza; hepatitis A; hepatitis B; and human papillomavirus vaccines) were a potential trigger for a flare or the onset of chronic inflammatory diseases. The NAM review concluded that the evidence was inadequate to establish or refute a causal relationship between these vaccines and onset or exacerbation of multiple sclerosis, systemic lupus erythematosus, vasculitis, rheumatoid arthritis, or juvenile idiopathic arthritis.¹ Additionally, NAM concluded that clinical evidence overall indicated that vaccines should not be withheld because concerns about their potential trigger for chronic inflammatory diseases.

Immunization in American Indian/Alaska Native Children and Adolescents

Indigenous populations worldwide have high morbidity and mortality from infectious diseases, including vaccine-preventable infections (wwwnc.cdc.gov/eid/article/7/77/pdfs/01-7732.pdf). This chapter focuses on the US population of American Indian and Alaska Native (AI/AN) people and considerations for use of vaccines and biologic products that are special to these populations. For AI/AN people, persistent elevated rates of infectious diseases are driven by barriers to care seeking related to geographic isolation and historical trauma, socioeconomic factors such as poverty, household crowding, substandard housing, and poor indoor air quality.

¹ Stratton K, Andrew F, Rusch E, Clayton E. *Adverse Effects of Vaccines: Evidence and Causality*. Washington, DC: National Academies Press; 2012

Historically, compared with children from other US racial or ethnic groups, AI/AN children living on reservation lands or in Alaska Native villages have higher rates of certain vaccine-preventable diseases, such as *Haemophilus influenzae* type b, *Streptococcus pneumoniae*, hepatitis A, and hepatitis B. Although the rate of mortality from pneumonia and influenza among AI/AN infants has steadily declined over recent decades, disparities persist.

During the past 2 decades, childhood immunizations for hepatitis A and hepatitis B in the US have eliminated disease disparities for these pathogens in most populations of AI/AN children. Significant decreases have been documented in varicella hospitalizations and invasive disease caused by *H influenzae* type b and *S pneumoniae*. However, the historically high rates of infection and ongoing disparities highlight the importance of ensuring that recommendations for universal childhood immunization be implemented for all AI/AN children. Specific vulnerabilities are as follows.

- ***H influenzae* type b.** There are important differences among the currently available *Haemophilus influenzae* type b (Hib) vaccines that should be considered by clinicians caring for AI/AN children. Before routine use of Hib, the incidence of invasive *H influenzae* type b disease was up to 10 times higher among young AI/AN children compared with non-AI/AN children. Because of the historically high risk of invasive *H influenzae* type b disease within the first 6 months of life in many AI/AN infant populations, the CDC Advisory Committee on Immunization Practices (ACIP) and the American Academy of Pediatrics (AAP) recommend the preferential use of PedvaxHIB, which contains polyribosylribitol phosphate-meningococcal outer membrane protein (PRP-OMP), as the first dose in the Hib series. The administration of the PRP-OMP-containing vaccine leads to more rapid development of protective concentrations of antibody compared with Hib containing polyribosylribitol phosphate-tetanus toxoid (PRP-T), and failure to use Hib containing PRP-OMP has been associated with excess cases of *H influenzae* type b disease in Alaska Native infants. Until information is available on the kinetics of antibody development following the first dose of the PRP-OMP-containing combination vaccine (DTaP-IPV-Hib-HepB [Vaxelis]), there is no preferential recommendation for its use in AI/AN infants. If the first dose of PRP-OMP-containing PedvaxHIB or Vaxelis is delayed by >1 month, the recommended catch-up schedule should be followed (available at https://redbook.solutions.aap.org/SS/Immunization_Schedules.aspx). A booster dose (dose 3) in the PRP-OMP Hib schedule or dose 4 in other Hib schedules is recommended at age 12 through 15 months; regardless of vaccine used in the primary Hib series, there is no preferred Hib formulation for the booster dose (www.cdc.gov/mmwr/preview/mmwrhtml/rr6301a1.htm). Availability of more than one Hib product in a clinic, however, has been shown to lead to errors in vaccine administration. To avoid confusion for health care professionals who serve AI/AN children predominantly, it may be prudent to stock only PRP-OMP-containing Hib.
- ***S pneumoniae*.** Recommendations for pneumococcal conjugate vaccine (PCV) for AI/AN children are the same as for other children in the United States. Before introduction of heptavalent pneumococcal conjugate vaccine (PCV7), the incidence of invasive pneumococcal disease (IPD) in certain AI/AN children (Alaska Native, Navajo, and White Mountain Apache) was 5 to 24 times higher than the incidence among other children in the United States. Use of PCV7 in AI/AN infants resulted

in near-elimination of IPD caused by vaccine serotypes and decreased incidence of overall IPD caused by all serotypes of *S pneumoniae*. Although the use of 13-valent pneumococcal conjugate vaccine (PCV13) has further reduced the incidence of IPD in AI/AN children, rates of overall IPD among some AI/AN children (Alaska Native, Navajo, and White Mountain Apache) remain more than fourfold higher than those among children in the general US population.

- **Hepatitis A and hepatitis B viruses.** Before the introduction of hepatitis vaccines, rates of hepatitis A and hepatitis B in the AI/AN population exceeded those of the general US population. In 1970, Alaska Native people had an overall prevalence of hepatitis B surface antigen (HBsAg) positivity of >6%, leading to high rates of hepatocellular carcinoma. Universal infant immunization with the hepatitis B vaccine and population-wide screening and vaccination eliminated symptomatic hepatitis B virus infection and hepatocellular carcinoma in Alaska Native people younger than age 20 years. Similarly, after initiation of universal childhood hepatitis A vaccination, hepatitis A virus infection rates among AI/AN people declined 20-fold during 1997-2001 to a rate lower than that of the general US population.
- **Influenza virus.** The disparity in influenza-related mortality rates in the AI/AN population compared with the general US population was confirmed during the 2009 H1N1 epidemic; the H1N1 death rate among AI/AN people in 12 states (representing 50% of the AI/AN population in the United States) was 4 times higher than the H1N1 death rate for all other racial and ethnic populations combined. For this reason, the AI/AN population is listed among the groups at risk of severe complications from influenza. When vaccine or antiviral medication supplies are limited or delayed, AI/AN people are considered a high-risk priority group. Studies have also documented the value of influenza immunization during pregnancy to protect both the pregnant person and infant too young to be vaccinated.
- **Respiratory syncytial virus (RSV).** The rates of hospitalization for RSV have been much higher for AI/AN infants in rural Alaska and southwest Indian Health Service (IHS) regions than for other infants in the United States. Hospitalization rates for AI/AN infants attributable to RSV infection in these areas are similar to rates among medically high-risk and preterm infants in the overall US population. Use of RSV-specific monoclonal antibody prophylaxis (palivizumab or nirsevimab), as recommended by the AAP, should be optimized among high-risk AI/AN infants (see Respiratory Syncytial Virus, p 713). The RSV season may be different in northern latitudes, including Alaska, and RSV prophylaxis should reflect local seasonality and risk factors in these areas. The new RSVpreF vaccine (Abrysvo) is approved and recommended for use in pregnant people as a single intramuscular injection administered between 32 through 36 weeks' gestation. Among the general US population, vaccination during pregnancy reduces RSV-associated lower respiratory tract disease, including severe disease, throughout the first 6 months following the infant's birth. This efficacy of this vaccine has not been specifically studied in AI/AN populations.
- **Rotavirus.** In the 1990s, the percentage of AI/AN infants hospitalized with diarrheal illnesses was nearly twice that of the general infant population in the United States. Following introduction of rotavirus vaccination, diarrhea-associated hospitalizations of AI/AN children younger than 5 years have declined substantially, reinforcing the importance of this vaccine for AI/AN infants.

- **Pertussis.** A study of pertussis-related mortality from 1991-2008 showed that AI/AN infants aged ≥ 42 days had the highest risk for fatal outcome (odds ratio [OR], 3.7; 95% confidence interval [CI]: 1.8–7.8) compared with white infants, higher than infants of any other racial or ethnic group. This risk nearly doubled when other factors were controlled, including age, receipt of antibiotics, or receipt of at least 1 dose of diphtheria, tetanus, and acellular pertussis vaccine (DTaP). These disparities emphasize the importance of AI/AN infant immunization and immunization of AI/AN pregnant people with pertussis-containing vaccine.
- **COVID-19.** AI/AN people have had substantially higher rates of COVID-19 cases and COVID-19–related deaths compared with people from most other racial and ethnic groups, underscoring the importance of vaccination for this population. Further data are needed to understand the severity of COVID-19 for AI/AN children regarding hospitalization, death, prolonged illness, and multisystem inflammatory syndrome in children (MIS-C) and other COVID-19 sequelae. See Coronavirus Disease 2019 (COVID-19), p 324.

Immunization in Adolescent and College Populations

Immunization recommendations for adolescents and college students have become routine and are reflected on the adolescent immunization schedule that is published annually (www.cdc.gov/vaccines/schedules/index.html). The adolescent and young adult population presents many immunization challenges, including less frequent visits for preventive care, missed opportunities to immunize when they present for sports physicals and sick visits, and scheduling conflicts because of age-appropriate activities. In addition, the ability of minors to consent to immunization varies by state. Providers should know and abide by the laws in their state governing minor consent for immunizations. The Society for Adolescent Health and Medicine has a position paper on adolescents consenting for vaccination and the potential impact on immunization rates (www.adolescenthealth.org/SAHM_Main/media/Advocacy/Positions/Oct-13-Consent-Vaccination.pdf). Updates on state laws are available from the Centers for Disease Control and Prevention (CDC).¹

All youth should have an annual comprehensive preventive health visit. Visits at 11 through 12 years of age and 16 through 18 years of age are especially important for administration of age-appropriate vaccines.² Additionally, all adolescent visits should be seen as opportunities to review each adolescent's immunization record in order to administer vaccines that may be due or overdue according to the recommended immunization schedule. The use of patient reminder and recall systems, provider reminders, and standing orders have been shown to increase immunization rates. Linking to state-wide or regional immunization information systems will facilitate keeping adolescents appropriately immunized. Lapses in the immunization schedule do not necessitate reinitiation of a vaccine series or extra doses for any vaccine.

Tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine (Tdap); serogroups A, C, W, and Y meningococcal vaccine (MenACWY); and human

¹ www.cdc.gov/php/publications/topic/vaccinationlaws.html

² American Academy of Pediatrics, Committee on Practice and Ambulatory Medicine, Bright Futures Periodicity Schedule Workgroup. 2023 recommendations for preventive pediatric health care. *Pediatrics*. 2023;151(4):e2023061451

papillomavirus (HPV) vaccine should be administered at the 11- through 12-year-old visit, although the HPV vaccine series can be started as early as 9 years of age (see below). Only 2 doses of human papillomavirus (HPV) vaccine are required for individuals whose first dose was given before their 15th birthday, while 3 doses are required for those starting HPV vaccination at 15 years or older and for immunocompromised persons (see Human Papillomaviruses, p 503). If possible, making appointments for subsequent doses of HPV vaccine at the conclusion of the first visit can enhance series completion. Providers can choose to begin the HPV vaccine series as early as 9 years of age if they deem this the optimal age to attain acceptance and completion prior to the risk of acquisition of HPV. When HPV vaccine is begun at 9 or 10 years, other adolescent vaccines (eg, MenACWY and Tdap) still are recommended to be initiated at 11 to 12 years. A MenACWY booster dose is recommended at 16 years of age. Serogroup B meningococcal vaccine (MenB) is not routinely recommended for adolescents in the absence of an outbreak or an underlying high-risk condition (eg, complement deficiency or asplenia) (see Meningococcal Infections, p 585), although vaccine providers may choose to administer a MenB vaccine to adolescents and young adults 16 through 23 years of age through shared clinical decision making with patients or their parents. When administered, the preferred age for MenB to be given is 16 through 18 years.

VACCINATION OF COLLEGE-AGED PEOPLE

A history should be obtained from all older adolescents to assess missing vaccines and risk factors that would require consideration for administration of additional vaccines, such as hepatitis A vaccine (HepA), MenB, *Haemophilus influenzae* type b vaccine (Hib), pneumococcal conjugate vaccine (PCV), and 23-valent pneumococcal polysaccharide vaccine (PPSV23). Specific indications for each of these vaccines are provided in the respective disease-specific chapters in Section 3.

Residential schools, colleges, and universities should establish a system to ensure all students are protected against vaccine-preventable diseases and also to identify unimmunized or underimmunized students in the event of an outbreak. Because outbreaks of vaccine-preventable diseases, including measles, mumps, meningococcal disease, and COVID-19, have occurred at colleges and universities, the American College Health Association encourages a comprehensive institutional prematriculation immunization policy consistent with recommendations from the CDC Advisory Committee on Immunization Practices (www.acha.org/ACHA/Resources/Topics/Vaccine.aspx). Many colleges and universities are mandated by state law to require vaccination for specific vaccines, either for all matriculating students or only those living in campus housing. Information regarding state laws requiring prematriculation immunization is available (www.immunize.org/laws).

The suspected occurrence of illness attributable to a vaccine-preventable disease in a school or college should be reported promptly to local health officials for aid in management, for assessment of public health implications, and to comply with state law (see Appendix III, Nationally Notifiable Infectious Diseases in the United States, p 1141).

Immunization in Health Care Personnel

People whose occupations place them in contact with patients with contagious diseases are at risk of contracting vaccine-preventable diseases and, if infected, transmitting them to their coworkers and patients. For the purposes of this section, health care

personnel (HCP) are defined as those who have face-to-face contact with patients or anyone who works in a building where patient care is delivered or is employed or contracted by a health care facility (eg, laboratory personnel). The definition of HCP includes trainees and volunteers. All HCP should protect themselves and susceptible patients by receiving appropriate immunizations. Physicians, health care facilities, and schools for health care professionals should play an active role in promoting policies to maximize immunization of HCP. Vaccine-preventable diseases of special concern to people involved in the health care of children are as follows (see the disease-specific chapters in Section 3 for further recommendations).

- **Pertussis.** Pertussis outbreaks involving adults occur in the community and the workplace. HCP frequently are exposed to *Bordetella pertussis*, have substantial risk of illness, and can be sources for spread of infection to patients, colleagues, families, and the community. HCP of all ages who work in hospitals or ambulatory care settings should receive a dose of tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine (Tdap) as soon as is feasible if they previously have not received Tdap. Hospitals and ambulatory care facilities should provide Tdap for HCP using approaches that maximize immunization rates.

Either Td or Tdap can be used regardless of prior receipt of Tdap for the routine decennial tetanus-diphtheria booster and for wound prophylaxis when indicated.

In addition, if there is an increased risk of pertussis in a health care setting, as evidenced by documented or suspected health care-associated transmission of pertussis, revaccination of HCP with Tdap vaccine may be considered (www.cdc.gov/vaccines/vpd/pertussis/tdap-revac-hcp.html). In these cases, it is important to consider that vaccinating HCP with Tdap is not a substitute for infection prevention and control measures, including postexposure antimicrobial prophylaxis, and therefore, revaccinated HCP still should receive postexposure antimicrobial prophylaxis when applicable. If implemented, HCP who work with infants or pregnant people should be prioritized for revaccination.

- **Hepatitis B.** Hepatitis B vaccine (HepB) is recommended for all HCP whose work- and training-related activities involve reasonably anticipated risk of exposure to blood or other infectious body fluids. The Occupational Safety and Health Administration (OSHA) of the US Department of Labor issued a regulation requiring employers of personnel at risk of occupational exposure to hepatitis B to offer HepB immunization to personnel at the employer's expense. The employer shall ensure that employees who decline to accept HepB immunization offered by the employer sign a declination statement. To determine the need for revaccination and to guide postexposure prophylaxis, postvaccination serologic testing should be performed for all recently vaccinated HCP at risk of occupational percutaneous or mucosal exposure to blood or body fluids. Postvaccination serologic testing is performed 1 to 2 months after administration of the last dose of the vaccine series using a method that allows detection of the protective concentration of hepatitis B surface antibody (anti-HBs ≥ 10 mIU/mL). People determined to have anti-HBs concentrations of ≥ 10 mIU/mL at any time after receipt of the primary vaccine series are considered immune and the result should be documented. Future testing is not required.

Although vaccine-induced anti-HBs wanes over time, protection persists for immunocompetent vaccine responders (eg, those with anti-HBs ≥ 10 mIU/mL at

their postvaccination serologic testing). Therefore, testing HCP for anti-HBs years after vaccination (eg, when HepB vaccination was received as part of routine infant immunization) might not distinguish vaccine responders from nonresponders. Preexposure assessment of anti-HBs results at the time of hiring or matriculation, followed by one or more additional doses of HepB vaccine when needed helps to ensure that remotely vaccinated HCP will be protected. HCP who lack documentation of prior immunity to hepatitis B and who have anti-HBs <10 mIU/mL should be reimmunized with a single dose of vaccine and retested for anti-HBs within 1 to 2 months after that dose. HCP whose anti-HBs remains <10 mIU/mL should receive additional doses to complete the second vaccine series. For the 3-dose vaccine series using Engerix-B, PreHevbrio, or Recombivax HB, this would require 2 additional doses of vaccine, and for the 2-dose series using Heplisav-B, this would require 1 additional dose. For very recently vaccinated HCP with anti-HBs <10 mIU/mL, in whom the low antibody concentration is more likely to reflect a failure to respond rather than waning antibody concentration, it may be more practical to revaccinate with an entire second series (3 doses of Engerix-B, PreHevbrio, or Recombivax HB; 2 doses of Heplisav-B) followed by anti-HBs testing 1 to 2 months after the last dose. Heplisav-B or PreHevbrio may be used for revaccination following an initial HepB vaccine series that consisted of doses from a different manufacturer.^{1,2}

People who do not respond to the second series and remain hepatitis B surface antigen (HBsAg) negative should be considered susceptible to hepatitis B virus infection and will need to receive hepatitis B immune globulin (HBIG) prophylaxis after any known or probable exposure to blood or body fluids infected with hepatitis B virus.

- **Influenza.** Because HCP can transmit influenza to patients and because health care-associated outbreaks of influenza do occur, annual influenza immunization should be considered a patient safety responsibility and a requirement for employment in a health care facility unless an individual has a recognized medical contraindication to immunization.³ HCP should be educated about the benefits of influenza immunization and the potential health consequences of influenza illness for themselves and their patients. Influenza vaccine should be offered at no cost, and efforts should be made to ensure that vaccine is readily available to HCP on all shifts. A signed declination form should be obtained from personnel who decline for reasons other than medical contraindications in any facility that does not have a mandatory vaccine policy. Mandatory education about the benefits of vaccination should be required for all people who decline influenza immunization. Any approved influenza vaccine product is appropriate if otherwise indicated with the exception of live attenuated vaccine, which should not be used for personnel who will have close contact

² Schillie S, Harris A, Link-Gelles R, et al. Recommendations of the Advisory Committee on Immunization Practices for Use of a Hepatitis B Vaccine with a Novel Adjuvant. *MMWR Morb Mortal Wkly Rep*. 2018;67(15):455–458

³ American Academy of Pediatrics, Committee on Infectious Diseases. Policy statement: Influenza immunization for all health care personnel: keep it mandatory. *Pediatrics*. 2015;136(4):809–818

with patients with altered immunocompetence who are in a protected environment; HCP receiving LAIV should avoid close contact with these immunocompromised people for 7 days following vaccination.

- **COVID-19.** Because HCP can transmit SARS-CoV-2 to patients and because health care-associated transmission of COVID-19 does occur, COVID-19 immunization should be considered a patient safety responsibility and a requirement for employment in a health care facility unless an individual has a recognized medical contraindication to immunization. HCP should be educated about the benefits of COVID-19 immunization and the potential health consequences of COVID-19 illness for themselves and their patients. COVID-19 vaccine should be offered at no cost, and efforts should be made to ensure that vaccine is readily available to HCP on all shifts. A signed declination form should be obtained from personnel who decline for reasons other than medical contraindications in any facility that does not have a mandatory vaccine policy. Mandatory education about the benefits of vaccination should be required for all people who decline COVID-19 immunization. HCP can receive any FDA-approved or -authorized vaccine. It is important that HCP be up to date with their COVID-19 vaccine series based on the latest CDC guidance.¹
- **Measles.** Because measles in HCP has contributed to spread of this disease during outbreaks, evidence of immunity to measles should be required for HCP. Evidence of immunity is established by laboratory confirmation of infection, laboratory evidence of immunity (positive serologic test result for measles antibody), or documented receipt of 2 appropriately spaced doses of live virus-containing measles vaccine, the first of which was administered on or after the first birthday. People born before 1957 generally are considered immune to measles. However, because measles cases have occurred in HCP in this age group, health care facilities should consider offering 2 doses of measles-containing vaccine to HCP who lack proof of immunity to measles. In communities with documented measles outbreaks, 2 doses of MMR vaccine are recommended for unvaccinated HCP born before 1957 unless evidence of serologic immunity is demonstrated.
- **Mumps.** All people who work in health care facilities should be immune to mumps. Evidence of immunity is established by laboratory confirmation of infection, laboratory evidence of immunity (positive serologic test result for mumps antibody), documented receipt of 2 appropriately spaced doses of live virus-containing mumps vaccine, the first of which was administered on or after the first birthday, or birth before 1957. During an outbreak, a second dose of MMR vaccine should be offered to HCP born during or after 1957 who have only received 1 dose of MMR vaccine. HCP born before 1957 without a history of MMR immunization should obtain a mumps antibody titer to document their immune status and, if negative, should receive 2 appropriately spaced doses of MMR vaccine.
- **Rubella.** Transmission of rubella from HCP to pregnant individuals has been reported. Although the disease is mild in adults, the risk to a fetus necessitates documentation of rubella immunity in all HCP. People should be considered immune on the basis of a positive serologic test result for rubella antibody or documented proof of 1 dose of rubella-containing vaccine. A history of rubella disease is unreliable and should not be used in determining immune status. All susceptible HCP who may be exposed to patients with rubella or who take care of pregnant patients, as

¹ www.cdc.gov/coronavirus/2019-ncov/vaccines/stay-up-to-date.html

well as people who work in educational institutions or provide child care, should be immunized with 1 dose of MMR to prevent infection for themselves and to prevent transmission of rubella to pregnant patients.

- **Varicella.** Evidence of varicella immunity is recommended for all HCP. Evidence of immunity to varicella in HCP includes any of the following: 1) documentation of 2 doses of varicella vaccine at least 28 days apart, the first of which was administered on or after the first birthday; 2) history of varicella diagnosed or verified by a physician (for a patient reporting a history of or presenting with an atypical case, a mild case, or both, the physician should seek either an epidemiologic link with a typical varicella case or evidence of laboratory confirmation, if it was performed at the time of acute disease); 3) history of herpes zoster diagnosed by a physician; or 4) laboratory evidence of immunity or laboratory confirmation of disease. Birth in the United States before 1980 should not be considered as evidence of immunity for HCP, pregnant women, or immunocompromised people (www.cdc.gov/chickenpox/hcp/immunity.html). The Centers for Disease Control and Prevention's Advisory Committee on Immunization Practices (ACIP) and Health Infection Control Practices Advisory Committee (HICPAC) do not recommend serologic testing of HCP for immunity to varicella after receiving varicella-zoster virus vaccine, because commercially available serologic assays may not be sufficiently sensitive to detect immunization-induced antibody.
- **Meningococcus.** Meningococcal vaccination is not recommended for HCP performing direct patient care. However, clinical microbiologists routinely exposed to isolates of *Neisseria meningitidis* are at increased risk of severe meningococcal disease if exposed to a clinical isolate and should be vaccinated with serogroups A, C, W, and Y meningococcal vaccine (MenACWY) and serogroup B meningococcal vaccine (MenB).
- **Poliovirus.** The recent detections of circulating vaccine-derived poliovirus in the United States, decades after poliovirus was eliminated from the country, raises the possibility of the infection of HCPs with either wild-type or vaccine-related polioviruses while caring for patients in areas of the United States where poliovirus has been detected and circulating. The majority of adults born after 1955 are protected against poliomyelitis because they were vaccinated during childhood. HCPs who have had 3 or more doses of poliovirus vaccine previously and are at increased risk of exposure to poliovirus may receive 1 lifetime booster dose of non-live poliovirus vaccine (IPV). Unvaccinated or incompletely vaccinated HCPs should complete the poliovirus vaccination series with IPV (www.cdc.gov/vaccines/vpd/polio/hcp/recommendations.html).

Children Who Received Immunizations Outside the United States or Whose Immunization Status is Unknown or Uncertain

IMMUNIZATIONS RECEIVED OUTSIDE THE UNITED STATES

People immunized in other countries, including international students, internationally adopted children, refugees, and other immigrants, should be immunized according to recommended schedules (including minimal ages and intervals) in the United

States (www.cdc.gov/vaccines/schedules/index.html). The Immigration and Nationality Act (INA) of 1996 requires all people immigrating to the United States as legal permanent residents (ie, green card holders) to provide “proof of vaccination” with vaccines recommended by the Centers for Disease Control and Prevention (CDC) Advisory Committee on Immunization Practices (ACIP) before entry into the United States. Vaccines required for immigration must fulfill the following criteria: 1) must be an age-appropriate vaccine as recommended by the ACIP for the general US population; and 2) either must protect against a disease that has the potential to cause an outbreak or protect against a disease that has been eliminated or is in the process of being eliminated in the United States. For example, human papillomavirus (HPV) vaccine is not required. For vaccination instructions, including the list of required vaccines, see www.cdc.gov/immigrantrefugeehealth/panel-physicians/vaccinations.html.

Internationally adopted children who are 10 years and younger may obtain a waiver of exemption from the INA regulations pertaining to immunization of immigrants before arrival in the United States (www.cdc.gov/immigrantrefugeehealth/adoption/overseas-exam.html). Children adopted from countries that are not part of the Hague Convention can receive waivers to have their immunizations delayed until arrival in the United States (<https://travel.state.gov/content/travel/en/Intercountry-Adoption/Adoption-Process/understanding-the-hague-convention.html>). When an exemption is granted, adoptive parents are required to sign an affidavit indicating their intention to comply with ACIP-recommended immunizations within 30 days after the child arrives in the United States.

Refugees are not required to meet immunization requirements of the INA at the time of initial entry into the United States but must show proof of immunization when they apply for permanent residency, typically 1 year after arrival. Some refugees bound for the United States are immunized in their country of departure before arrival in the United States. Clinicians may review the CDC Refugee Health Guidelines for the current overseas immunization schedule for US-bound refugees at www.cdc.gov/immigrantrefugeehealth/guidelines/refugee-guidelines.html. Guidance on evaluating and updating immunizations during the domestic medical examination for refugees after arrival in the United States is available at www.cdc.gov/immigrantrefugeehealth/guidelines/domestic/immunizations-guidelines.html.

An increasing number of vaccines are being incorporated into routine immunization schedules in countries outside the United States. In general, written documentation of immunizations can be accepted as evidence of previous immunization if the vaccines, dates of administration, number of doses, intervals between doses, and age of the child at the time of immunization are comparable to current US or World Health Organization schedules (www.who.int/immunization/policy/immunization_tables/en/). Doses of vaccines that do not comply with US schedules may need to be repeated (such as MMR before age 1 year). Any vaccination documented on the official Department of State health immigration form (DS-3025) should be accepted. Inaccuracies, inconsistencies, and fraudulent data (such as doses given before the date of birth, or different names or dates of birth on vaccine records compared with other official documents) should be considered during review of records.

Record review also should include consideration of ACIP recommendations for poliovirus vaccination, which require protection against all 3 poliovirus types by

age-appropriate vaccination with non-live poliovirus (IPV) or trivalent oral poliovirus (tOPV) vaccines. Some countries may have provided monovalent or bivalent oral poliovirus (OPV) vaccine during poliovirus vaccination campaigns after April 1, 2016. If OPV was administered before April 1, 2016, OPV can be counted as tOPV. If OPV was administered on or after April 1, 2016, it may not be counted as tOPV and is not valid toward US vaccination requirements; in the absence of adequate written vaccination records documenting the doses as tOPV, vaccination or revaccination in accordance with the age-appropriate US IPV schedule is recommended (see Poliovirus Infections, p 682, for further recommendations).

Studies performed in internationally adopted children are inconclusive with regard to the extent to which the child's immunization record reflects protection. Many children adopted internationally lived in institutional settings where there was extremely limited capacity to store, administer, and record vaccines safely and accurately. Vaccine records of internationally adopted children should be assessed considering these capacities in the child's prior location. Re-immunizing or using serologic verification may be indicated when these uncertainties exist, even if there is a written immunization record.

Limited country-specific data are available regarding serologic verification of immunization records for other categories of immigrant children. Evaluation of concentrations of antibody to vaccine-preventable diseases can be useful in some circumstances to ensure that vaccines were administered and were immunogenic and to document immunity from past infection (see Serologic Testing to Document Immunization Status).

UNKNOWN OR UNCERTAIN IMMUNIZATION STATUS IN US CHILDREN

There are circumstances in which the immunization status for a child born in the United States is uncertain or unknown because of lack of documentation, an incomplete or inaccurate record, or a recording inconsistent with a recommended product or schedule. Serologic testing can be considered to assist in determining whether antibody concentrations are present for some of the vaccine-preventable diseases (see Serologic Testing to Document Immunization Status). A combined strategy of serologic testing for antibodies to some vaccine antigens and immunization for others may be used, or the vaccines may be repeated, administering those appropriate for the child's current age.

SEROLOGIC TESTING TO DOCUMENT IMMUNIZATION STATUS

Usefulness, validity, and interpretation of serologic testing to guide management of vaccinations can be complex and varies by age (Table 1.19). Cost and effort of testing versus cost of administering a given immunization, complexity of interpretation of results, and likelihood of adherence for completing the immunization series should be considered in these decisions. If serologic testing is not available, is too costly, or if a positive result would not mitigate need for further immunization, the prudent course is to repeat or administer the immunizations in question. Some state laws stipulate that only certain serologic tests are accepted for school attendance; testing may not be worthwhile in this circumstance, as vaccine will still be needed. Considerations for specific vaccines are discussed below.

Table 1.19. Utility of Antibody Testing for Vaccine-Preventable Diseases in Unimmunized or Underimmunized Children^a

Vaccine	Immunize Without Testing in Most Circumstances	Antibody Testing Available and Appropriate in Specific Circumstances	Antibody Testing Available but not Generally Performed	Considerations for Use of Testing	Notes
COVID-19	X		X		
Dengue		X		A positive test result or a history of laboratory-confirmed dengue infection is required prior to immunization with dengue vaccine	Recommended for individuals 9 through 16 years of age who reside in areas with endemic dengue and who have a history of a laboratory-confirmed dengue infection or a positive result of a highly accurate serodiagnostic screening test
Diphtheria	X		X	To confirm receipt of documented vaccine; to document response to vaccine	May not be affordable by all patients; may result in immunization delay
Hepatitis A	X	X		Not useful for children <1 y because of transplacentally acquired antibody; most appropriate for older children, history of jaundice, or birth in or migration through high-prevalence areas	Testing may be cost-effective in circumstances of high pretest probability of positive antibody

Table 1.19. Utility of Antibody Testing for Vaccine-Preventable Diseases in Unimmunized or Underimmunized Children,^a continued

Vaccine	Immunize Without Testing in Most Circumstances	Antibody Testing Available and Appropriate in Specific Circumstances	Antibody Testing Available but not Generally Performed	Considerations for Use of Testing	Notes
Hepatitis B	X	X		May identify immunity from prior hepatitis B infection or from prior vaccination	An anti-HBs of ≥ 10 mIU/mL is considered protective only when measured after documented vaccine series completion
Hib	X		X	To confirm receipt of documented vaccine in children ≥ 6 mo; to document response to vaccine	May not be affordable by all patients; may result in immunization delay; not appropriate for children ≥ 5 y
HPV	X		X		
Influenza	X		X		
Measles	X		X	Not useful for children < 1 y because of transplacentally acquired antibody	May not be affordable by all patients; may result in immunization delay; most informative if tests for mumps and rubella also performed
Meningococcus	X		X		
Mumps	X		X	Not useful for children < 1 y because of transplacentally acquired antibody	May not be affordable by all patients; may result in immunization delay; most informative if tests for measles and rubella also performed

Table 1.19. Utility of Antibody Testing for Vaccine-Preventable Diseases in Unimmunized or Underimmunized Children,^a continued

Vaccine	Immunize Without Testing in Most Circumstances	Antibody Testing Available and Appropriate in Specific Circumstances	Antibody Testing Available but not Generally Performed	Considerations for Use of Testing	Notes
PCV	X				
Pertussis	X		X		
Poliovirus	X		X		
Rotavirus	X		X		
Rubella	X		X	Not useful for children <1 year because of transplacentally acquired antibody	May not be affordable by all patients; may result in immunization delay; most informative if tests for measles and mumps also performed
Tetanus	X		X	To confirm receipt of documented vaccine; to document response to vaccine	May not be affordable by all patients; may result in immunization delay
Varicella	X	X		Not useful for children <1 y because of transplacentally acquired antibody; most appropriate for older children or history of varicella in patient or close family members	Testing may be cost-effective in circumstances of high pretest probability of positive antibody

anti-HBs indicates hepatitis B surface antibody; Hib, *Haemophilus influenzae* type b; HPV, human papillomavirus vaccine; PCV, pneumococcal conjugate vaccine.

^aSee the disease-specific chapters in Section 3 for additional information.

When validity of immunization records is in doubt, or when documentation of response to vaccine is desired for other reasons in children 6 months or older, serologic testing to document antibodies to diphtheria and tetanus toxoids (ie, ≥ 0.1 IU/mL) or *Haemophilus influenzae* type b for a child younger than 60 months (ie, ≥ 1.0 μ g/mL) may be considered to determine whether the child likely has received and responded to dose(s) of the vaccine in question. Even if the child has a “protective” level of antibodies, the immunization series should be completed as appropriate for that child’s age. If a child does not have a protective level of antibodies, the series should be restarted, with the understanding that for some vaccine-preventable diseases, fewer doses of vaccine are needed to complete the series as a child ages. The immunization record, plus presence of antibody to diphtheria and tetanus toxoids, can be used as proxy for receipt of pertussis-containing vaccine dose(s).

Hepatitis A, measles, mumps, rubella, and varicella antibody concentrations could be measured in children 12 months or older to determine whether the child is immune; these antibody tests should not be performed in children younger than 12 months because of the potential presence of maternal antibody. Prevaccination serologic testing is not recommended for hepatitis A, but children who were born or migrated through regions with high prevalence of hepatitis A may have had hepatitis A infection, and presence of immunoglobulin (Ig) G-specific antibody to hepatitis A virus in such patients would preclude need for hepatitis A vaccine. Usefulness of measuring measles antibody alone is limited, because many foreign-born children will need mumps and rubella vaccines as these vaccines are administered less frequently in resource-limited countries and they are available in the United States only as MMR vaccine. Two doses of MMR vaccine should be administered for mumps coverage, even if measles antibodies are present. Rubella coverage is achieved following 1 dose of a rubella-containing vaccine. Documented receipt of 2 doses of varicella vaccine or positive varicella antibody is the best indication of immunity to varicella. *H influenzae* type b vaccine (Hib) is not indicated for immunocompetent children 5 years or older, even if none was administered previously; serologic testing should not be performed, because children in this age group frequently have antibody concentrations <1.0 μ g/mL yet are not susceptible to *H influenzae* type b infection. Age-appropriate pneumococcal vaccine dose(s) should be administered if a completed series is not documented; serologic testing should not be performed for validation or evidence of immunity. Serologic tests to assess immunity to poliovirus and rotavirus are not recommended.

Hepatitis B requires additional considerations when considering testing for antibody. Hepatitis B antibody testing is not indicated routinely before immunization of children or adolescents. High seroconversion rates and protective concentrations of hepatitis B surface antibody (anti-HBs [≥ 10 mIU/mL]) are achieved when HepB vaccine is administered in any of the recommended schedules, including schedules begun soon after birth in term infants. Serologic testing for identifying HBV infection (positive HBsAg) is indicated in specific circumstances, including an infant whose birthing parent is HBsAg positive, foreign-born individuals, and those in risk groups for hepatitis B infection. Before immunizing with hepatitis B vaccine without testing, children should be assessed for risk of hepatitis B infection and tested for infection if risk is present (see Serologic Testing section of Hepatitis B chapter, p 448).

International Travel

Children are at risk for illness when traveling internationally, and some may require medical care or hospitalization. US-born children of immigrants are especially likely to travel at young ages to visit relatives. A pretravel consultation with a health care professional who is knowledgeable or specializes in travel medicine can mitigate risk of travel-associated health problems but requires advance planning to allow time to complete necessary vaccinations and obtain necessary medications. Parents should be made aware that there is increased risk of exposure to vaccine-preventable diseases when traveling outside the United States, even in middle and high-income countries perceived to be without substantial risk of infectious diseases. Routine immunizations should be up-to-date before international travel; some may be administered early or on an accelerated schedule to optimize protection. Vaccines to prevent typhoid fever, yellow fever, meningococcal disease, rabies, Japanese encephalitis (JE), tick-borne encephalitis (TBE), and cholera may be indicated depending on the age of the child, destination, season of travel, duration of the trip, and activities during travel (see disease-specific chapters in Section 3). Families should arrange travel consultation to occur at least 4 to 6 weeks before planned departure, because travel vaccines may not be available at all sites and some vaccines, such as JE, TBE, and rabies vaccines, require multiple doses before departure.

Travelers also may be at risk for exposure to malaria, dengue, chikungunya, Zika, other mosquito-borne and tick-borne infections, diarrheal and respiratory illnesses, and skin conditions for which vaccines are not available. Although a dengue vaccine was licensed in 2019 by the US Food and Drug Administration (FDA) for use in individuals 9 through 16 years of age who reside in areas with endemic dengue and who have laboratory confirmation of a previous dengue infection, no dengue vaccine is licensed currently for travelers. Antimalarial chemoprophylaxis is recommended for travelers to areas with endemic malaria, and insect precautions should be addressed for all travelers at risk of vectorborne diseases. Attending to hand hygiene, choosing safer foods, and limiting exposure to animals, contaminated sand, soil, and water may reduce travelers' risk of acquiring other diseases.

Up-to-date information, including CDC Travel Health Notices about current disease outbreaks that may affect international travelers, is available on the CDC Travelers' Health website (wwwnc.cdc.gov/travel/). Country-level information can be quickly accessed at wwwnc.cdc.gov/travel/destinations/list. Disease Outbreak News can be found on the WHO website (www.who.int/emergencies/disease-outbreak-news). *Health Information for International Travel* (the "Yellow Book," wwwnc.cdc.gov/travel/page/yellowbook-home) is revised every 2 years by the CDC and is available to travelers and health professionals. Local and state health departments and travel clinics¹ also can provide updated information. Many colleges have clinics where pretravel counseling and immunizations can be obtained. Information about cruise ship sanitation inspection scores and reports can be found on the CDC website (www.cdc.gov/nceh/vsp/default.htm).

¹ Sources for travel clinics: Center for Disease Control and Prevention (wwwnc.cdc.gov/travel/page/find-clinic), American Society of Tropical Medicine and Hygiene (www.astmh.org/for-astmh-members/clinical-consultants-directory), and International Society for Travel Medicine (www.istm.org/AF_CstmClinicDirectory.asp).

RECOMMENDED IMMUNIZATIONS

Infants and children traveling internationally should be up-to-date with immunizations recommended for their age. Some vaccines may be administered before the age of routine immunization (hepatitis A vaccine [HepA]; meningococcal conjugate vaccine; measles, mumps, and rubella vaccine [MMR]) or be administered on an accelerated schedule (MMR) to optimize immunity before departure.

COVID-19. SARS-CoV-2 is the respiratory virus that causes COVID-19. Immunization is recommended for all children ≥ 6 months of age and should be completed before travel. Risk of acquiring COVID-19 during travel depends on personal safety measures, destination, and characteristics of the trip (see Coronavirus Disease-2019 [COVID-19], p 324). Some countries may have vaccination or testing requirements for entry (see <https://travel.state.gov/content/travel/en/international-travel/International-Travel-Country-Information-Pages.html>).

HEPATITIS A. HepA is recommended routinely in a 2-dose series ≥ 6 months apart for all children at 12 through 23 months of age in the United States, with catch-up vaccination recommended through 18 years of age. HepA also is recommended for all people ≥ 6 months of age who are unimmunized and traveling to areas with intermediate or high rates of hepatitis A infection (see Table 3.19, p 435), although some travel medicine experts provide vaccine even to those traveling to areas with low prevalence. For children 6 through 11 months of age, a dose of HepA does not count toward the routine 2-dose series, which should be started at age 12 months. Immune globulin intramuscular (IGIM) is recommended for hepatitis A preexposure prophylaxis prior to travel for infants < 6 months of age. People with chronic liver disease as well as adults aged > 40 years, immunocompromised people, and people with other chronic medical conditions planning to depart to an area with high or intermediate hepatitis A endemicity in < 2 weeks should receive the initial dose of HepA vaccine and also simultaneously may receive IGIM at a separate anatomic injection site (www.cdc.gov/mmwr/volumes/67/wr/mm6743a5.htm). The dose of IGIM administered for hepatitis A prevention may interfere with the immune response to varicella and MMR vaccines for several months (see Table 1.11, p 69, for details). A combination HepA-HepB (hepatitis B) vaccine (Twinrix) is available for people 18 years and older.

HEPATITIS B. HepB is recommended for all children and adults through age 59 years in the United States and for people traveling to areas where the prevalence of chronic hepatitis B virus infection is 2% or greater (see Hepatitis B, p 437). Ideally, HepB vaccination should be administered ≥ 6 months before travel so that a 3-dose regimen can be completed. If fewer than 4 months are available before departure, the alternative 4-dose schedule of 0, 1, 2, and 12 months, licensed for the Engerix-B vaccine (see Table 3.21, p 445), can be considered. Individual health care providers also may choose to use an accelerated schedule (eg, 0, 1, and 2 months; or 0, 2, and 4 months) for travelers who will depart before an approved immunization schedule can be completed. An accelerated schedule of Twinrix (doses at days 0, 7, and 21–30, with a booster at 12 months) is available for those ≥ 18 years of age. People who receive immunization on an accelerated schedule that is not licensed by the FDA also should receive a dose at 12 months after initiation of the series to promote long-term immunity. For adults, the 2-dose regimen of Heplisav-B can be completed in 1 month.

MEASLES. Travelers are an important source of measles cases in the United States. People traveling anywhere outside the United States should be immune to measles to provide personal protection and minimize importation. Immunity to measles is defined by laboratory confirmation of prior infection; laboratory evidence of immunity (positive serologic test result for measles antibody); documented receipt of 2 appropriately spaced doses of live virus-containing measles vaccine, the first of which was administered on or after the first birthday; or birth in the United States before 1957 (see Measles, p 570). Children who travel anywhere outside the United States should be vaccinated beginning at 6 months of age. Children 6 through 11 months of age should receive 1 dose of MMR vaccine at least 2 weeks before departure if possible, and then should receive a second dose of measles-containing vaccine at 12 through 15 months of age (at least 28 days after the initial measles immunization) and a third dose at 4 through 6 years of age. Children 12 months or older as well as adults who have received 1 dose and are traveling outside the United States should receive their second dose before departure, provided the interval between doses is 28 days or more. MMR should not be administered to pregnant individuals, and pregnancy should be avoided for 28 days following the receipt of MMR. Live-virus vaccines (MMR, varicella, yellow fever) generally either should be administered on the same day or should be separated by at least 4 weeks, and attention should be paid to the timing of immune globulin product administration if these are indicated (see Simultaneous Administration of Multiple Vaccines, p 63, and Table 1.11, p 69).

POLIOVIRUS. Significant efforts have been made to achieve global eradication of poliovirus, but spread continues in some areas. Travelers should be up-to-date with poliovirus immunization for age before travel. Travelers to countries with wild-type or vaccine-derived poliovirus circulation (<http://polioeradication.org/polio-today/polio-now/public-health-emergency-status/>) within the past 12 months may require additional doses of vaccine according to current CDC guidance. Travelers 18 years or older visiting regions identified on the CDC Travelers' Health website (wwwnc.cdc.gov/travel) as being at risk for circulation of poliovirus should receive a single lifetime booster dose of non-live poliovirus vaccine (IPV). Current recommendations should be verified before departure (wwwnc.cdc.gov/travel/yellowbook/2024/infections-diseases/poliomyelitis).

TRAVEL-RELATED IMMUNIZATIONS

Other immunizations may be required or recommended for international travelers depending on factors such as destination, planned activities, and length of stay (see wwwnc.cdc.gov/travel/, wwwnc.cdc.gov/travel/destinations/list, and disease-specific chapters in Section 3).

CHOLERA. An oral cholera vaccine (Vaxchora [CVD 103-HgR, PaxVax Bermuda Ltd, Redwood City, CA]) is approved in the United States for use in people 2 through 64 years of age. Vaccine is not recommended routinely for most travelers. Immunization is recommended for travelers going to areas with active cholera transmission (wwwnc.cdc.gov/travel/news-announcements/cholera-vaccine-for-travelers).

INFLUENZA. Influenza immunization is recommended for travelers ≥ 6 months of age and may be needed outside the times when annual influenza immunization is recommended in the United States. Influenza season is different in the northern and southern hemispheres and epidemic strains may differ. Antigenic composition of influenza vaccines used in Northern and Southern hemispheres may be different, and timing of administration may vary (see Influenza, p 511).

JAPANESE ENCEPHALITIS.¹ Japanese encephalitis (JE) virus, a mosquito-borne Flavivirus, is the most common vaccine-preventable cause of encephalitis in Asia. Risk of JE is low for most travelers to Asia but varies based on destination, duration, season, accommodations, and activities (wwwnc.cdc.gov/travel/yellowbook/2024/infections-diseases/japanese-encephalitis). Travelers to countries with endemic JE in Asia, Oceania, and Australia should be informed about the disease and should use personal protective measures to reduce the risk of mosquito bites, especially during the night. JE vaccine can reduce the risk for infection further, and is recommended for those taking up residence in a JE endemic country, longer-term travelers (eg, a month or longer), and frequent travelers to areas with endemic JE. JE vaccine also should be considered for shorter-term travelers if they plan to travel outside of an urban area and have an itinerary or activities that will increase their risk of mosquito exposure in an area with endemic infection. Information on the location of JE virus transmission and detailed information on vaccine recommendations and adverse events can be obtained from the Centers for Disease Control and Prevention (CDC [www.cdc.gov/vaccines/hcp/acip-recs/vacc-specific/je.html]).

An inactivated Vero cell culture-derived JE virus vaccine (Ixiaro) is approved and available in the United States for use in adults and children 2 months and older. The primary vaccination series for children and adolescents aged < 18 years is 2 doses administered 28 days apart. An interval of as short as 7 days may be used for travelers 18 to 65 years of age with imminent departures. A booster dose may be administered at 1 year or longer after the primary series if ongoing exposure or reexposure is expected.

MENINGOCOCCUS. Meningococcal conjugate vaccines against serogroups A, C, W, and Y (MenACWY) are recommended for use in people age ≥ 2 months traveling to areas where there is a high burden of meningococcal disease, such as the “meningitis belt” of sub-Saharan Africa where disease is more common during the dry season (December to June), or other areas of the world with ongoing meningococcal outbreaks. Meningococcal conjugate vaccines vary in conjugating protein, ages of approved use, and dosing schedules. The following MenACWY vaccines are available for travelers: MenACWY-CRM (Menveo; ages 2 months through 55 years of age), and MenACWY-TT (MenQuadfi; ages 2 years and older). Completion of the entire series before travel is preferred. Booster doses are recommended for people who are at continuous or repeated increased risk of meningococcal infection—after 3 years for those who received their last dose at < 7 years of age and after 5 years for those who received their last dose at ≥ 7 years of age, and every 5 years thereafter for people at

¹ Hills SL, Walter EB, Atmar RL, Fischer M. Japanese encephalitis vaccine: recommendations of the Advisory Committee on Immunization Practices. *MMWR Recomm Rep.* 2019;68(RR-2):1–33

continued risk. The Kingdom of Saudi Arabia requires an International Certificate of Vaccination or Prophylaxis (ICVP) documenting immunization against meningococcal serogroups A, C, W, and Y for pilgrims attending the Hajj or Umrah pilgrimages (www.saudiembassy.net/hajj-and-umrah-health-requirements). Immunization against serogroup B meningococcal disease is not recommended routinely for travel unless there are other indications to provide this vaccine or there is an outbreak at the travel destination (see Meningococcal Infections, p 585).

RABIES. The mainstay of prevention of rabies is education of families about avoidance of animals and the need for immediate medical care if a bite or other exposure occurs. Rabies preexposure prophylaxis should be considered for children who will be traveling to areas with endemic rabies where they may encounter wild or domestic animals (particularly dogs). Preexposure prophylaxis consists of a 2-dose series of rabies vaccine administered on days 0 and 7, by intramuscular injection (see Rabies, p 702, and www.cdc.gov/mmwr/volumes/71/wr/mm7118a2.htm). Postexposure prophylaxis includes cleaning wounds thoroughly with soap and water and then receiving postexposure prophylaxis promptly (PEP; see Rabies, p 702). For individuals who have not received the 2 doses of vaccine for preexposure prophylaxis, PEP consists of rabies immune globulin (RIG), 20 IU/kg infiltrated into the wound (if this dose is too much to infiltrate the full amount into the wound, the remaining RIG is injected intramuscularly), plus 4 doses of rabies vaccine (days 0, 3, 7, and 14). For those who have received preexposure prophylaxis, 2 doses of rabies vaccine (days 0 and 3) is sufficient for PEP. The need for boosters after completion of the 2-dose preexposure series will depend on the ongoing or future risk for exposure and rabies antibody titers, if done. The WHO has recommended use of intradermal rabies immunization as an alternative to intramuscular administration to reduce costs, but the FDA and the Advisory Committee on Immunization Practices (ACIP) of the CDC have not endorsed this recommendation. Travelers can be informed that the treatment they may be offered for an exposure outside the United States may differ from what they would receive in the United States.

TICK-BORNE ENCEPHALITIS. Tick-borne encephalitis (TBE) occurs in parts of the region stretching from western and northern Europe through northern and eastern Asia. Risk for TBE for most travelers to areas with endemic infection is very low, but some individuals are at increased risk for infection based on the season and location of travel and their activities, including consumption of unpasteurized dairy products. All people who travel to areas with endemic TBE should be advised to take precautions to avoid tick bites (see Prevention of Mosquito-borne and Tick-borne Infections, p 207) and to avoid unpasteurized milk and cheese. An inactivated TBE vaccine is available in the United States for use in adults and children 1 year and older. The primary vaccination series for children and adolescents aged <16 years consists of doses on day 0 (dose 1), at 1–3 months after the first vaccination (dose 2), and 5–12 months after the second vaccination (dose 3). The schedule for people 16 years and older is similar, but dose 2 can be administered as early as 14 days after dose 1. A booster dose may be administered at least 3 years after completion of the primary series if ongoing exposure or reexposure is expected. TBE vaccine is recommended for people who are moving or traveling to an area with endemic TBE and will have extensive exposure to ticks based on their planned outdoor activities and itinerary. TBE vaccine also may be considered

for others who might engage in outdoor activities in areas ticks are likely to be found, with the decision to vaccinate based on an assessment of their planned activities and itinerary, risk factors for a poorer medical outcome, and personal perception and tolerance of risk. Information on the location of TBE virus transmission and detailed information on risk factors for infection and vaccine considerations can be found on the CDC website (www.cdc.gov/tick-borne-encephalitis/index.html).

TUBERCULOSIS. Risk of being infected with *Mycobacterium tuberculosis* during international travel depends on the activities of the traveler, duration of travel, and the epidemiology of tuberculosis at the destination. Risk of acquiring infection during usual tourist activities appears to be low, and pre- or post-travel testing is not recommended routinely. Risk may be higher for travelers living or working among the general population of a country with a high prevalence of tuberculosis (www.who.int/publications/digital/global-tuberculosis-report-2021/tb-disease-burden/incidence). Children with a history of significant travel to countries with endemic tuberculosis infection who have substantial contact with the resident population should be tested with an interferon-gamma release assay (IGRA) or a tuberculin skin test (TST). Some experts define significant travel as birth, travel, or residence in a country with an elevated tuberculosis rate for at least 1 month. If the child is well and has no history of exposure, the IGRA or TST should be delayed for 10 weeks after return. Pretravel administration of bacille Calmette-Guérin vaccine generally is not recommended.

TYPHOID. Typhoid vaccine is recommended for travelers who may be exposed to contaminated food or water. Two typhoid vaccines are available in the United States: an oral vaccine containing live attenuated *Salmonella enterica* serovar Typhi (Ty21a strain), approved for people 6 years and older (the capsules must be swallowed whole), and a parenteral Vi capsular polysaccharide (ViCPS) vaccine, approved for people 2 years and older. The Ty21a vaccine consists of 1 enteric-coated capsule taken every other day for a total of 4 capsules; the series should be completed at least 1 week before anticipated exposure. The ViCPS vaccine is administered as a single intramuscular injection that should be given at least 2 weeks before anticipated exposure. Typhoid immunization is not 100% effective; both vaccines protect 50% to 80% of recipients and do not provide adequate protection against paratyphoid fever. Revaccination is recommended 5 years after Ty21a vaccine and 2 years after ViCPS vaccine if continued or subsequent exposure to *Salmonella enterica* serovar Typhi is expected. Reimmunization includes the 4-capsule Ty21a oral vaccine or receiving 1 intramuscular dose for the ViCPS parenteral vaccine. For specific recommendations, see *Salmonella* Infections (p 742). The oral live-attenuated Ty21a vaccine capsules should be refrigerated, should be taken on an empty stomach, and should not be administered together with Vaxchora (begin the oral typhoid vaccine 8 hours after the dose of cholera vaccine) or during use of any antimicrobial agent other than the antimalarial agents mefloquine, chloroquine, or atovaquone-proguanil (www.cdc.gov/mmwr/preview/mmwrhtml/mm6411a4.htm). Typhoid immunization is not a substitute for careful selection of food and beverages.

YELLOW FEVER. Yellow fever (YF) occurs in parts of sub-Saharan Africa and tropical South America. YF is reported rarely among unimmunized travelers but may be fatal. Prevention measures against YF include immunization and protection against

mosquito bites (see Prevention of Mosquito-borne and Tick-borne Infections, p 207). Current country requirements and recommendations for YF immunization can change and are available at the CDC Travelers' Health website (wwwnc.cdc.gov/travel/). Travelers should verify entry requirements for their destination. YF vaccine should be administered at least 10 days before travel.

The yellow fever vaccine YF-VAX (Sanofi Pasteur) is available in the United States and is recommended for people 9 months and older who are traveling to or living in areas of South America and Africa in which risk exists for YF virus transmission. Booster doses of yellow fever vaccine are no longer recommended for most travelers, because a single dose of YF vaccine provides long-lasting protection.¹ An additional dose of YF vaccine is recommended for people who were pregnant when they received their initial dose of vaccine and people who received a hematopoietic stem cell transplant after receiving a dose of YF vaccine. People infected with HIV when they received their first dose of YF vaccine should receive a dose every 10 years if ongoing risk for infection is present (wwwnc.cdc.gov/travel/yellowbook/2024/infections-diseases/yellow-fever).

YF immunization should be limited to people at risk of exposure to YF or who require proof of vaccination for country entry because of risk of rare but serious adverse events including vaccine-associated neurologic and viscerotropic (multiple-organ system failure) disease.

OTHER CONSIDERATIONS. Travelers outside the United States may be exposed to mosquito-borne diseases, such as malaria, which can be life threatening; dengue or chikungunya viruses; or Zika virus, which poses a risk to fetuses of individuals infected during pregnancy. Prevention strategies include mosquito-bite prevention (see Prevention of Mosquito-borne and Tick-borne Infections, p 207) and, for malaria, use of antimalarial chemoprophylaxis. For recommendations on appropriate use of chemoprophylaxis, including recommendations for pregnant people, infants, and breastfeeding individuals, see Malaria (p 561) and Table 3.31 (p 566).

Travelers' diarrhea affects up to 60% of travelers but may be mitigated by good hand hygiene and attention to foods and beverages ingested (such as avoiding ice). Chemoprophylaxis generally is not recommended. Educating families about self-treatment, particularly oral rehydration, is critical. Packets of oral rehydration salts can be obtained before travel and are available in most pharmacies throughout the world, including in resource-limited countries, where diarrheal diseases are common. Some families may choose to carry an antimicrobial agent (eg, azithromycin) for treatment of travelers' diarrhea when offered by their travel medicine professional. Taking antimicrobial agents increases risk of colonization with resistant bacteria, so treatment should be reserved for moderate to severe cases of travelers' diarrhea. Bacteria that cause travelers' diarrhea (eg, *Campylobacter* species) may be resistant to fluoroquinolones, so this class should be used with caution. Antimotility agents may be considered for older children and adolescents (see *Escherichia coli* Diarrhea, p 376) for mild to moderate diarrhea (and may be used along with an antimicrobial agent) but generally should be avoided in cases of bloody diarrhea or diarrhea associated with fever. Bismuth subsalicylate

¹ Staples JE, Bocchini JA, Rubin L, Fischer M. Yellow fever vaccine booster doses: recommendations of the Advisory Committee on Immunization Practices, 2015. *MMWR Morb Mortal Wkly Rep*. 2015;64(23):647–650

has been shown to reduce risk and severity of travelers' diarrhea and is available over the counter. Dosing information is available for children ≥ 12 years of age; it should not be used in children younger than 12 years because of the risk of Reye syndrome (wwwnc.cdc.gov/travel/yellowbook/2024/preparing/travelers-diarrhea).

Travelers should be aware of potential acquisition of respiratory tract viruses, including COVID-19 and influenza. They should be counseled on the wearing of face masks while on airplanes and in enclosed, poorly ventilated spaces during respiratory virus season. Hand hygiene and avoidance of close contact with animals (dead or live) should also be emphasized. Swimming, water sports, and ecotourism involving exposure to fresh water carry risks of acquisition of infections from environmental contamination (notably schistosomiasis, giardiasis, and leptospirosis from lakes, streams, or rivers) and exposure to beaches contaminated with dog or cat feces can lead to risk of hookworm skin infection (cutaneous larva migrans, creeping eruption).

Recommendations for Care of Children in Special Circumstances

..... BREASTFEEDING AND HUMAN MILK

Breastfeeding provides numerous health benefits to infants, including protection against morbidity and mortality from infectious diseases of bacterial, viral, and parasitic origin. In addition to providing an optimal source of infant nutrition, human milk contains immune-modulating factors, including secretory antibodies, glycoconjugates, anti-inflammatory components, prebiotics, probiotics, and antimicrobial compounds such as lysozyme and lactoferrin, which contribute to the formation of a health-promoting microbiota and an optimally functioning immune system. Breastfed infants have high concentrations of protective bifidobacteria and lactobacilli in their gastrointestinal tracts, which diminish the risk of colonization and infection with pathogenic organisms. Protection by human milk is established most clearly for pathogens causing gastrointestinal tract infection. In addition, there is substantial evidence that human milk provides protection against otitis media and upper and lower respiratory tract infections. Breastfeeding decreases the severity of upper and lower respiratory tract respiratory infections, including bronchiolitis, resulting in more than 70% reduction in hospitalizations. Evidence indicates that human milk may modulate the development of the immune system of infants. Human milk (including pasteurized donor human milk) is superior to formula for preterm and very low birth weight infants, as it is associated with decreased rates of serious infections and necrotizing enterocolitis and better feeding tolerance and neurodevelopmental outcomes.¹⁻⁴

AAP Recommendations on Breastfeeding

The American Academy of Pediatrics (AAP) recommends exclusive breastfeeding for the first 6 months of life, with introduction of complementary foods at about 6 months of age, while continuing breastfeeding up to 2 years of age or longer as mutually

¹ World Health Organization. *Guidelines on Optimal Feeding of Low Birth-Weight Infants in Low- and Middle-Income Countries*. Geneva, Switzerland: World Health Organization; 2011. Available at: www.who.int/publications/i/item/9789241548366

desired by breastfeeding parent and infant.¹ The AAP publishes policy statements^{1–3} and a manual on infant feeding⁴ that provide additional information about the benefits of breastfeeding, recommended feeding practices, and potential contaminants of human milk. In the *Pediatric Nutrition Handbook*⁵ and in the AAP policy statements on human milk and pasteurized donor human milk, issues regarding immunization of lactating parents and breastfeeding infants, transmission of infectious agents via human milk, and potential effects on breastfed infants of antimicrobial agents administered to lactating parents are addressed.

Contraindications to Breastfeeding

Breastfeeding provides the most complete nutrition for infants, including preterm and ill newborn infants, and therefore, health care providers should carefully consider a parent's decision not to start, to interrupt, or to stop breastfeeding. Providers should engage in shared decision making with parents. In certain situations, parents should be counseled that avoidance of breastfeeding is the only option that completely eliminates the risk of pathogen transmission. These include the breastfeeding parent's infection with human immunodeficiency virus (HIV), human T-cell lymphotropic virus type I or type II, or Ebola virus. For additional considerations related to breastfeeding and HIV, see the Human Immunodeficiency Virus section (p 139). Temporary suspension of breastfeeding is recommended when the breastfeeding parent has active herpetic (herpes simplex virus) lesions on the breast (see p 138) or untreated brucellosis. Parents with infections that require airborne precautions (varicella, measles) should avoid contact with the infant, but the infant can be fed the parent's expressed human milk.

Transmission of Infectious Agents via Human Milk

BACTERIA

Postpartum mastitis occurs in one third of breastfeeding people in the United States and leads to breast abscesses in up to 10% of cases. Assessment of the parent's breasts for trauma or maternal oversupply of milk and of the infant's latch should be considered and addressed as underlying mitigating causes. Both mastitis and breast abscesses have been associated with the presence of bacterial pathogens in human milk. In cases

⁵ American Academy of Pediatrics, Committee on Nutrition. *Pediatric Nutrition Handbook*. Kleinman RE, Greer FR, eds. 8th ed. Itasca, IL: American Academy of Pediatrics; 2019

of breast abscess or cellulitis, breastfeeding on the affected breast should continue, even if a drain is present, as long as the infant's mouth is not in direct contact with purulent drainage or infected tissue. In general, infectious mastitis resolves with continued lactation during appropriate antimicrobial therapy and does not pose a significant risk for the infant. Breastfeeding on the affected side in cases of mastitis generally is recommended; however, even when breastfeeding is interrupted on the affected breast, breastfeeding may continue on the unaffected breast.

Breastfeeding individuals with tuberculosis who have been treated appropriately for 2 or more weeks or who are not considered contagious (negative sputum) may breastfeed. Breastfeeding individuals with tuberculosis disease suspected of being contagious should refrain from breastfeeding and from other close contact with the infant because of potential spread of *Mycobacterium tuberculosis* through respiratory tract droplets or airborne transmission (see Tuberculosis, p 888). However, expressed human milk can be fed to the infant, as long as there is no evidence of tuberculosis mastitis, which is extremely rare.

Expressed human milk can become contaminated with a variety of bacterial pathogens. Outbreaks of gram-negative bacterial infections in neonatal intensive care units occasionally have been attributed to contaminated milk processing equipment and, rarely, bacteria from the parent's pumping equipment. Breast pumps and components should be thoroughly cleaned between pumping sessions. Liquid human milk fortifiers are preferred, because receipt of powdered human milk fortifiers and powdered infant formula has been associated with invasive bacteremia and meningitis attributable to *Cronobacter* species (formerly *Enterobacter sakazakii*), resulting in death in approximately 40% of cases. Consequently, the AAP has advised against the use of powdered infant formulas/human milk fortifiers in preterm or immunocompromised infants. Routine culturing or heat treatment of a parent's milk fed to the infant has not been demonstrated to be necessary or cost-effective (see Human Milk Banks, p 143). Because of the immune-protective factors in human milk, there is a hierarchical preference for the parent's freshly expressed milk, followed by the parent's previously refrigerated or frozen milk, followed by pasteurized donor milk as the third best option for feeding of sick and/or preterm infants.¹

VIRUSES

CYTOMEGALOVIRUS. Cytomegalovirus (CMV) may be shed intermittently in human milk. Nearly all term infants who acquire CMV through breastfeeding do not develop clinical illness. In contrast, among very preterm infants, postnatal acquisition of CMV can be associated with sepsis-like illness. The long-term impact of postnatally acquired CMV through human milk among preterm infants is unclear and studies have yielded mixed results. Decisions about breastfeeding of preterm infants by parents known to be CMV seropositive should include consideration of the potential benefits of human milk and the risk of CMV transmission. Parents who give birth to infants at <32 weeks' gestation can be screened for CMV. When available, Holder

¹ Abrams SA, Landers S, Noble LM, Poindexter BB; American Academy of Pediatrics, Committee on Nutrition, Section on Breastfeeding, Committee on Fetus and Newborn. Policy statement. Donor human milk for the high-risk infant: preparation, safety, and usage options in the United States. *Pediatrics*. 2017;139(1):e20163440

pasteurization (62.5°C [144.5°F] for 30 minutes) and short-term pasteurization (72°C [161.6°F] for 5 seconds) of human milk appear to inactivate CMV; however, this is impractical in many settings. Short-term pasteurization may be less harmful to the beneficial constituents of human milk. Freezing human milk at −20°C (−4°F) for the sole purpose of reducing CMV infectivity is not advised, because although it may reduce the viral load of CMV, it does not change the risk of CMV sepsis-like syndrome, and freezing reduces the bioactivity of human milk. There is insufficient evidence to support withholding the parent's own milk because of risk for CMV transmission.¹

EBOLA VIRUS. Ebola virus has been detected in human milk during and in the first month after infection. The duration of Ebola virus shedding in human milk is unknown. Genomic analysis in a case of fatal Ebola in a 9-month-old strongly suggested Ebola virus transmission through human milk. When safe alternatives to breastfeeding and infant care exist, a parent with confirmed or suspected Ebola virus infection should not have close contact with the infant (including breastfeeding) to reduce the risk of transmitting Ebola virus to the child. There is not enough evidence to provide guidance on precisely when it is safe to resume breastfeeding after recovery. Where available, testing of human milk for the presence of Ebola virus RNA can help to guide decisions about when breastfeeding can be safely resumed. Additional recommendations may be found at www.cdc.gov/vhf/ebola/clinicians/evd/neonatal-care.html and www.cdc.gov/vhf/ebola/clinicians/evd/pregnant-women.html.

HEPATITIS B VIRUS. Hepatitis B surface antigen (HBsAg) has been detected in human milk from HBsAg-positive people. However, studies have indicated that breastfeeding by HBsAg-positive people does not significantly increase the risk of infection among their infants. In the United States, infants born to known HBsAg-positive people should receive the initial dose of hepatitis B vaccine within 12 hours of birth, and Hepatitis B Immune Globulin should be administered concurrently but at a different anatomic site. This combination effectively will eliminate any theoretical risk of transmission through breastfeeding (see Hepatitis B, p 437). There is no need to delay initiation of breastfeeding until after the infant is immunized.

HEPATITIS C VIRUS. Hepatitis C virus (HCV) RNA and antibody to HCV have been detected in human milk from people infected with HCV, but transmission of HCV via breastfeeding has not been documented in people with HCV infection in the absence of HIV infection. According to current guidelines from the Centers for Disease Control and Prevention (CDC), American Association for the Study of Liver Diseases, and Infectious Diseases Society of America, parental HCV infection is not a contraindication to breastfeeding. However, parents infected with HCV should abstain from breastfeeding from a breast with cracked or bleeding nipples.

HERPES SIMPLEX VIRUS TYPE 1. Breastfeeding parents with herpetic lesions can transmit herpes simplex virus (HSV) to their infants by direct contact with the lesions. Transmission may be reduced with meticulous hand hygiene and covering of lesions with which the infant might come into contact. Parents with herpetic lesions on a

¹ Parker MG, Stellwagen LM, Noble L, et al; American Academy of Pediatrics, Section on Breastfeeding, Committee on Nutrition, Committee on Fetus and Newborn. Promoting human milk and breastfeeding for the very low birth weight infant. *Pediatrics*. 2021;148(5):e2021054272

breast or nipple should refrain from breastfeeding an infant from the affected breast until lesions have resolved, but may breastfeed from the unaffected breast when lesions on the affected breast are covered completely to avoid transmission. In addition, a parent with active herpes lesions on the breast can feed expressed milk from that breast to the infant, as there is no concern of herpes transmission via the milk. However, no part of the breast pump or expressed milk should come in contact with the lesions during expression, if the milk will be fed to the infant. If the pump does come in contact with the herpetic lesions, the parent should still express milk to maintain milk supply and prevent mastitis, but the expressed milk should be discarded.

HUMAN IMMUNODEFICIENCY VIRUS.¹ All pregnant people in the United States should be screened for human immunodeficiency virus (HIV) infection as part of a prenatal testing panel (see Human Immunodeficiency Virus Infection, p 489). Transmission of HIV by breastfeeding accounted for one third to one half of perinatal transmission of HIV worldwide in the pre-antiretroviral therapy (ART) era. Transmission is more likely among pregnant people who acquire HIV infection late in pregnancy or during the postpartum period. In resource-limited settings, the World Health Organization recommends that people living with HIV breastfeed their infants exclusively for the first 6 months of life, because infant morbidity associated with formula feeding is unacceptably high and safe alternatives to human milk may not be readily available.

Replacement (formula) feeding is recommended for all infants born to people living with HIV infection in the United States, because this is the option that eliminates risk of transmission of HIV to the infant.² Replacement feeding should be recommended if the birth parent is not receiving ART or is not adherent and has a detectable viral load. Parents with HIV infection with fully suppressed viral load and who are adherent with ART who wish to breastfeed should be supported in their decision to do so. If a parent chooses to breastfeed, an appropriate plan of management can be developed, including encouraging adherence with ART during breastfeeding, use of antiretrovirals in the infant as prophylaxis while breastfeeding, exclusive breastfeeding for 6 months followed by weaning and introduction of complementary foods, lactation counseling, frequent viral load monitoring in the breastfeeding parent, and frequent infant testing for HIV infection (<https://clinicalinfo.hiv.gov/en/guidelines/perinatal/counseling-and-managing-women-living-hiv-united-states-who-desire-breastfeed>).

HUMAN T-LYMPHOTROPIC VIRUS TYPE 1. Human T-lymphotropic virus type 1 (HTLV-1), which is endemic in Japan, the Caribbean, and parts of South America, is associated with development of malignant neoplasms and neurologic disorders among adults. Epidemiologic and laboratory studies suggest that vertical transmission of human HTLV-1 occurs primarily through breastfeeding, although freezing/thawing of expressed human milk may decrease infectivity of human milk. People in the United States who are HTLV-1 seropositive should be advised to not breastfeed or donate to human milk banks.

¹ American Academy of Pediatrics, Committee on Pediatrics AIDS, Section on Breastfeeding. Policy statement. Infant feeding for persons living with HIV in the United States. *Pediatrics*. 2023; in press

² Meek JY, Noble L; American Academy of Pediatrics, Section on Breastfeeding. Technical report. Breastfeeding and the use of human milk. *Pediatrics*. 2022;150(1):e2022057989

HUMAN T-LYMPHOTROPIC VIRUS TYPE 2. Human T-lymphotropic virus type 2 (HTLV-2) is a retrovirus that has been detected among American and European injection drug users and some American Indian/Alaska Native people. Although apparent vertical transmission has been reported, the rate and timing of transmission have not been established. Until additional data about possible transmission through breastfeeding become available, parents in the United States who are HTLV-2 seropositive should be counseled regarding the risk of transmission of HTLV-2 with breastfeeding and advised not to donate to human milk banks. Routine screening for both HTLV-1 or HTLV-2 during pregnancy is not recommended.

MPOX. The mpox virus is spread by close contact, and neonatal mpox infection may be severe; thus, breastfeeding should be delayed until all mpox lesions have resolved, the scabs have fallen off, and a fresh layer of intact skin has formed. It is unknown whether mpox virus is present in human milk. Expressed milk from infected parents should be discarded until their lesions have healed and they can resume direct breastfeeding.

RUBELLA. Wild and vaccine strains of rubella virus have been isolated from human milk. However, the presence of rubella virus in human milk has not been associated with significant disease in infants, and transmission is more likely to occur via other routes. Parents with rubella or those who have been immunized recently with a live attenuated rubella virus-containing vaccine may continue to breastfeed.

SARS-COV-2. SARS-CoV-2 has been detected rarely in human milk, but viable infectious virus has not been detected in human milk samples and there have been no documented cases of transmission to breastfeeding infants. Given these findings, direct breastfeeding is encouraged. Acutely infected breastfeeding parents should properly wash their hands with soap and water before handling the infant and be advised to wear a mask while nursing. When not nursing, the infant can be cared for by a healthy caregiver, if available, and/or maintained in the same room at least 6 feet away from the breastfeeding parent. Parents shedding SARS-CoV-2 may express milk after appropriate breast and hand hygiene, and this milk may be fed to the infant by designated caregivers. Breast pumps and components should be thoroughly cleaned between pumping sessions using disinfectant wipes on the pump and washing pump attachments with hot, soapy water.

TICK-BORNE ENCEPHALITIS. Tick-borne encephalitis (TBE) virus has not been identified in human milk, but likely transmission of tick-borne encephalitis virus via human milk has been reported in 2 cases, 1 probable and 1 possible. A non-live TBE vaccine is available for travelers to areas in Europe and Asia where TBE virus is endemic. Breastfeeding is not a contraindication or precaution to vaccination.

VARICELLA. Expressed/pumped milk from a parent with varicella or zoster can be fed to the infant, provided no lesions are on the breast. Breastfeeding is not a contraindication or precaution to vaccination (see *Varicella-Zoster Infections*, p 938).

WEST NILE VIRUS. West Nile virus RNA has been detected in human milk collected from a person with disease attributable to West Nile virus. The breastfed infant developed West Nile virus immunoglobulin M antibodies but remained asymptomatic. Such transmission appears to be rare, and no adverse effects on infants have been described.

Because the benefits of breastfeeding outweigh the risk of WNV disease in breastfeeding infants, parents should be encouraged to breastfeed even in areas with ongoing WNV transmission.

ZIKA VIRUS. Although Zika virus has been detected in human milk, only a few probable cases of transmission of Zika virus via breastfeeding have been reported. The infants did not develop clinical disease. To date there is no consistent evidence that infants acquire Zika virus through breastfeeding. Cases have occurred in areas where Zika virus infection is endemic and where mosquito-borne transmission could not be excluded. Current evidence suggests that the benefits of breastfeeding outweigh the theoretical risks of Zika virus transmission through human milk. The World Health Organization and CDC recommend infants born to people with suspected, probable, or confirmed Zika virus infection or to individuals who live in or have traveled to areas with Zika virus should continue to breastfeed.

Immunization of Breastfeeding Parents and Infants

EFFECT OF IMMUNIZATION OF BIRTH PARENT

Parents who have not received recommended immunizations before or during pregnancy may be immunized during the postpartum period, regardless of lactation status. With the exception of yellow fever vaccine (see below),¹ no evidence exists to validate any clinical concern about the presence of other live vaccine viruses in human milk if the parent is immunized while lactating. Lactating parents should be immunized as recommended for adults and adolescents (www.cdc.gov/vaccines). If previously unimmunized or if traveling to an area with endemic poliovirus circulation, a lactating parent may receive inactivated (non-live) poliovirus vaccine (IPV). Breastfeeding parents who are susceptible to any of the viruses contained in the measles, mumps, and rubella vaccine (MMR) should be immunized during the early postpartum period. Breastfeeding is not a contraindication to varicella immunization. In lactating parents who receive live attenuated varicella vaccine, neither varicella DNA in human milk (by polymerase chain reaction assay) nor varicella antibody in the infant can be detected. If not administered during pregnancy, tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine (Tdap) should be administered immediately postpartum. Nonimmunized breastfeeding parents should receive COVID-19 and influenza vaccine.^{2,3} Inactivated (non-live) influenza vaccine (IIV) or live attenuated influenza vaccine (LAIV) may be administered during the postpartum period, if not otherwise contraindicated. All

licensed and authorized vaccines against COVID-19 are safe while breastfeeding. JYNNEOS is a live, non-replicating viral vaccine licensed for prevention of both smallpox and mpox disease; JYNNEOS can be offered to people who are pregnant or breastfeeding who are otherwise eligible.

Breastfeeding is a precaution for yellow fever vaccine administration. Three cases of yellow fever vaccine-associated neurologic disease have been reported in exclusively breastfed infants whose parents received yellow fever vaccine while lactating. All 3 infants were younger than 1 month at the time of exposure and had a diagnosis of encephalitis. The risk of potential yellow fever vaccine virus exposure through breastfeeding is unknown and is likely dependent on how old the infant is when the lactating parent is vaccinated and when the infant is breastfed after the parent's vaccination. Pregnant and breastfeeding people should avoid travel to areas with yellow fever. If travel is unavoidable and the risks of vaccination are believed to outweigh the likelihood of yellow fever virus exposure, a pregnant or breastfeeding person should be issued a medical waiver to fulfill health regulations. If the risk of yellow fever virus exposure outweighs the vaccination risks, a pregnant or breastfeeding person should be vaccinated. Although there are no data, some experts recommend that breastfeeding people who receive yellow fever vaccine should temporarily suspend breastfeeding and pump and discard expressed milk for at least 2 weeks. Others recommend that the benefits of breastfeeding in an area with endemic infection or during outbreaks are likely to far outweigh the risk of potential transmission of vaccine virus to infants.

The world's first Ebola vaccine, ERVEBO, is a vesicular stomatitis platform-based live-virus (sVSV-ZEBOV) vaccine. No information is yet available on the safety of this vaccine during lactation. Similarly, no data are available on the live attenuated cholera vaccine in breastfeeding people. However, the live attenuated cholera vaccine is not absorbed from the gastrointestinal tract, so maternal exposure to the vaccine is not expected to result in exposure of the fetus. Pregnant people and their clinicians should consider the risks associated with traveling to areas of active cholera transmission.

EFFICACY AND SAFETY OF IMMUNIZATION IN BREASTFED INFANTS

Infants should be immunized according to the recommended childhood and adolescent immunization schedule (https://redbook.solutions.aap.org/SS/Immunization_Schedules.aspx), regardless of the mode of infant feeding. Theoretically, high concentrations of poliovirus antibody in human milk could interfere with the immunogenicity of oral, but not non-live, poliovirus vaccine. However, in areas using oral poliovirus, vaccinated lactating parents should be counseled to breastfeed. There is in vitro evidence that human milk from people who live in areas with endemic rotavirus contains antibodies that can neutralize live rotavirus vaccine virus. However, in licensing trials, the effectiveness of rotavirus vaccine in breastfed infants was comparable to that in nonbreastfed infants. Postmarketing immunogenicity studies conducted outside the United States did not demonstrate improved antibody response following rotavirus vaccine when breastfeeding was temporarily withheld before and after vaccine administration. Furthermore, breastfeeding reduces the likelihood of rotavirus disease in infancy.

Human Milk Banks

In some circumstances, ill or preterm hospitalized infants are not able to receive their own parents' milk. These infants may be fed pasteurized donor human milk from an accredited milk bank to accrue the health benefits it offers.^{1,2} The potential for transmission of infectious agents through donor human milk requires appropriate selection and screening of donors and careful collection, processing, and storage of human milk.^{3,4} Currently, US nonprofit donor milk banks that belong to the Human Milk Banking Association of North America (www.hmbana.org/) voluntarily follow pasteurization guidelines drafted in consultation with the US Food and Drug Administration and the CDC. Other pasteurization methods also are acceptable, but use of nonpasteurized donor milk is not recommended. These guidelines include screening all donors for hepatitis B virus, hepatitis C virus, HIV 1 and 2, HTLV 1 and 2, and syphilis. Donor milk is dispensed after it is heat treated at 62.5°C (144.5°F) for 30 minutes (Holder pasteurization) and no viable bacteria are present after pasteurization.

Although milk banks support infants and children in the hospital and at home, informal milk sharing has become more common. Parents should be informed of the safety risks of milk obtained from unscreened donors and milk that has not been safely collected, pasteurized, processed, handled, and stored. Parents who decide to use shared milk should be instructed on minimizing risk by screening donors for contraindicated illnesses and medications and ensuring that the milk was safely collected, stored, and delivered. Milk obtained through the internet should be discouraged, as the donors cannot be screened and there are risks of contamination with chemicals and prescription and/or illicit drugs and even adulteration with cow milk.

Inadvertent Human Milk Exposure

Policies have been developed to deal with occasions when an infant inadvertently is fed expressed human milk not obtained from the infant's parent. These policies require documentation, counseling, and observation of the affected infant for signs of infection and potential testing of the source of the human milk for infections that could be transmitted via the milk. Recommendations for management of a situation involving an accidental exposure may be found on the CDC website (www.cdc.gov/breastfeeding/recommendations/other_mothers_milk.htm). Decisions about medical management and diagnostic testing of the infant who received another

parent's milk should be based on the details of the individual situation and be determined collaboratively between the infant's physician and parent(s) or guardian(s). A summary of the recommendations includes the following:

1. Inform the donor about the inadvertent exposure, and ask:
 - When was the milk expressed and how it was handled?
 - Would the donor be willing to share information about current medication use, recent infectious disease history, and presence of cracked or bleeding nipples during milk expression with the other family or the infant's treating physician?
2. Discuss inadvertent administration of the donor milk with the parent(s) or legal guardian of the recipient infant.
 - Inform them that their child was given another person's expressed human milk.
 - Inform them that the risk of transmission of infectious diseases (eg, HIV, hepatitis B, or hepatitis C) is small.
 - If possible, provide the family with information on when the milk was expressed and how the milk was handled prior to being delivered to the caregiver.
 - Encourage the parent(s) or guardian(s) to notify the infant's treating physician of the situation and share any specific details known.

Antimicrobial Agents and Other Drugs in Human Milk

Antimicrobial agents often are prescribed for lactating people. Although these drugs may be detected in human milk, the potential risk to an infant must be weighed against the known benefits of continued breastfeeding. As a general guideline, an antimicrobial agent is safe to administer to a lactating person if the drug is safe to administer to an infant. Only in rare cases will interruption of breastfeeding be necessary because of antimicrobial use by the lactating parent. A breastfed infant who requires antimicrobial therapy should receive the recommended doses, independent of administration of the agent to the breastfeeding parent.

Current information about drugs and lactation can be found on the NIH's Drugs and Lactation Database (LactMed) (www.ncbi.nlm.nih.gov/books/NBK501922/). Data for drugs, including antimicrobial agents, administered to lactating people are provided in several categories, including drug concentrations in infants and lactating people, effects in breastfed infants, possible effects on lactation, alternative drugs to consider, and references. Information on potential risks for drugs and vaccines administered during lactation, including potential effects on the breastfed child, can also be found in US Food and Drug Administration-approved labeling for the medication.

Anti-TNF Biologic Response Modifiers in Human Milk

Available evidence supports a lack of any significant transfer of anti-tumor necrosis factor (anti-TNF) drugs to human milk. Anti-TNF drugs include adalimumab, certolizumab pegol, etanercept, golimumab, and infliximab. People receiving treatment with anti-TNF drugs should be advised to continue breastfeeding. Infants of breastfeeding parents who are receiving anti-TNF drugs should receive recommended vaccines, including live virus vaccines, as indicated and according to the recommended schedule, unless vaccination is being withheld because of in utero exposure to the biologic response modifier (see Biologic Response-Modifying Drugs Used to Decrease Inflammation, p 104).

CHILDREN IN GROUP CHILD CARE AND SCHOOLS

Infants and young children who are cared for in group child care settings (child care centers and home-based child care) and schools¹ have an increased rate of communicable infectious diseases. Children in group child care settings and schools transmit infections among themselves and spread these infections to their families and child care or school staff. Risk of communicable diseases decreases gradually as children advance through school. Respiratory infections are more common than gastrointestinal tract or skin infections. Health department interventions are often necessary when outbreaks of infectious diseases occur in these settings.

Children in child care are more likely to receive antimicrobial agents; hence, they may also be colonized or infected with antimicrobial-resistant organisms. Younger age, more time in group child care settings, and exposure to larger group size are all strongly associated with more frequent infections. As children get older and increase their time in group care, they develop lasting immunity to common infections earlier compared with peers with less exposure.

Compared with children in child care, school-aged children experience a lower incidence of infectious diseases because of increased immunity as well as improved infection control measures such as hand hygiene and respiratory etiquette. However, schools remain important sites of transmission of common infectious diseases including rhinovirus infections, influenza, pertussis, COVID-19, and others, including additional vaccine-preventable diseases.

Modes of Spread of Infectious Diseases

RESPIRATORY TRACT DISEASES

Children, especially young children in child care, spread respiratory pathogens efficiently because of suboptimal social distancing and respiratory etiquette (Table 2.1). Pathogens spread by the respiratory route include bacteria, sometimes associated with invasive infections, and viruses. Viral infections of the respiratory tract are common in children in group child care settings. Possible modes of transmission of respiratory tract pathogens include aerosols, respiratory droplets, direct contact with secretions, or indirect contact with contaminated fomites. The most common viral pathogens responsible for respiratory tract disease in child care settings include respiratory syncytial virus (RSV) and human metapneumovirus as well as viruses that also affect children in schools, including parainfluenza virus, influenza virus, adenovirus, rhinovirus, and SARS-CoV-2. Respiratory tract viruses are associated with exacerbations of asthma and an increase in the incidence of otitis media and can cause significant complications for children with chronic respiratory tract disease, such as cystic fibrosis and chronic lung disease of prematurity, and for children who are immunocompromised.

¹ American Academy of Pediatrics. *Managing Infectious Diseases in Child Care and Schools: A Quick Reference Guide*. Shope TR, Hashikawa AN, eds. 6th ed. Itasca, IL: American Academy of Pediatrics; 2023

Table 2.1. Modes of Transmission of Organisms

Usual Route of Transmission ^a	Bacteria	Viruses	Other ^b
Fecal-oral	<i>Campylobacter</i> species, <i>Salmonella</i> species; <i>Shigella</i> species; <i>Shiga</i> toxin-producing <i>Escherichia coli</i> , including <i>E coli</i> O157:H7	Astrovirus, enteric adenovirus, enteroviruses, hepatitis A virus, norovirus, rotaviruses, sapovirus	<i>Cryptosporidium</i> species, <i>Enterobius vermicularis</i> , <i>Giardia duodenalis</i>
Respiratory	<i>Bordetella pertussis</i> , group A <i>Streptococcus</i> , <i>Haemophilus influenzae</i> type b, <i>Kingella kingae</i> , <i>Mycobacterium tuberculosis</i> (children ≥10 years and adults), <i>Neisseria meningitidis</i> , <i>Streptococcus pneumoniae</i>	Adenovirus, coronavirus (including SARS-CoV-2), influenza virus, human metapneumovirus, measles virus, mumps virus, parainfluenza virus, parvovirus B19, respiratory syncytial virus, rhinovirus, rubella virus, varicella-zoster virus	...
Person-to-person contact	Group A <i>Streptococcus</i> , <i>Staphylococcus aureus</i>	Herpes simplex virus, varicella-zoster virus	Agents causing pediculosis, scabies, and ringworm ^c
Contact with blood, urine, and/or saliva	...	Cytomegalovirus, herpes simplex virus, hepatitis C virus	...
Bloodborne	...	Hepatitis B virus, hepatitis C virus, human immunodeficiency virus	...

^aThe potential for transmission of microorganisms in the child care setting by food and animals also exists (see Appendix VI, Clinical Syndromes Associated With Foodborne Diseases, p 1150, and Appendix VII, Diseases Transmitted by Animals [Zoonoses], p 1157).

^bParasites, fungi, mites, and lice.

^cTransmission also may occur from contact with objects in the environment.

Seasonal outbreaks of common respiratory infections, such as hand-foot-and-mouth disease (enterovirus) and bronchiolitis, are common in group child care settings, and influenza outbreaks occur annually in child care settings and schools. Other respiratory pathogens that can cause sporadic outbreaks include group A streptococcal pharyngitis, *Neisseria meningitidis*, *Mycoplasma pneumoniae* (in schools), and some vaccine-preventable diseases such as pertussis, varicella, measles, mumps, rubella, COVID-19 and, rarely, *Haemophilus influenzae* type b. The incidence of vaccine-preventable diseases has markedly decreased since routine immunizations were implemented. Seasonal outbreaks of influenza continue to be common and, notably, most states do not require influenza vaccine for these settings. Communities with low vaccination rates continue to be at increased risk for vaccine-preventable disease outbreaks. More detailed recommendations for management and exclusion and return to care for these conditions are available in Table 2.2 and Table 2.3, as well as the relevant disease-specific chapters in Section 3 and other resources from the American Academy of Pediatrics (AAP).^{1,2}

ENTERIC DISEASES

Diarrheal illness is much more common in child care settings than in schools, because young children and adult caregivers spread enteric diseases primarily by contact with pathogens during diapering and toileting procedures. Enteric diseases can also occur in schools if a person fails to maintain good hygiene after toilet use or if contaminated food is shared among classmates. Organisms spread by the fecal-oral route include common viruses, bacterial pathogens, and parasites. Seasonal enteric pathogens include noroviruses (which are a frequent cause of illness in children), enteric adenoviruses, and astroviruses (see Table 2.1). Rotavirus vaccination has dramatically decreased seasonal outbreaks attributable to this virus, but illness still occurs. Hepatitis A virus can cause outbreaks in child care settings and schools but similarly is much less common since widespread implementation of routine hepatitis A immunization. Bacterial enteropathogens such as *Shigella* species and *Escherichia coli* O157:H7 can cause significant outbreaks in group child care settings and require a very small infective dose of organisms, whereas *Salmonella* species and *Campylobacter* species are less frequent causes of outbreaks. Parasites like *Giardia duodenalis* and *Cryptosporidium* species can cause outbreaks in child care settings, particularly where shared pools are used in water play activities, because their spores are resistant to chlorination in water sources and to alcohol-based hand sanitizers (see Prevention of Illnesses Associated with Recreational Water Use, p 214). More detailed recommendations for management, exclusion, and return to care for these conditions are available in the relevant disease-specific chapters in Section 3 or other references,^{1,2} and local public health authorities should be consulted.

² American Academy of Pediatrics, American Public Health Association, National Resource Center for Health and Safety in Child Care and Early Education. *Caring for Our Children: National Health and Safety Performance Standards: Guidelines for Out-of-Home Child Care*. 4th ed. Itasca, IL: American Academy of Pediatrics; and Washington, DC: American Public Health Association; 2019

Table 2.2. General Recommendations for Exclusion of Children From Group Child Care and School

Symptom(s)	Management
Illness preventing participation in activities, as determined by child care staff	Exclusion until the child can participate in activities
Illness that requires a level of care that is greater than staff can provide without compromising health and safety of others	Exclusion until the child no longer requires extra care to the extent staff cannot adequately attend to the health and safety of others in their care
Severe illness suggested by fever with behavior changes, lethargy, irritability, persistent crying, difficulty breathing, progressive rash with above symptoms	Medical evaluation and exclusion until severe symptoms have resolved and child can participate in activities and does not require excessive care
Persistent abdominal pain (2 hours or more) or intermittent abdominal pain associated with fever, dehydration, or other systemic signs and symptoms	Medical evaluation and exclusion until severe symptoms have resolved and child can participate and does not require excessive care
Vomiting 2 or more times in preceding 24 hours	Exclusion until symptoms have resolved, unless vomiting is determined to be caused by a noncommunicable condition and child is able to remain hydrated and participate in activities
Diarrhea if stool not contained in diaper or if fecal accidents occur in a child who is normally continent, if stool frequency exceeds 2 stools above normal for that child, or stools contain blood or mucus	Medical evaluation for stools with blood or mucus; exclusion until stools are contained in the diaper or when toilet-trained children no longer have accidents using the toilet, and when stool frequency becomes no more than 2 stools above that child's normal frequency for the time the child is in the program, even if the stools remain loose
Oral lesions	Exclusion if unable to contain drool or if unable to participate because of other symptoms
Skin lesions	Exclusion if lesions are weeping and cannot be covered with a waterproof dressing

BLOODBORNE INFECTIONS

Bloodborne infections are a potential concern in group child care settings and schools. Hepatitis B virus (HBV) transmission from an infected child biting a susceptible child has occurred in child care, but this is rare, especially given high hepatitis B immunization rates. Human immunodeficiency virus (HIV) transmission in a child care setting has never been documented. School-aged children infected with HIV, HBV, or hepatitis C virus (HCV) do not need to be identified to school personnel. Rather, policies and procedures to manage all potential exposures to blood or blood-containing materials should be established and universally implemented. Care required for school-aged children with physical or intellectual disabilities may expose caregivers to urine,

Table 2.3. Disease- or Condition-Specific Recommendations for Exclusion of Children from Group Child Care^a

Condition	Management of Case	Management of Contacts
COVID-19	See CDC (www.cdc.gov/coronavirus/2019-ncov/community/schools-childcare/child-care-guidance.html), state, and local health department recommendations	See CDC (www.cdc.gov/coronavirus/2019-ncov/community/schools-childcare/child-care-guidance.html), state, and local health department recommendations
Hand-foot-and mouth disease (caused by enteroviruses)	Because hand-foot-and mouth disease is normally mild, children can continue to attend child care and school as long as they have no fever, have no uncontrolled drooling, and are able to participate normally in classroom activities. In some cases, the health department may require children with hand-foot-and-mouth disease to stay home to control an outbreak.	In the event of an enterovirus A71 outbreak, consult the local or state health department for recommendations on exclusion and return to care.
Hepatitis A virus (HAV)	Serologic testing to confirm HAV infection in suspected cases. Exclusion until 1 week after onset of illness.	Hepatitis A outbreaks in child care are now rare because of the widespread adoption of universal childhood vaccination. In facilities with diapered children, if 1 or more cases confirmed in child or staff attendees or 2 or more cases in households of staff or attendees, hepatitis A vaccine (HepA) or immune globulin intramuscular (IGIM) should be administered within 14 days of exposure to all unimmunized staff and attendees. In centers without diapered children, HepA or IGIM should be administered only to unimmunized classroom contacts of index case. Asymptomatic contacts may return after receipt of IGIM or HepA (see Hepatitis A, p 430, for further discussion on indications for HepA or IGIM).

Table 2.3. Disease- or Condition-Specific Recommendations for Exclusion of Children from Group Child Care,^a continued

Condition	Management of Case	Management of Contacts
Herpes simplex virus	Only children with HSV gingivostomatitis (ie, primary infection) who do not have control of oral secretions should be excluded from child care. Exclusion of children with cold sores (ie, recurrent infection) from child care or school is not indicated. HSV lesions on other parts of the body should be covered with clothing or a bandage, if practical, for children attending school or child care.	Avoid the sharing of respiratory secretions through contact with objects and washing and sanitizing mouthed toys, bottle nipples, and utensils that have come in contact with saliva.
Impetigo	No exclusion if treatment has been initiated and as long as lesions on exposed skin are covered.	No intervention unless additional lesions develop.
Measles	Exclusion until 4 days after beginning of rash and when the child is able to participate.	In outbreak setting, people without documentation of immunity should be immunized within 72 hours of exposure or excluded. Immediate readmission to group child care may occur following immunization. Unimmunized people and those who do not receive vaccine within 72 hours of exposure should be excluded for at least 21 days after onset of rash in the last case of measles. For use of immune globulin, see Measles (p 570).

Table 2.3. Disease- or Condition-Specific Recommendations for Exclusion of Children from Group Child Care,^a continued

Condition	Management of Case	Management of Contacts
Mumps	Exclusion until 5 days after onset of parotid gland swelling.	In outbreak setting, people without documentation of immunity should be immunized or excluded. Immediate readmission may occur following immunization. Unimmunized people should be excluded until at least 26 days after onset of parotitis in the last person with mumps. A second dose of measles, mumps, and rubella vaccine (MMR) (or measles, mumps, rubella, and varicella vaccine [MMRV], if age appropriate) should be offered to all students (including those in postsecondary school) and to all health care personnel born in or after 1957 who have only received 1 dose of MMR vaccine. A second dose of MMR also may be considered during outbreaks for preschool-aged children who have received 1 MMR dose. People previously vaccinated with 2 doses of a mumps-containing vaccine who are identified by public health as at increased risk for mumps because of an outbreak should receive a third dose of a mumps-containing vaccine to improve protection against mumps disease and related complications (see Mumps, p 611).
<i>Pediculosis capitis</i> (head lice) infestation	Children should not be excluded or sent home early from school or child care because of head lice, because head lice have a low contagion in these settings. “No-nit” policies requiring that children be free of nits before they return to a child care facility or school should be discouraged.	Household and close contacts should be examined and treated if infested. No exclusion necessary.
Pertussis	Exclusion until completion of 5 days of the recommended course of antimicrobial therapy if pertussis is suspected; children and providers who refuse treatment should be excluded until 21 days have elapsed from cough onset (see Pertussis, p 656).	Immunization and chemoprophylaxis should be administered as recommended for household and child care contacts. Contacts should be observed for respiratory tract symptoms for 21 days and if they develop symptoms, then they should be treated (see Pertussis, p 656).

Table 2.3. Disease- or Condition-Specific Recommendations for Exclusion of Children from Group Child Care,^a continued

Condition	Management of Case	Management of Contacts
Rubella	Exclusion for 7 days after onset of rash for postnatal infection.	In outbreak setting, children without evidence of immunity should be immunized or excluded for 21 days after onset of rash of the last case in the outbreak. Pregnant contacts should be evaluated (see Rubella, p 735).
Infection with <i>Salmonella</i> serotypes Typhi or Paratyphi	Exclusion until 3 consecutive stool cultures obtained at least 48 hours after cessation of antimicrobial therapy are negative, stools are contained in the diaper or child is continent, and stool frequency is no more than 2 stools above that child's normal frequency for the time the child is in the program.	When <i>Salmonella</i> serotype Typhi infection is identified in a child care staff member, local or state health departments should be consulted regarding regulations for length of exclusion and testing, which may vary by jurisdiction.
Infection with nontyphoidal <i>Salmonella</i> species, <i>Salmonella</i> of unknown serotype	Exclusion until stools are contained in the diaper or child is continent and stool frequency is no more than 2 stools above that child's normal frequency for the time the child is in the program. Stool consistency does not need to return to normal to be able to return to child care. Negative stool culture results generally are not required for nonserotype Typhi or Paratyphi <i>Salmonella</i> species.	Symptomatic contacts should be excluded until stools are contained in the diaper or child is continent and stool frequency is no more than 2 stools above that child's normal frequency for the time the child is in the program. Stool cultures are not required for asymptomatic contacts.
Scabies	Treatment at end of program day and readmission on completion of first treatment. Children should not be excluded or sent home early from school because of scabies, because scabies has a low contagion within classrooms.	Close contacts with prolonged skin-to-skin contact should receive prophylactic therapy. Bedding and clothing in contact with skin of infected people should be laundered (see Scabies, p 750).

Table 2.3. Disease- or Condition-Specific Recommendations for Exclusion of Children from Group Child Care,^a continued

Condition	Management of Case	Management of Contacts
Infection with Shiga toxin-producing <i>Escherichia coli</i> (STEC), including <i>E. coli</i> O157:H7	Exclusion until 2 stool cultures (obtained at least 48 hours after any antimicrobial therapy, if administered, has been discontinued) are negative, and stools are contained in the diaper or child is continent, and stool frequency is no more than 2 stools above that child’s normal frequency. Report to and consult with local or state public health officials. Some state health departments have less stringent exclusion policies for children who have recovered from less virulent STEC infection.	Meticulous hand hygiene; stool cultures should be performed for any symptomatic contacts. In outbreak situations involving virulent STEC strains, stool cultures of asymptomatic contacts may aid controlling spread. Center(s) with cases should be closed to new admissions during STEC outbreak (see <i>Escherichia coli</i> Diarrhea, p 376).
Shigellosis	Exclusion until the state or local health department has deemed it safe to return to work per state or local child care exclusion regulations. Following this, children can return to child care facilities if stools are contained in the diaper or when toilet-trained children are continent and when stool frequency becomes no more than 2 stools above that child’s normal baseline for the time the child is in the program, even if the stools remain loose.	Meticulous hand hygiene; stool cultures should be performed for any symptomatic contacts (see <i>Shigella</i> Infections, p 756).
<i>Staphylococcus aureus</i> skin infections	Exclusion only if skin lesions are draining and cannot be covered with a watertight dressing.	Meticulous hand hygiene; cultures of contacts are not recommended.

Table 2.3. Disease- or Condition-Specific Recommendations for Exclusion of Children from Group Child Care,^a continued

Condition	Management of Case	Management of Contacts
Streptococcal pharyngitis	Exclusion until at least 12 hours after treatment has been initiated. In the setting of an outbreak, exclusion for at least 24 hours after treatment has been initiated should be considered, and consultation with the state or local public health department is recommended.	Symptomatic contacts of documented cases of group A streptococcal infection should be tested and treated if test results are positive.
Tuberculosis	Most children younger than 10 years are not considered contagious. For those with active disease, exclusion until determined to be noninfectious by physician or health department authority. No exclusion for latent tuberculosis infection.	Local health department personnel should be informed for contact investigation (see Tuberculosis, p 888).
Varicella (see Varicella-Zoster Infections, p 938)	Exclusion until all lesions have crusted or, in immunized people without crusts, until no new lesions appear within a 24-hour period.	For people without evidence of immunity, varicella vaccine should be administered ideally within 3 days but up to 5 days after exposure. If vaccine cannot be administered, varicella-zoster immune globulin or antiviral postexposure prophylaxis can be given (see Varicella-Zoster Virus, p 938). Varicella-zoster immune globulin should be administered up to 10 days after exposure, while valacyclovir or acyclovir should be administered beginning 7 days after exposure and continuing for 7 days.

^aMany of these illnesses also require exclusion from school and other activities. Many of these diseases are reportable to local or state public health authorities, and reporting rules for local jurisdictions should be consulted. Public health authorities should be consulted if there are questions about exclusion criteria.

saliva, and in some cases, blood. Therefore, the application of Standard Precautions and appropriate hand hygiene, as recommended for children in group child care,¹ is the optimal means to prevent spread of infection from these exposures. Parents and students should be educated about the types of exposure that present a risk for school contacts. Although a student's right to privacy should be maintained, decisions about activities at school should be made by parents or guardians together with the child's physician, on a case-by-case basis, keeping the health needs of the infected student and the student's classmates in mind. School nurses are often helpful to consult, as they are familiar with the school landscape.

Although no prospective studies have been conducted to determine the risk of transmission of HIV, HBV, or HCV during contact sports among high school students, available evidence indicates that the transmission risk is low. Guidelines for management of bleeding injuries have been developed for college and professional athletes in recognition of the possibility of unidentified HIV, HBV, or HCV infection in any athlete. The following are recommendations for preventing transmission of HIV and other bloodborne pathogens in the athletic setting.

- Athletes infected with HIV, HBV, or HCV should be allowed to participate in competitive sports.
- Physicians should respect the rights of infected athletes to confidentiality. The infection status of patients should not be disclosed to other participants or the staff of athletic programs.
- Testing for bloodborne pathogens should not be mandatory for athletes or sports participants.
- Pediatricians are encouraged to counsel athletes who are infected with HIV, HBV, or HCV and to assure them that they have a low risk of infecting other competitors. Infected athletes should consider choosing a sport in which this transmission risk is minimal. This choice may be protective both for other participants and for the infected athletes themselves, decreasing their possible exposure to bloodborne pathogens other than the one(s) with which they are infected. Contact and collision sports such as wrestling and boxing have the greatest potential for contamination of injured skin by blood. The AAP opposes boxing as a sport for youth for other reasons.²
- Athletic programs should inform athletes and their parents that the program is operating under the policies of the aforementioned recommendations and that the athletes have a low risk of becoming infected with a bloodborne pathogen.
- Athletic programs should promote HBV immunization among all athletes, coaches, athletic trainers, equipment handlers, laundry personnel, janitorial staff, and other people who may be exposed to blood as an occupational hazard. HBV immunization is universally recommended for everyone aged 59 years and younger and for those who are older who have risk factors or who wish to be protected.
- Each coach and athletic trainer must receive training in first aid and emergency care.
- Coaches and members of the health care team should educate athletes that, in contrast to the assumed low risk of transmission during athletics, there are greater risks

¹ American Academy of Pediatrics. *Managing Infectious Diseases in Child Care and Schools: A Quick Reference Guide*. Shope TR, Hashikawa AN, eds. 6th ed. Itasca, IL: American Academy of Pediatrics; 2023

² American Academy of Pediatrics, Council on Sports Medicine and Fitness; Canadian Paediatric Society, Healthy Active Living and Sports Medicine Committee. Boxing participation by children and adolescents. *Pediatrics*. 2011;128(3):617–623 (Reaffirmed February 2015, March 2020)

of transmission of HIV and other bloodborne pathogens through sexual activity and needle sharing during the use of injection drugs, including anabolic steroids. Athletes should be told not to share personal items, such as razors, toothbrushes, and nail clippers, that might be contaminated with blood.

- Depending on the law in some states, schools may need to comply with Occupational Safety and Health Administration (OSHA) regulations (**www.osha.gov**) for prevention of bloodborne pathogens. The athletic program must determine which OSHA rules are applicable for their enterprise. Compliance with OSHA regulations is a reasonable and recommended precaution even if this is not required specifically by the state.
- The following precautions should be adopted in sports with direct body contact and other sports in which an athlete's blood or other body fluids visibly tinged with blood may contaminate the skin or mucous membranes of other participants or staff members of the athletic program. These precautions will not eliminate the risk that a participant or staff member may become infected with a bloodborne pathogen in the athletic setting but will reduce the risk substantially.
 - ♦ Athletes must cover existing cuts, abrasions, wounds, or other areas of broken skin with an occlusive dressing before and during participation. Caregivers should cover their own damaged skin to prevent transmission of infection to or from an injured athlete.
 - ♦ Disposable, waterproof gloves should be worn to avoid contact with blood or other body fluids visibly tinged with blood and any objects, such as equipment, bandages, or uniforms, contaminated with these fluids. Hands should be cleaned with soap and water or an alcohol-based antiseptic agent as soon as possible after gloves are removed.
 - ♦ Athletes with active bleeding should be removed from competition as soon as possible. Wounds should be cleaned with soap and water. Skin antiseptic agents may be used if soap and water are not available. Athletes may return to competition once bleeding has stopped, and cleansed wounds are covered with an occlusive dressing that will remain intact and not become soaked through during further play.
 - ♦ Athletes should be advised to report injuries and wounds in a timely fashion before or during competition.
 - ♦ Minor cuts or abrasions that are not bleeding do not require interruption of play but can be cleaned and covered during scheduled breaks. During these breaks, if an athlete's equipment or uniform fabric is wet with blood, the equipment should be cleaned and disinfected (see next bullet), or the uniform should be replaced.
 - ♦ Equipment and playing areas contaminated with blood must be cleaned using gloves and disposable absorbent material until all visible blood is gone and then disinfected with a product registered with the Environmental Protection Agency and applied in the manner and time recommended.¹ If the disinfecting product is bleach (1:80 dilution of household bleach), the decontaminated equipment or area should be in contact with the bleach solution for at least 30 seconds. The area then may be wiped with a disposable cloth after the minimum contact time or allowed to air dry.
 - ♦ Emergency care must not be delayed because gloves or other protective equipment are not available. If the responder does not have appropriate protective

¹ Centers for Disease Control and Prevention. Guidelines for environmental infection control in health-care facilities. Recommendations of CDC and the Healthcare Infection Control Practices Advisory Committee (HICPAC). *MMWR Recomm Rep*. 2003;52(RR-10):1-48 (updated July 2019)

equipment, a towel may be used to cover the wound until an off-the-field location is reached where gloves can be used during definitive treatment.

- ♦ Breathing bags (eg, Ambu manual resuscitators) and oropharyngeal airways should be available for use during resuscitation.
- ♦ Equipment handlers, laundry personnel, and janitorial staff must be educated in proper procedures for handling washable or disposable materials contaminated with blood.

OTHER INFECTIONS

Other common infections (Table 2.1, p 146) among children in group child care and schools may occur by direct contact with infected lesions, such as *Staphylococcus aureus*, group A *Streptococcus*, and herpes simplex virus. Shared fomites, such as towels, athletic equipment, and razors, have been implicated in the spread of methicillin-resistant *S aureus* (MRSA) within school settings. The AAP has guidance on control and prevention of MRSA and other infections in athletes and other school settings.¹ *Trichophyton tonsurans*, the predominant cause of tinea capitis (ringworm), remains viable for long periods on combs, hair brushes, furniture, and fabric. Tinea cruris (jock itch) and tinea pedis (athlete's foot) occur in adolescents and young adults. *Sarcoptes scabiei* (scabies) and *Pediculus capitis* (head lice) are transmitted primarily through person-to-person contact. In schools and group child care settings, transmission of scabies is unlikely without prolonged skin-to-skin contact; for lice, transmission occurs by direct head-to-head contact. Transmission of scabies and head lice through shared articles of clothing or hair accessories (combs, hair brushes, hats, and hair ornaments) is possible but uncommon. Cytomegalovirus (CMV) is common in children in child care settings and spreads via contact with infected bodily secretions; it is estimated that up to 70% of children 1 to 3 years of age who attend group child care may shed the virus in saliva or urine. CMV and parvovirus infections can have effects on the fetus of a pregnant child care worker, and those employed or volunteering in child care should discuss this occupational risk with their health care providers. Finally, human-animal contact involving family and classroom pets, animal displays, and petting zoos exposes children to pathogens harbored by these animals. Some animals are commonly colonized with *Salmonella* species, *Campylobacter* species, Shiga toxin-producing *E coli*, lymphocytic choriomeningitis virus, and other viruses that may be transmitted to children via contact (see Appendix VII, Diseases Transmitted by Animals [Zoonoses], p 1157). Detailed recommendations for management and exclusion and return-to-care or -school for these conditions are available in Table 2.2, Table 2.3, as well as the relevant disease-specific chapters in Section 3 and other references.^{2,3}

Management and Prevention of Infectious Diseases

There are 3 primary methods for reducing the transmission of infectious diseases in group child care and school settings: immunization, infection prevention and control, and exclusion and return-to-care or -school policies and practices.

IMMUNIZATION

Immunizations are by far the most effective means of preventing childhood infectious diseases. The United States relies on child care and school entry vaccination requirements to achieve and sustain high levels of vaccination coverage. Most states require vaccination of children entering child care programs, all states require vaccination of children at the time of entry into school, and many states have vaccination requirements for children throughout elementary school and high school and at the time of entry to college. Child care programs should require that all enrollees and staff members receive age-appropriate immunizations as recommended by the AAP and the Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention (CDC). Parents should be required to report their child's immunization status and programs should keep and review these records. Unless contraindications exist or children have recognized exemptions (as per state immunization laws), immunizations documented through vaccine cards or medical records should demonstrate complete immunization for age (https://redbook.solutions.aap.org/SS/Immunization_Schedules.aspx). The immunization mandates for children in child care and schools vary by state and can be found online (www.immunize.org/laws) and from the National Network for Immunization Information (www.immunizationinfo.org/). The AAP views nonmedical exemptions to child care- and school-required immunizations as inappropriate for individual, public health, and ethical reasons and advocates for their elimination.¹ State requirements often lag behind AAP and ACIP recommendations.

Children who have not received recommended age-appropriate immunizations before enrollment should be encouraged to be immunized as soon as possible, and the series should be completed according to the recommended childhood and adolescent immunization catch-up schedule as appropriate (https://redbook.solutions.aap.org/SS/Immunization_Schedules.aspx). Whether unimmunized or inadequately immunized children may attend child care or school will depend on state and local public health guidance. Parents need to be informed that if a vaccine-preventable disease occurs in a child care program or school, all unimmunized and underimmunized children will be excluded for the duration of possible exposure or until they have completed their immunizations. Local public health jurisdictions should be consulted for guidance.

All adults who work in a child care facility or school should receive all vaccines routinely recommended for adults (see adult immunization schedule at www.cdc.gov/vaccines/schedules/hcp/adult.html). By being fully immunized, child care providers and teachers protect not only themselves but also infants too young to

¹ American Academy of Pediatrics, Committee on Practice and Ambulatory Medicine, Committee on Infectious Diseases, Committee on State Government Affairs, Council on School Health, Section on Administration and Practice Management. Medical versus nonmedical immunization exemptions for child care and school attendance. *Pediatrics*. 2016;138(3):e20162145 (Reaffirmed February 2022)

receive or have completed their immunization series and children who have medical contraindications to immunizations. More detailed information about adult child care provider and teacher immunization requirements can be found in other references.^{1,2}

INFECTION PREVENTION AND CONTROL

Group child care settings and schools both are rich environments for pathogens. However, group child care settings are much more problematic than schools, because young children are in close contact with each other, touching and sharing; they cough and sneeze without proper respiratory etiquette; and they need to be supervised or assisted with toileting and hand hygiene. As a result, viral, bacterial, fungal, and parasitic pathogens can be present in the air, on surfaces, in bodily secretions, and on the skin. Efforts to control the transmission of infectious diseases in child care settings are important but also difficult to implement effectively; as such, infection prevention and control in these settings requires a multifaceted approach. Programs should have written policies and training for staff to be sure they properly implement the best methods. These policies should include procedures for food and medication preparation; diaper changing; cleaning, sanitizing, and disinfecting surfaces; hand hygiene; respiratory etiquette; and other Standard Precautions.

It is difficult to decrease the spread of respiratory pathogens in group child care settings, with intensive education and infection control measures producing only modest reductions in incidence of respiratory illness, probably because respiratory pathogens are primarily spread by droplets expelled by sneezing and coughing. Young children have difficulty anticipating sneezing and coughing and do not effectively practice respiratory etiquette and hand hygiene. In addition, their social nature causes them to play in close proximity to each other, within the radius most contaminated large droplets may travel before contacting another child's mucous membranes. Nevertheless, immunization, hand hygiene, and respiratory etiquette are essential elements of infection control in child care settings, and it is important that staff practice these measures for themselves as well as educate and assist young children to properly do so. Aerosolized droplets that land on surfaces may contain microorganisms capable of causing infections. Therefore, surface cleaning, disinfecting, and sanitizing are important to prevent the spread of respiratory illness. In schools, however, efforts to improve hand hygiene and respiratory etiquette—covering mouth and nose with tissue when coughing or sneezing (if no tissue is available, use the upper arm or elbow area rather than hands)—to reduce transmission of respiratory infections such as influenza are more effective and should be taught and implemented. Recommendations about use of well-fitting face masks for children ≥ 2 years to prevent spread of COVID-19 were introduced during the COVID-19 pandemic (see COVID-19, p 324). Child care and schools should consult current public health recommendations for current guidance.

Infection control procedures in group child care settings are more effective in reducing diarrheal illness than respiratory illness. Adhering to diaper-changing procedures as

¹ American Academy of Pediatrics. *Managing Infectious Diseases in Child Care and Schools: A Quick Reference Guide*. Shope TR, Hashikawa AN, eds. 6th ed. Itasca, IL: American Academy of Pediatrics; 2023

² American Academy of Pediatrics, American Public Health Association, National Resource Center for Health and Safety in Child Care and Early Education. *Caring for Our Children: National Health and Safety Performance Standards: Guidelines for Out-of-Home Child Care*. 4th ed. Itasca, IL: American Academy of Pediatrics; and Washington, DC: American Public Health Association; 2019

recommended by the AAP¹ is a critical step to reduce fecal contamination and should be applied in child care settings as well as in schools that have diapered students with physical and intellectual disabilities. Surface cleaning, sanitizing, and disinfecting are especially important for reducing gastrointestinal tract illnesses. Cleaning removes visible soil to increase the effectiveness of sanitizing or disinfecting agents. Sanitizing reduces the amount of potential pathogens on food preparation surfaces, utensils, tables, countertops, and plastic toys. Disinfection requires stronger concentration or different agents than sanitizing and is used for areas with higher likelihood of pathogens, such as door handles, drinking fountains, and toilet and diaper changing areas.

As with respiratory tract infections, hand hygiene is essential to prevent the fecal-oral spread of gastrointestinal tract pathogens. Hand hygiene should occur for staff and children on arrival; when moving from one group to another; before and after contact with food or medication administration; after diaper changing, toileting, and contact with nasal or other body secretions, animals, or garbage; and after playing outside. Hand washing for 20 seconds with soap and water is the preferred method for hand hygiene, should be prioritized in child care and school settings, and is required whenever there is visible particulate matter. However, alcohol-based hand sanitizer may be substituted when soap and water is not available. Alcohol-based hand sanitizers have high alcohol content (60%–95%), which can be ingested or aerosolized; therefore, adult supervision is required. Hand hygiene using soap and water is preferred for *Cryptosporidium* species and norovirus because alcohol-based hand sanitizers are not as effective against these pathogens.

Other important environmental infection control and prevention measures for child care facilities include having adequate ventilation in the building (see www.cdc.gov/coronavirus/2019-ncov/community/schools-childcare/ventilation.html for ways to increase ventilation); providing enough physical space in the facility and between cots for naps (which may increase social distancing and reduce droplet spread); ensuring physical separation and separate personnel (if possible) involved in food preparation and diaper changing; requiring appropriate handling of animals (and excluding reptiles, turtles, amphibians, birds, primates, live poultry, ferrets, or rodents in the facility), with hand hygiene before and after contact; and adhering to recommended ratios of children to care providers.

Health departments should have plans for responding to reportable and non-reportable outbreaks of communicable diseases in child care programs and schools and should provide training, written information, and technical consultation when requested or alerted. In some instances, administration of appropriate antimicrobial therapy to a patient will limit further spread of infection (eg, *Shigella* species, streptococcal pharyngitis, pertussis). Antimicrobial prophylaxis administered to close contacts of children with infections caused by specific pathogens may be warranted in some circumstances (eg, meningococcal infection [see p 585], invasive *H influenzae* type a or type b [see p 400], and pertussis [see p 656]). Decisions about postexposure prophylaxis after an in-school exposure are best made in conjunction with local public health authorities and the primary care pediatrician. Temporary closure of classrooms or entire child care programs or schools can be used in limited circumstances: (1) to prevent spread of infection; (2) when an infection is expected to affect a large number of susceptible students and available control measures are considered inadequate;

¹ American Academy of Pediatrics. *Managing Infectious Diseases in Child Care and Schools: A Quick Reference Guide*. Shope TR, Hashikawa AN, eds. 6th ed. Itasca, IL: American Academy of Pediatrics; 2023

(3) when an infection affects a large number of staff and adequate staffing cannot be achieved; or (4) when an infection is expected to have a high rate of morbidity or mortality. Prolonged or frequent closures may result in unintended consequences for children and families including reduced learning and emotional and mental health impact. Collaborative efforts of public health officials, teachers, licensing agencies, child care providers, child care health consultants, physicians, nurses, parents, employers, and other members of the community are necessary to address problems of infection prevention and management in child care settings and schools. People involved with early education and child care and schools can use the published national standards¹ related to these topics to provide specific education and implementation measures.

EXCLUSION AND RETURN TO CARE OR SCHOOL

General recommendations for exclusion of children in group child care and schools are provided in Table 2.2 (p 148). Exclusions can put a significant economic strain on families, as parents may need to miss work to care for an ill child, and many exclusion decisions made by early child care and education professionals are not evidence-based and are inappropriate. No studies demonstrate that excluding children in group care and schools who are ill with common infectious diseases reduces the likelihood of spread to other children. However, to try to control environmental contamination and/or spread because the clinical consequences are significant, there are some infectious diseases for which exclusion is recommended (Table 2.2, p 148). Many children are infectious before developing symptoms. Asymptomatic infection, high carriage rates, and prolonged shedding of pathogens in body secretions are common and make it difficult to curb transmission by targeting only symptomatic children. Because mild illness is common among children and most minor illnesses do not constitute a reason for excluding a child from child care or school, decisions about exclusion should be primarily based on the child's behavior. A mildly ill child can remain in child care or school unless the illness prevents the child from participating in normal activities, as determined by the child care staff or teachers, or the illness requires a need for care that is greater than child care staff or teachers can provide.

Each day as the child enters the program or school, and throughout the day as needed, staff members and teachers should evaluate the well-being of the child and observe for signs of illness. Parents should be encouraged to share information with child care staff and teachers about their child's acute and chronic illnesses and medication use utilizing a formal care plan that is signed by the child's health care provider. Examples of illnesses and conditions that do not necessitate exclusion include:

- Common cold (however, because symptoms can be similar to COVID-19, during periods of high COVID-19 transmission, referral to public health guidance is recommended).
- Diarrhea, as long as stools are contained in the diaper (for infants), there are no accidents using the toilet (for older children), and stool frequency is no more than 2 stools above normal for that child.
- Rash without fever and without behavioral change.

¹ American Academy of Pediatrics, American Public Health Association, National Resource Center for Health and Safety in Child Care and Early Education. *Caring for Our Children: National Health and Safety Performance Standards: Guidelines for Out-of-Home Child Care*. 4th ed. Itasca, IL: American Academy of Pediatrics; and Washington, DC: American Public Health Association; 2019

- Hand-foot-and-mouth disease as long as children have no fever, have no uncontrolled drooling with mouth sores, and can participate normally in classroom activities. In some cases, particularly in cases of enterovirus A71, the health department may require children with hand-foot-and-mouth disease to stay home to control an outbreak.
- Lice. Children should not be excluded or sent home early from school or child care because of head lice, because head lice have a low contagion in these settings. “No-nit” policies requiring that children be free of nits before they return to a child care facility or school should be discouraged.¹
- Ringworm and scabies (treatment can occur at the end of the day, with return the following day).
- Thrush.
- Fifth disease (parvovirus B19 infection) in an immunocompetent child.
- CMV infection.
- Herpes simplex virus (HSV) infection, as long as a child with HSV gingivostomatitis (ie, primary infection) has control of oral secretions. Exclusion of children with cold sores (ie, recurrent infection) from child care or school is not indicated.
- Chronic HBV infection (see p 437 for possible exceptions).
- Conjunctivitis without fever and without behavioral change.
- HIV infection (see p 489 for possible exceptions).
- Colonization with MRSA in children who do not have active lesions or illness that would otherwise require exclusion.

Asymptomatic children who excrete an enteropathogen usually do not need to be excluded (exceptions include children who are infected with Shiga toxin-producing *E coli*, *Shigella* species, or *Salmonella* serotype Typhi or Paratyphi).

Disease- or condition-specific recommendations for exclusion from child care and schools and management of contacts are shown in Table 2.3 (p 149). Despite the existence of national recommendations for exclusion since 1992,^{2,3} states have been slow to adopt these. Each state has its own regulations pertaining to exclusion and return to care/school, and these may not be evidence based. Child care programs are required to follow these state-specific guidelines to maintain licensing, which can be found at <https://childcareta.acf.hhs.gov/licensing>. Exclusion and return to care guidelines for schools may be addressed by state departments of health or other public health agencies.

During outbreaks of certain diseases, the responsible local and state public health authorities are helpful for determining the benefits and risks of excluding children from their usual care program or school. All states have laws about reporting and isolation of people with specific communicable diseases. Local or state health departments should be contacted for information about these laws, and public health authorities in these areas should be notified about cases of nationally notifiable infectious diseases and unusual outbreaks of other illnesses involving children or adults in the child care

¹ Devore CD, Schutz GE; American Academy of Pediatrics, Council on School Health, Committee on Infectious Diseases. Head lice. *Pediatrics*. 2015;135(5):e1355-e1365 (Reaffirmed June 2020)

² American Academy of Pediatrics. *Managing Infectious Diseases in Child Care and Schools: A Quick Reference Guide*. Shope TR, Hashikawa AN, eds. 6th ed. Itasca, IL: American Academy of Pediatrics; 2023

³ American Academy of Pediatrics, American Public Health Association, National Resource Center for Health and Safety in Child Care and Early Education. *Caring for Our Children: National Health and Safety Performance Standards: Guidelines for Out-of-Home Child Care*. 4th ed. Itasca, IL: American Academy of Pediatrics; and Washington, DC: American Public Health Association; 2019

environment or schools (see Appendix III, Nationally Notifiable Infectious Diseases in the United States, p 1141). For most outbreaks of vaccine-preventable illnesses, unvaccinated children should be excluded until they are vaccinated and the risk of transmission no longer exists. In circumstances requiring intervention to prevent spread of infection within the school setting, the privacy of children who are infected should be protected.

..... INFECTION PREVENTION AND CONTROL FOR HOSPITALIZED CHILDREN

Health care-associated infections (HAIs) are a threat to patient safety in hospitalized children. A comprehensive set of guidelines for preventing and controlling HAIs, including isolation precautions, occupational health recommendations, and guidelines for prevention of postoperative and device-related infections, can be found on the Centers for Disease Control and Prevention (CDC) website (www.cdc.gov/infectioncontrol/guidelines/index.html). Additional guidelines are available from the principal infection prevention and control societies in the United States (the Society for Healthcare Epidemiology of America and the Association for Professionals in Infection Control and Epidemiology), as well as other groups such as the Occupational Safety and Health Administration and the Cystic Fibrosis Foundation.¹ The investigation and control of outbreaks that occur in special pediatric settings (eg, hematopoietic stem cell transplant units, neonatal and surgical units) should always involve the infection prevention and control team in each facility. Accrediting organizations, such as The Joint Commission, have established infection prevention and control standards. Pediatricians and infection prevention and control professionals should be familiar with this increasingly complex array of guidelines, regulations, and standards. To accomplish this goal, infection prevention and control programs led by pediatric infectious diseases specialists are increasingly used in hospital settings. These programs require adequate institutional support to be sustainable over time. Ongoing infection prevention and control programs should include education, implementation, reinforcement, documentation, and evaluation of recommendations on a regular basis. Such activities should include conducting surveillance for high-risk HAIs, participating in improvement projects to reduce the incidence of HAIs, sharing data describing the incidence of specifically targeted HAIs, and measuring health care personnel compliance with key prevention activities, such as hand hygiene.

Infection preventionists should be familiar with the Targeted Assessment for Prevention (TAP) strategy developed by the CDC. This strategy targets health care facilities and specific units within facilities with a disproportionate burden of HAIs so that gaps in infection prevention in these locations can be addressed. The TAP report uses data in the National Healthcare Safety Network system to calculate a metric called the “cumulative attributable difference,” which is the number of infections that must be prevented within a group, facility, or unit to achieve an HAI reduction goal (www.cdc.gov/hai/prevent/tap.html).

¹ Saiman L, Seigel JD, LiPuma JJ, et al. Infection prevention and control guideline for cystic fibrosis: 2013 update. *Infect Control Hosp Epidemiol*. 2014;35(Suppl 1): S1-S67; www.cff.org/Care/Clinical-Care-Guidelines/Infection-Prevention-and-Control-Clinical-Care-Guidelines/Infection-Prevention-and-Control-Clinical-Care-Guidelines/

Infection Prevention and Control Precautions

Infection prevention and control precautions are designed to protect hospitalized children, health care personnel, and visitors by limiting transmission of potential pathogens within the health care setting. The Healthcare Infection Control Practices Advisory Committee (HICPAC) of the CDC has recommended a core set of infection prevention and control practices that are required in all health care settings, regardless of the type of health care provided (www.cdc.gov/infectioncontrol/guidelines/core-practices/index.html). These core practices represent fundamental standards of care that are not expected to change based on emerging evidence or to be regularly altered by changes in technology or practices. Additional evidence-based guidelines detailing transmission-based isolation precautions were published in 2007 (www.cdc.gov/hicpac/pdf/isolation/Isolation2007.pdf) with updates at www.cdc.gov/infectioncontrol/guidelines/isolation/updates.html. Adherence to this guidance, supplemented by health care facility policies and procedures for other aspects of infection and environmental control and occupational health, should reduce HAIs and result in safer patient care. Adaptations should be made according to the conditions and populations served by each facility, especially in the setting of an emerging infectious disease.

Routine and optimal performance of **Standard Precautions** is appropriate for care of *all* patients, regardless of diagnosis or suspected or confirmed infectious status. In addition to Standard Precautions, **Transmission-Based Precautions** are used when caring for patients who are infected or colonized with pathogens transmitted by airborne, droplet, or contact routes. Table 2.4 lists syndromes and conditions that are suggestive of contagious infection and require empiric isolation precautions pending identification of a specific pathogen. When the specific pathogen is known, isolation recommendations and duration of isolation are provided in the pathogen- or disease-specific chapters in Section 3 and can be found in the HICPAC guidelines (www.cdc.gov/infectioncontrol/guidelines/isolation/appendix/type-duration-precautions.html).

In November 2023, HICPAC recommended changes to existing categories of transmission-based precautions. Contact precautions would continue to be recommended to interrupt transmission of pathogens spread by touch. Droplet and airborne precautions would be replaced by 3 new categories of transmission-based precautions to interrupt transmission of pathogens spread by air. These include Routine Air Precautions, Special Air Precautions, and Extended Air Precautions, and are intended to better address the continuum of respiratory pathogen transmission through air. If these recommendations are ultimately adopted by the CDC, HICPAC will update pathogen-specific recommendations.

STANDARD PRECAUTIONS

Standard Precautions are used for all patient care and during every patient encounter, regardless of diagnosis or concern for a transmissible infection. Standard Precautions are based on health care personnel's assessment of how to protect themselves from exposure and how to prevent the spread of pathogens from patient to patient. Standard Precautions include the following practices:

- **Respiratory hygiene/ cough etiquette** (www.cdc.gov/flu/professionals/infectioncontrol/resphygiene.htm) includes source containment of infectious respiratory tract secretions in symptomatic patients beginning at the initial point of

Table 2.4. Clinical Syndromes or Conditions Warranting Precautions in Addition to Standard Precautions to Prevent Transmission of Epidemiologically Important Pathogens Pending Confirmation of Diagnosis^a

Clinical Syndrome or Condition ^b	Potential Pathogens ^c	Empiric Precautions ^d
Diarrhea		
Acute diarrhea with a likely infectious cause	Enteric pathogens ^e	Contact
Diarrhea in patient with a history of recent antimicrobial use	<i>Clostridioides difficile</i>	Contact; use soap and water for handwashing
Meningitis	<i>Neisseria meningitidis</i> , <i>Haemophilus influenzae</i> type b	Droplet
	Enteroviruses	Contact (and Droplet, if patient has respiratory symptoms)
Rash or exanthems, generalized, cause unknown		
Petechial or ecchymotic with fever	<i>Neisseria meningitidis</i>	Droplet
	Hemorrhagic fever viruses	Contact and Airborne
	Enteroviruses	Contact (and Droplet, if patient has respiratory symptoms)
Vesicular	Varicella-zoster virus	Contact and Airborne
Maculopapular with coryza and fever	Measles virus	Airborne
Respiratory tract infections		
Pulmonary cavitory disease	<i>Mycobacterium tuberculosis</i>	Airborne
Paroxysmal or severe persistent cough during periods of pertussis activity in the community	<i>Bordetella pertussis</i>	Droplet

Table 2.4. Clinical Syndromes or Conditions Warranting Precautions in Addition to Standard Precautions to Prevent Transmission of Epidemiologically Important Pathogens Pending Confirmation of Diagnosis,^a continued

Clinical Syndrome or Condition ^b	Potential Pathogens ^c	Empiric Precautions ^d
Viral bronchiolitis and croup, in infants and young children	Respiratory viral pathogens	Contact and Droplet
Risk of multidrug-resistant microorganisms^f		
Infection or colonization with a multidrug-resistant organism	Multi-drug resistant bacteria, <i>Candida auris</i>	Contact
Skin, wound, or urinary tract infection in a patient with a recent stay in a hospital or chronic care facility	Multi-drug resistant bacteria, <i>C. auris</i>	Contact until resistant organism is excluded by cultures
Skin or wound infection		
Abscess or draining wound that cannot be covered	<i>Staphylococcus aureus</i> , group A <i>Streptococcus</i>	Contact

^aInfection control professionals should modify or adapt this table according to local conditions. To ensure that appropriate empiric precautions are implemented, hospitals must have systems in place to evaluate patients routinely according to these criteria as part of their preadmission and admission care.

^bPatients with the syndromes or conditions listed may have atypical signs or symptoms (eg, pertussis in neonates may present with apnea; paroxysmal or severe cough may be absent in pertussis in adults). The clinician's index of suspicion should be guided by the prevalence of specific conditions in the community and clinical judgment.

^cThe organisms listed in this column are not intended to represent the complete or even most likely diagnoses but, rather, possible causative agents that require additional precautions beyond **Standard Precautions** until a causative agent is identified or excluded.

^dDuration of isolation precautions is not addressed in this table.

^eThese pathogens include Shiga toxin-producing *Escherichia coli* including *E. coli* O157:H7, *Shigella* organisms, *Salmonella* organisms, *Campylobacter* organisms, hepatitis A virus, enteric viruses such as rotavirus, *Cryptosporidium* organisms, and *Giardia* organisms. Use masks when cleaning vomitus or stool during norovirus outbreak.

^fMultidrug-resistant organisms should be defined by the infection control program on the basis of current state, regional, or national recommendations to be of special clinical or epidemiologic significance.

encounter (eg, emergency department triage and ambulatory clinic reception areas). Symptomatic children and their caregivers should cover their mouths/noses when sneezing/coughing, use tissues and dispose of them in no-touch receptacles, observe hand hygiene after soiling of hands with respiratory tract secretions, wear a disposable mask if tolerated, and maintain physical distancing as space permits.

- **Hand hygiene** (www.cdc.gov/handhygiene/) is necessary before and after all patient contact and after touching blood, body fluids, secretions, excretions, and contaminated items, including after removing (doffing) disposable gloves. Hand hygiene should also be performed after contact with the patient environment to ensure that health care personnel are not transmitting potential pathogens from contaminated surfaces that surround the patient. Hand hygiene should be performed either with soap and water or with alcohol-based agents. A helpful reference is the World Health Organization's Hand Hygiene: How, Why, and When document (cdn.who.int/media/docs/default-source/documents/health-topics/hand-hygiene-why-how-and-when-brochure.pdf).
- When hands are visibly dirty or contaminated with blood or other body fluids, they should be washed with soap and water for at least 20 seconds (including wrists). During an outbreak, handwashing with soap and water is preferred over alcohol-based agents for preventing transmission of spores (eg, *Clostridioides difficile*) and some viruses like norovirus.
- **Gloves** (clean, nonsterile, single use) should be worn when touching blood, body fluids, secretions, excretions, and items contaminated with these fluids. Clean gloves should be used by health care personnel before touching mucous membranes and nonintact skin or when contact with body fluids is possible. Gloves should be changed after contact with potentially infectious material (eg, purulent drainage) and high-touch surfaces and between tasks and procedures on the same patient. Hand hygiene should be performed before donning gloves and after removing them.
- **Masks, eye protection, and face shields** should be worn to protect mucous membranes of the eyes, nose, and mouth whenever there is an expectation of possible exposure to blood, body fluids, secretions, or excretions.
- **Nonsterile gowns** that are fluid-resistant will protect skin and prevent soiling of clothing during procedures and patient care whenever there is an expectation of possible exposure to infectious material. Soiled gowns should be removed promptly and carefully to avoid contamination of clothing.
- **Cleaning and disinfection of multipatient care equipment (eg, stethoscopes) and instruments/devices** should be performed according to the manufacturer's recommendations to prevent pathogen transmission from contaminated items.
- **All used textiles (linens)** are considered contaminated and should be handled, transported, and processed in a manner that prevents aerosolization of microorganisms, skin and mucous membrane exposure, and contamination of clothing.
- **Care of the environment**, which includes shared toys and high-touch surfaces, requires that policies and procedures are established for routine and targeted cleaning of environmental surfaces as indicated by the level of patient contact and degree of soiling. A hospital disinfectant registered by the Environmental Protection Agency should be used.

- **Safe injection practices should be followed to prevent risks to patients and health care personnel.** Syringes should *never* be reused for more than one patient even if the needle is changed. Likewise, insulin pens and lancing devices must not be used for multiple patients. Do not use medications packaged as single-dose or single-use for more than one patient and do not enter a vial with a used syringe or needle. Limit the use of multidose vials and dedicate them to a single patient whenever possible. More information is available from the CDC at www.cdc.gov/injectionsafety. Bloodborne pathogen exposure of health care personnel should be avoided by taking precautions to prevent injuries caused by needles, scalpels, and other sharp instruments or devices during procedures; when handling sharp instruments after procedures; when cleaning used instruments; and during disposal of used needles. To prevent needlestick injuries, safety devices should be used whenever they are available. Needles should not be recapped, purposely bent or broken, removed from disposable syringes, or otherwise manipulated by hand. After use, disposable syringes and needles, scalpel blades, and other sharp items should be placed in puncture-resistant containers for disposal. These containers should be located as close as practicable to the usage area. Large-bore, reusable needles should be placed in a puncture-resistant container located close to the site of usage for easy transport to the reprocessing area to ensure maximal patient safety. Sharp devices with safety features are preferred whenever such devices have equivalent function to conventional sharp devices. Written policies and procedures relating to needlestick or sharp injuries are mandated by the Occupational Safety and Health Administration (www.osha.gov/healthcare).
- **During spinal procedures** (eg, lumbar puncture or placing a catheter), surgical masks should be worn to prevent contamination of the lumbar area with the health care personnel's respiratory flora and subsequent health care-associated meningitis or contaminated culture results.
- **Source control** refers to wearing respirators or well-fitting facemasks to cover a person's mouth and nose to prevent spread of respiratory secretions when they are breathing, talking, sneezing, or coughing. This infection prevention measure was initially recommended for all health care personnel by the CDC during the COVID-19 pandemic to prevent presymptomatic transmission of SARS-CoV-2 in health care settings and has been proven to be an effective means of limiting spread of respiratory viruses. See www.cdc.gov/infectioncontrol/guidelines/isolation/index.html for further information.

TRANSMISSION-BASED PRECAUTIONS

Transmission-Based Precautions are designed for patients documented or suspected to have colonization or infection with pathogens for which additional precautions beyond **Standard Precautions** are recommended to prevent transmission. The 3 types of transmission routes on which these precautions are based are airborne, droplet, and contact. Recent evidence suggests that airborne and droplet transmission are not discrete categories but exist on a continuum, influenced by many factors including their environment and their initial sizes.

- **Airborne transmission** occurs by dissemination of airborne droplet nuclei (small-particle residue [traditionally defined as $\leq 5 \mu\text{m}$ in size, although this definition has been challenged by data showing that droplets/aerosols $20 \mu\text{m}$ in size travel like

aerosols from cough jets and air conditioning] of evaporated droplets containing microorganisms that remain suspended in the air for long periods) or small respirable particles containing the infectious agent or spores. Microorganisms transmitted by the airborne route can be dispersed widely by air currents and can be inhaled by a susceptible host within the same room or at a long distance from the source patient, depending on environmental factors. Special air handling and ventilation are required to prevent airborne transmission. Some examples of microorganisms transmitted by airborne droplet nuclei are *Mycobacterium tuberculosis*, measles virus, and varicella-zoster virus. Specific recommendations for **Airborne Precautions** are as follows:

- ♦ When possible, the patient should wear a mask while health care personnel are inside the room and during patient transport outside of the room.
- ♦ Contagious patients and care partners should be placed in a single-patient room (if unavailable, consult an infection preventionist), and the door should be kept closed at all times.
- ♦ The isolation room should provide at least 6 to 12 air changes per hour, air flow direction from the surrounding area to the room (“negative pressure”), and room air exhausted directly to the outside or recirculated through high-efficiency particulate air (HEPA) filters.
- ♦ Health care personnel should be trained to use respiratory protective devices appropriately, such as a fit-tested National Institute for Occupational Safety and Health-approved N95 or higher-level respirator, while inside the patient’s room. The Centers for Disease Control and Prevention provides guidance on using respirators at www.cdc.gov/coronavirus/2019-ncov/prevent-getting-sick/use-n95-respirator.html.
- ♦ Susceptible health care personnel should not enter rooms of patients with known or suspected measles or varicella-zoster virus infections. If susceptible people must enter the room of a patient with measles or varicella infection or an immunocompromised patient with local or disseminated zoster infection, a respiratory protective device, such as a fit-tested N95 (or higher-level) respirator or a powered air-purifying respirator, should be worn.
- **Droplet transmission** occurs when respiratory droplets containing microorganisms are generated from an infected person, primarily during coughing, sneezing, or talking, and during the performance of certain procedures, such as suctioning and bronchoscopy, and are propelled a short distance (generally less than 3 feet, but in some cases more like aerosols) and deposited into the conjunctivae, nasal mucosa, or mouth of a susceptible person. Because these relatively large droplets do not remain suspended in air, special air handling and ventilation are not required to prevent droplet transmission. A few examples of the many microorganisms transmitted by droplets are *Bordetella pertussis*, group A *Streptococcus* species, rhinovirus, influenza virus, and *Neisseria meningitidis*. Specific recommendations for **Droplet Precautions** are as follows:
 - ♦ When possible, the patient and care partners should wear a mask while health care personnel are inside the room and during patient transport outside of the room.
 - ♦ The patient should be placed in a single-patient room, if possible. If unavailable, the facility may consider cohorting patients infected with the same organism. Spatial separation of more than 6 feet should be maintained between the bed of the infected patient and the beds of the other patients in multiple-bed rooms.

- ♦ A mask and eye protection or face shield should be worn on entry into the room or into the cubical space, and droplet precautions should be maintained when within 3 to 6 feet of the patient.
- ♦ Staff who enter the room of a patient with suspected or confirmed SARS-CoV-2 infection should use a fit-tested N95 (or higher-level) respirator.
- ♦ Masks and other personal protective equipment (PPE) should be removed before leaving the room or caring for another patient in the same room. Hand hygiene should be performed immediately after PPE removal.
- **Contact transmission** is the most common route of transmission of HAIs. *Direct contact* transmission involves the physical transfer of microorganisms from a person with infection or colonization to a susceptible host through direct contact with infectious agents, such as occurs when a health care professional examines a patient or performs other patient care activities that require direct personal contact. Direct contact transmission also can occur between 2 patients when one serves as the source of the infectious microorganisms and the other serves as a susceptible host. *Indirect contact* transmission involves contact of a susceptible host with a contaminated intermediate object (“fomite”), usually inanimate, such as contaminated instruments, needles, dressings, toys, or contaminated hands that are not cleansed or gloves that are not changed between patients. A few examples of the many microorganisms transmitted by contact include respiratory syncytial virus, *C. difficile*, enterovirus, *Salmonella* species, *Shigella* species, and Shiga toxin-producing *Escherichia coli*. In addition, specific situations requiring **Contact Precautions** include the following:
 - ♦ Conjunctivitis (viral and hemorrhagic).
 - ♦ Colonization or infection with a specific multidrug-resistant organism (MDRO), as determined by the facility’s infection prevention and control program based on current state, regional, or national recommendations to be of special clinical and epidemiologic significance (eg, carbapenemase-producing gram-negative bacilli, *Candida auris*, other MDROs), or another epidemiologically important organism (which may or may not be an MDRO). Information on the CDC containment strategy for responding to emerging antibiotic resistant threats is available on the CDC website (www.cdc.gov/hai/containment/index.html).

Specific recommendations for **Contact Precautions** are as follows:

- ♦ The patient and care partners should be placed in a single-patient room if possible. If unavailable, cohorting patients who are likely to be infected with the same organism and use of Standard and Contact Precautions is permissible.
- ♦ Gloves (clean, nonsterile, single use) should be used at all times.
- ♦ Gown and gloves should be used on entry into a patient room and during direct contact with a patient, environmental surfaces, or items in the patient room. Gown and gloves should be removed before leaving the patient’s room or area, immediately followed by hand hygiene.
- ♦ When transport or movement outside of the room is necessary, infected or colonized areas of the patient’s body should be covered and any potentially infectious drainage or secretions should be contained.
- ♦ Disposable noncritical patient-care equipment (eg, blood pressure cuffs) should be used, or patient-dedicated use of such equipment should be implemented. If common use of equipment for multiple patients is unavoidable, such equipment should be cleaned and disinfected per manufacturer’s recommendations before use on another patient.

Airborne, Droplet, and Contact Precautions should be combined for diseases caused by organisms that have multiple routes of transmission. If available testing cannot differentiate between 2 organisms, the recommended precautions for each organism should be combined. When used alone or in combination, these **Transmission-Based Precautions** are always to be used in addition to Standard Precautions, which are recommended for all patients. The care of patients with a highly transmissible and highly lethal infection, such as Ebola virus, requires additional extensive infection prevention and control measures (www.cdc.gov/vhf/ebola/clinicians/evd/infection-control.html). Novel pathogens may also require additional infection prevention measures when the mode(s) of transmission are still unknown. Some pathogens, including SARS-CoV-2, may not be spread exclusively by distinct droplet versus airborne routes. Consultation with the facility's infection prevention department or public health authority is recommended.

PEDIATRIC CONSIDERATIONS

Unique differences in pediatric care necessitate modifications of these guidelines, including the following: (1) use of single-patient room isolation; (2) use of common areas, such as hospital waiting rooms, playrooms, and schoolrooms; and (3) family-centered care. More patients and their care partners or visitors with transmissible infections may be present in pediatric health care settings than in adult ones, especially during seasonal epidemics.

Single-patient rooms are recommended for all patients requiring **Transmission-Based Precautions** (ie, **Airborne, Droplet, and Contact**). Single-patient rooms can also be prioritized if the patient is at increased risk of acquiring infection or of developing an adverse outcome following infection. Patients placed on **Transmission-Based Precautions** and their caregivers or visitors should not leave their rooms to use common areas on the unit, such as playrooms, schoolrooms, or waiting areas, or elsewhere in the hospital, such as cafeteria or gift shop, except under special circumstances as defined by the facility's infection preventionist. The guidelines for **Standard Precautions** state that patients who cannot control body excretions should be in single-patient rooms. Because many young children are incontinent, this recommendation does not apply to routine care of uninfected, diapered children.

The Society for Healthcare Epidemiology of America has published infection prevention and control guidelines for residential facilities that serve pediatric patients and their families.¹ These types of facilities provide support services, including overnight lodging, for ill and injured children (including immune compromised hosts) and their families.

Strategies to Prevent Health Care-Associated Infections

HAIs in patients in acute care hospitals are associated with substantial morbidity. Important HAIs include central line-associated bloodstream infections, central nervous system shunt infections, surgical site infections, urinary catheter-associated urinary tract infections, ventilator-associated pneumonias, infections caused by viruses (eg, respiratory syncytial virus, rotavirus), and colitis attributable to *C difficile*. Infection

¹ Guzman-Cottrill J, Ravin K, Bryant K, Zerr D, Kociolek L, Siegel J. Infection prevention and control in residential facilities for pediatric patients and their families. *Infect Control Hosp Epidemiol*. 2013;34(10):1003-1041. doi:10.1086/673141 or www.doi.org/10.1086/673141

prevention strategies exist for each of these infections. Evidence-based protocols have been shown to reduce HAIs by using “bundled strategies” (when multiple prevention activities are implemented simultaneously) and with multidisciplinary participation from members of the health care team, including administrators, physicians, nurses, therapists, and housekeeping services. Studies in pediatrics have demonstrated bundles to be effective in reducing central line-associated bloodstream infections, surgical site infections, and ventilator-associated pneumonias. High-quality recommendations are available online (www.solutionsforpatientsafety.org/s/CLABSI_Bundle_SPS.pdf and www.cdc.gov/infectioncontrol/guidelines/BSI/index.html). Supporting the establishment and maintenance of breastfeeding and human milk feeding has also been shown to reduce rates of neonatal infections and sepsis.

Occupational Health

Transmission of infectious agents within health care settings is facilitated by close contact between patients and health care personnel and by lack of hygienic practices by infants and young children. Guidelines for infection control in health care personnel, including requirements for infrastructure and routine practices, are available at www.cdc.gov/infectioncontrol/guidelines/healthcare-personnel/index.html.

The consequences to pediatric patients of acquiring infections from adult health care personnel can be significant. Mild illnesses in adults, such as viral gastroenteritis, upper respiratory tract viral infection, pertussis, or herpes simplex virus infection, can cause life-threatening disease in infants and children. Patients at greatest risk are pre-term infants, children who have chronic heart disease or pulmonary disease, and people who are immunocompromised. Health care personnel education, including understanding of hospital policies, is of paramount importance in infection prevention and preventing ill employees from reporting to work. Frequent educational sessions will reinforce safe techniques and the importance of infection prevention and control policies.

Standard Precautions and **Transmission-Based Precautions** are designed to prevent transmission of infectious agents in health care settings among patients and health care personnel. To further limit risks of transmission of organisms between children and health care personnel, health care facilities should have established occupational health policies and services. Specifically, personnel should be protected against vaccine-preventable diseases by establishing appropriate screening and immunization policies. Guidelines for immunization of health care personnel are available (www.cdc.gov/vaccines/adults/rec-vac/hcw.html).

For infections that are not vaccine-preventable, personnel should be counseled about exposures and the possible need for leave from work if they are exposed to, ill with, or a carrier of a specific pathogen, whether the exposure occurs in the home, community, or health care setting.

The frequency of and need for screening of health care personnel for tuberculosis should be determined by local epidemiologic data. The CDC has published guidance for the prevention of transmission of tuberculosis in health care settings (www.cdc.gov/tb/topic/infectioncontrol/default.htm and www.cdc.gov/tb/publications/guidelines/infectioncontrol.htm). People with commonly occurring infections, such as gastroenteritis, dermatitis, herpes simplex virus lesions on exposed skin, or upper respiratory tract infections, should be evaluated to determine the risk of transmission to patients or to other health care personnel.

Pregnant or lactating health care personnel who follow recommended precautions should not be at increased risk of most infections that have possible adverse effects on the fetus or infant (eg, parvovirus B19, cytomegalovirus, mpox, rubella, varicella, and Zika). Pregnant health care personnel should not care for patients with Ebola (www.cdc.gov/niosh/topics/repro/infectious.html). The CDC's National Institute for Occupational Safety and Health provides guidance for pregnant health care personnel and health care worker safety (www.cdc.gov/niosh/topics/repro/healthcaresafetyresources.html).

Health care personnel who are immunocompromised and at increased risk of severe infection (eg, *M tuberculosis*, measles virus, herpes simplex virus, and varicella-zoster virus) should seek advice from their primary health care professional.

Sibling Visitation

Sibling visits to birthing centers, postpartum rooms, pediatric wards, and intensive care units are encouraged, although some institutions restrict visitation of young children during times of peak respiratory viral activity because of their relatively high frequency of asymptomatic viral shedding and difficulties adhering to basic respiratory etiquette and hand hygiene practices.

Sibling visits may benefit hospitalized children. Neonatal intensive care often results in long hospital stays for the preterm or sick newborn infant, making family and caregiver visits important. Guidelines for sibling visits should be established to maximize opportunities for visiting while at the same time minimizing the risks of transmission of pathogens brought into the hospital setting by young visitors. Guidelines may need to be modified by local nursing, pediatric, obstetric, and infectious diseases staff members to address specific issues in their hospital settings and during outbreaks. Basic guidelines for sibling visits to pediatric patients are as follows:

- If a child has isolation precautions for a transmissible disease, visitation should be limited to parents and/or designated adult caregivers only, assuming that they do not have a similar isolation precaution for the same disease.
- Before the visit, a trained health care professional should interview the parent or guardian at a site outside the unit to assess the health of each sibling visitor. These interviews should be documented, and approval for each sibling visit should be noted. No child with fever or symptoms of an acute infection, including upper respiratory tract infection, gastroenteritis, or cellulitis, should be allowed to visit. Siblings who recently have been exposed to a person with a known communicable disease and are susceptible should not be allowed to visit.
- Siblings who are visiting should have received all recommended immunizations for their age. Before and during influenza season, siblings who visit should have received their annual influenza vaccine.
- The visiting sibling should visit only their sibling and be restricted from playrooms when other patients are present.
- Children should perform recommended hand hygiene before entry into the health care setting and before and after any patient contact, and as otherwise recommended (after using the toilet, before eating, etc).
- Throughout the visit, sibling activity should be supervised by a parent or responsible adult and limited to the patient room or other designated areas where other patients are not present.

- Whenever possible, special accommodations should be made for visitation of siblings who are currently breastfeeding when the mother is at the bedside of a hospitalized patient.

Adult Visitation

Guidelines should be established for adults who accompany hospitalized children. Guidelines may need to be modified by hospital staff to address specific issues and during outbreaks.

- People with fever or contagious illnesses should not visit.
- People who have had close contact with someone with SARS-CoV-2 infection or were in another situation that put them at risk for SARS-CoV-2 transmission should be counseled that it is safest to defer nonurgent in-person visitation until 10 days after their close contact, especially if they cannot wear respirators or well-fitting face masks to cover their mouth and nose (source control).
- If a child has isolation precautions for a contagious respiratory disease and a susceptible parent or guardian remains with the hospitalized child, the adult should follow source control precautions and wear a mask when health care personnel are inside the room.
- Medical and nursing staff should be vigilant about potential communicable diseases in parents and other adult visitors (eg, a relative with a cough who may have pertussis or tuberculosis; a parent with a cold visiting an immunosuppressed child). When identified, ill visitors should be asked to leave immediately.
- Before and during the winter respiratory virus season, all adult visitors should be encouraged to have received the annual influenza vaccine and COVID-19 vaccine, especially for oncology, hematopoietic stem cell transplant, and neonatal intensive care units.

Pet Visitation

- Pet visitation in the health care setting includes both visits by a child's personal pet and pet visitation as a part of child life therapeutic programs. Guidelines for pet visitation should be established to minimize risks of transmission of pathogens from pets to humans or injury from animals. The specific health care setting and the level of concern for zoonotic disease will influence establishment of pet visitation policies. The pet visitation policy should be developed in consultation with pediatricians, infection preventionists, nursing staff, the hospital epidemiologist, and veterinarians.¹
- Patients having contact with pets must have approval from the patient's physician, nurse, and the facility's infection prevention and control program prior to the visit. For patients who are immunocompromised, including those receiving immunosuppressive therapy, the risks of exposure to the microflora of pets may outweigh the benefits of contact. Contact of children with pets should be considered for approval on a case-by-case basis.
- Personal pets other than dogs should be excluded from the hospital. Pets should be housebroken and at least 1 year of age. Exceptions may be made for end-of-life patients who are in single-patient rooms.

¹ Murthy R, Bearman G, Brown S, et al. SHEA Expert Guidance. Animals in healthcare facilities: recommendations to minimize potential risks. *Infect Control Hosp Epidemiol*. 2015;36(50):495-516. DOI: <http://dx.doi.org/10.1017/ice.2015.15>

- Visiting pets should have a certificate of immunization from a licensed veterinarian and verification that the pet is healthy. Some institutions require an assessment of temperament (eg, Canine Good Citizen certificate).
- The pet should be bathed and groomed for the visit.
- Pet visitation should be discouraged in an intensive care unit or hematology-oncology unit, but individual circumstances can be considered. Involvement with the infection control and prevention team is recommended.
- The visit of a pet should also be approved by an appropriate personnel member (eg, the director of the child life therapy program), who should observe the pet for temperament and general health at the time of visit. The pet should be free of obvious bacterial skin infections, infections caused by superficial dermatophytes, and ectoparasites (fleas and ticks).
- Pet visitation should be confined to designated areas. Contact should be confined to the petting and holding of animals, as appropriate. All contact should be supervised throughout the visit by appropriate personnel.
- Hand hygiene should be performed by the patient and all who have contact with the pet, both before and after pet visitation. Supervisors should be familiar with institutional policies for managing animal bites and cleaning pet urine, feces, or vomitus.
- Care should be taken to protect all indwelling devices, including catheter exit sites (eg, central venous catheters, peritoneal dialysis catheters). These sites should have semi-occlusive dressings whenever possible that will provide an effective barrier to pet contact, including licking, and be covered with clothing or gown. Concern for contamination of other body sites should be considered on a case-by-case basis. Specifically, wounds should be protected from animal contact.
- The pet policy should not apply to professionally trained service animals. These animals are not pets and separate policies should govern their uses and presence in the hospital, according to the requirements of the Americans with Disabilities Act.

..... INFECTION PREVENTION AND CONTROL IN AMBULATORY SETTINGS

Infection prevention and control is an integral part of pediatric practice in ambulatory care settings.¹ All health care personnel should be aware of the routes of transmission and techniques to prevent transmission of infectious agents. Written policies and procedures for infection prevention and control should be readily available, implemented, updated regularly, and adherence regularly assessed. Facilities should have ready access to an individual with training in infection prevention and control. **Standard Precautions**, as outlined for the hospitalized child (see Infection Prevention and Control for Hospitalized Children, p 163) and by the Centers for Disease Control and Prevention (CDC),² with a modification by the American Academy of Pediatrics

¹ Rathore MH, Jackson MA; American Academy of Pediatrics, Committee on Infectious Diseases. Infection prevention and control in pediatric ambulatory settings. *Pediatrics*. 2017;140(5):e20172857

² Centers for Disease Control and Prevention. Guideline for isolation precautions: preventing transmission of infectious agents in health care settings 2007. Recommendations of the Healthcare Infection Control Practices Advisory Committee. Atlanta, GA: Centers for Disease Control and Prevention; 2007. Available at: www.cdc.gov/hicpac/2007IP/2007isolationPrecautions.html

exempting the use of gloves for routine diaper changes and wiping a child's nose or eyes,¹ are appropriate and should be utilized for all patient encounters. Additional **Transmission-Based Precautions** may be indicated based on the symptoms of the child being evaluated (eg, gown, gloves, N95 [or higher-level] respirator and eye protection for the child with suspected SARS-CoV-2 infection). Universal source control (the use of respirators or well-fitting face masks to cover the mouth and nose of the patient and their caregivers to prevent spread of respiratory secretions when they are breathing, talking, sneezing, or coughing) may be indicated when community transmission of SARS-CoV-2 or other respiratory pathogens is high. The CDC has created a guideline and a checklist (www.cdc.gov/infectioncontrol/pdf/outpatient/guide.pdf and www.cdc.gov/infectioncontrol/pdf/outpatient/guidechecklist.pdf) that health care professionals can use to ensure that appropriate infection-control practices are being followed and, thus, reduce ambulatory health care-associated infections. Health care professionals should be familiar with the most current CDC infection prevention and control guidance for SARS-CoV-2 (www.cdc.gov/coronavirus/2019-ncov/hcp/infection-control.html, www.cdc.gov/coronavirus/2019-ncov/hcp/facility-planning-operations.html, and www.cdc.gov/coronavirus/2019-ncov/hcp/facility-planning-operations.html).

In November 2023, HICPAC recommended changes to existing categories of transmission-based precautions. Contact precautions would continue to be recommended to interrupt transmission of pathogens spread by touch. Droplet and airborne precautions would be replaced by 3 new categories of transmission-based precautions to interrupt transmission of pathogens spread by air. These include Routine Air Precautions, Special Air Precautions, and Extended Air Precautions, and are intended to better address the continuum of respiratory pathogen transmission through air. If these recommendations are ultimately adopted by the CDC, HICPAC will update pathogen-specific recommendations.

Key principles of infection prevention and control in an outpatient setting are as follows:

- Infection prevention and control should begin when the child's appointment is scheduled (eg, triage questions, such as travel, exposures, and symptoms, may guide additional precautions for when the patient arrives) and initiated when the child enters the office or clinic.
- **Standard Precautions** should be used when caring for all patients. **Standard Precautions** are supplemented by **Transmission-Based Precautions** and should include instructions to health care personnel on the proper donning (putting on) and doffing (removing) of personal protective equipment (gowns, face masks, protective eyewear [or face shield], and gloves). Patients known to be infected or colonized with highly resistant organisms (eg, *Candida auris*, carbapenemase-producing *Enterobacteriales*) should be identified and placed on contact precautions during outpatient encounters. Any individual on the care team entering the room should follow the appropriate precautions, regardless of whether the patient is being examined. Contact between contagious children and uninfected children should be minimized. Children who are suspected of having highly contagious infections, such as varicella, measles, or COVID-19, should be promptly isolated. This may involve notification of clinic

¹ Rathore MH, Jackson MA; American Academy of Pediatrics, Committee on Infectious Diseases. Infection prevention and control in pediatric ambulatory settings. *Pediatrics*. 2017;140(5):e20172857

staff at the time of arrival so that the patient can be examined outside of the clinic or be routed directly to an examination room, minimizing wait times and/or bypassing the waiting room. Neonates and immunocompromised children should be promptly placed in a room and kept away from people with potentially contagious infections.

- In waiting rooms of ambulatory care facilities, respiratory hygiene/cough etiquette and use of masks should be implemented for patients with suspected respiratory tract infection as well as people accompanying them.¹
 - ♦ It is recommended that patients with cystic fibrosis be taken directly to an examination room at the time of arrival, whenever possible.² If it is not feasible to use separate waiting areas to prevent contact between patients with cystic fibrosis, a minimum of 6 feet should be used to ensure their separation (this does not apply to members of the same household). Patients with cystic fibrosis who are in the waiting room should be masked (mask may be removed in the examination room). Health care providers should use contact precautions (gown and gloves) when caring for a patient with cystic fibrosis.
- All health care personnel should perform hand hygiene before and after each patient contact. In health care settings, alcohol-based hand products are preferred for decontaminating hands routinely. Soap and water are preferred when hands are visibly dirty or contaminated with proteinaceous material, such as blood or other body fluids, and after caring for a patient with known or suspected infectious diarrhea (eg, *Clostridioides difficile* or norovirus) even if gloves are worn. Parents and children should be taught the importance of hand hygiene. Guidelines on hand hygiene can be found on the CDC website (www.cdc.gov/handhygiene/providers/guideline.html).
- Health care personnel should receive influenza vaccination annually and stay current on vaccinations against other vaccine-preventable infections, including SARS-CoV-2, that can be transmitted in an ambulatory setting to patients or to other health care personnel. Recommended vaccines include influenza; COVID-19; tetanus toxoid, reduced diphtheria toxoid and acellular pertussis (Tdap); measles, mumps, and rubella (MMR); varicella; and hepatitis B. The latest recommendations can be found at www.cdc.gov/vaccines/adults/rec-vac/hcw.html. Health care personnel do not need to take additional action regarding measles vaccination if they have written documentation of 2 doses of MMR or laboratory-confirmed measles or laboratory evidence of immunity (positive immunoglobulin G [IgG] titers). Those who were born before 1957 are generally considered immune; however, if no other evidence of immunity exists, administering 2 doses of MMR should be considered and is recommended in an outbreak.
- Ambulatory facilities should implement sick leave options for health care personnel that encourage reporting of potentially infectious exposures and reduce presenteeism (working while sick).
- Depending on the setting where they work, health care personnel should be familiar with aseptic technique, particularly regarding insertion or manipulation of

¹Centers for Disease Control and Prevention. Respiratory Hygiene/Cough Etiquette in Healthcare Settings. Available at: www.cdc.gov/flu/professionals/infectioncontrol/resphgiene.htm

²Saiman L, Seigel JD, LiPuma JJ, et al. Infection prevention and control guideline for cystic fibrosis: 2013 update. *Infect Control Hosp Epidemiol*. 2014;35(Suppl 1):S1-S67. Available at: www.cff.org/Care/Clinical-Care-Guidelines/Infection-Prevention-and-Control-Clinical-Care-Guidelines/Infection-Prevention-and-Control-Clinical-Care-Guidelines/

intravascular catheters, performance of other invasive procedures, and preparation and administration of parenteral medications. Aseptic technique includes selection and use of appropriate skin antiseptics. The preferred skin-preparation agent for immunization and venipuncture for routine blood collection is 70% isopropyl alcohol. For incision, suture, and collection of blood for culture, skin preparation with either 2% chlorhexidine gluconate (CHG) in 70% isopropyl alcohol-based solutions or iodine (1% or 2% tincture of iodine, 2% povidone-iodine) should be used.

- Medications should be drawn up in a designated clean medication preparation area that is not adjacent to potential sources of contamination, including sinks or other water sources or used items such as syringes, needles, intravenous tubing, or blood collection tubes. When administering medications, appropriate injection safety practices should be used (www.cdc.gov/infectioncontrol/pdf/outpatient/guide.pdf), including:
 - ♦ Cleansing the diaphragms of medication vials with alcohol before inserting a device into the vial.
 - ♦ Never administering medications from the same syringe to multiple patients, even if the needle is changed.
 - ♦ Never reusing a syringe to enter a medication vial or container.
 - ♦ Never administering medications from single-dose or single-use vials to more than one patient.
 - ♦ Dedicating multidose vials to a single patient whenever possible. If multidose vials will be used for more than one patient, they should be restricted to a centralized medication area and should not enter the immediate patient treatment area.
- Whenever available, medical devices designed to reduce the risk of needlesticks should be used. Sharps disposal containers that are impermeable and puncture resistant should be placed immediately adjacent to the areas where sharps are used (eg, areas where injections or venipunctures are performed). Sharps containers should be replaced when they are two-thirds full and kept out of reach of young children. Policies should be established for the removal and disposal of sharps containers consistent with state and local regulations. Guidance on safe injection practices is available on the CDC website (www.cdc.gov/injectionsafety/).
- Appropriate handling of medical waste should be outlined (www.cdc.gov/infectioncontrol/pdf/outpatient/guide.pdf).
- A written bloodborne pathogen exposure control plan that includes policies for management of exposures to blood and body fluids, such as through needlesticks and exposures of nonintact skin and mucous membranes, should be developed, readily available to all staff, and updated and reviewed with staff regularly (at least annually) (see Hepatitis B, p 437; Hepatitis C, p 458; Human Immunodeficiency Virus Infection, p 489; and www.cdc.gov/niosh/topics/bbp/genres.html).
- Manufacturer's guidelines for processing of medical devices and equipment, including cleaning, decontamination, disinfection, and sterilization, should be followed meticulously by personnel with training in the required reprocessing steps. Competency should be assessed periodically (at least annually). Once sterilized, devices and equipment should be kept in their sterile packaging until immediately prior to use.
- Cleaning of point-of-use equipment (eg, stethoscopes, otoscopes) should be performed after each patient encounter with Environmental Protection Agency (EPA)-registered disinfectants or detergents/disinfectants with label claims for use in health care.

- Policies and procedures should be established for cleaning and disinfection of environmental surfaces and general housekeeping. Supplies necessary for appropriate cleaning and disinfection procedures (eg, EPA-registered disinfectants) are available. Cleaners and disinfectants are used in accordance with manufacturer's instructions (eg, dilution, storage, shelf-life, contact time). Examination tables should be cleaned between use. Patients can be encouraged to bring their own toys. If toys are available in waiting areas, they should be disposable or able to be cleaned and disinfected or sanitized between each use.¹
- Appropriate use of antimicrobial agents is essential to limit the emergence and spread of drug-resistant bacteria (see Antimicrobial Stewardship, p 981).
- Policies and procedures should be developed for communication with local and state health authorities about reportable diseases and suspected outbreaks (www.cdc.gov/nndss/ and www.cdc.gov/hai/outbreaks/).
- Educational programs for health care personnel that encompass appropriate aspects of infection control should be implemented, reinforced, documented, and evaluated on a regular basis.
- Outpatient facilities and practices should have access to an individual with training in infection prevention who manages the infection prevention program (www.cdc.gov/infectioncontrol/pdf/outpatient/guidechecklist.pdf).
- Physicians should be aware of requirements of government agencies, such as the Occupational Safety and Health Administration (OSHA), as well as state and federal regulations that may apply to the operation of physicians' offices.

SEXUALLY TRANSMITTED INFECTIONS IN ADOLESCENTS AND CHILDREN

Physicians and other health care professionals perform a critical role in preventing and treating sexually transmitted infections (STIs) in the pediatric and adolescent population. STIs are a major problem for adolescents; an estimated 25% of adolescent females² will acquire an STI by 19 years of age. Although an STI in an infant or child early in life can be the result of vertical transmission, nonabusive horizontal transmission, or autoinoculation (particularly herpes simplex virus [HSV] and human papillomavirus [HPV]), STIs (eg, gonorrhea, syphilis, chlamydia, genital herpes, human immunodeficiency virus [HIV] infection, trichomoniasis, or anogenital warts) should raise suspicion of sexual abuse if acquired after the neonatal period. Whenever sexual abuse is suspected, appropriate social service and law enforcement agencies must be involved to evaluate the situation further, to ensure the child or adolescent's protection, and to provide appropriate counseling. When available, consultation with a child abuse pediatrician can help guide further evaluation, aid in decision making on reporting suspected abuse, and assist with rendering an opinion on the etiology of the STI.

² In this chapter, the terms male, female, men, and women are used to mean sex assigned at birth.

STIs During Preventive Health Care of Adolescents

EPIDEMIOLOGY OF STIs IN ADOLESCENTS

Adolescents and young adults have the highest rates of several STIs when compared with any other age group. Adolescents are at greater risk of STIs because of their potentially high-risk sexual behaviors, inability to understand the risks of STIs, and increased biologic susceptibility. In addition, adolescents may face several potential obstacles in accessing comprehensive sexual health care services.¹ Young women, particularly women of color, young men who have sex with men (MSM), and transgender women are at particularly high risk of STIs, including HIV infection. Health care professionals frequently fail to confidentially ask adolescents and young adults about sexual behaviors, assess for STI risks, counsel about risk reduction, and screen for STIs.²

EVALUATION OF STIs IN ADOLESCENTS

At each health care visit, the health care provider should allow some private time, apart from the parent(s) or guardian(s), to speak with the adolescent confidentially.³ In order to educate and prepare patients and families about the need for confidentiality as adolescence approaches, health care professionals should familiarize themselves with local statutes on minors' consent for HIV and STI services. Pediatricians should screen for STI risk by *routinely* asking all adolescent and young adult patients—apart from their parents—whether they ever have had any sexual encounters, are currently sexually active, or are planning to become sexually active, as well as about gender identity and sexual orientation. Pediatricians must be sure to clarify what is meant by the terms “sexual intercourse,” “gender identity,” “sexual orientation,” and “sexually active,” because these terms can have different meanings for adolescents. It is important that adolescents and young adults are educated to recognize that noncoital practices (oral/genital contact, anal intercourse, and hand/genital contact), as well as vaginal intercourse, put them at risk of STIs. If a patient indicates a history of sexual activity, the health care professional must further ascertain the types of sexual encounters, biological sex of the partner(s), and number of partners to determine what type(s) of STI testing to perform. More detailed recommendations for preventive health care for adolescents and young adults are available from the Centers for Disease Control and Prevention (CDC).⁴

TREATMENT OF STIs IN ADOLESCENTS

All 50 states allow minors to give their own consent for confidential STI testing and treatment. Pediatricians should consult their own state laws for further guidance. For specific STI treatment recommendations, see the disease-specific chapters in Section 3 and Tables 4.4 (p 1107) and 4.5 (p 1014). Single-dose therapies are available for many STIs, offering the advantage of high patient adherence; directly observed therapy should be provided where feasible. Patients and their partners treated for *Neisseria gonorrhoeae* infection, *Chlamydia trachomatis*, or *Trichomonas vaginalis* infection should be advised to refrain from sexual intercourse for at least 7 days after completion of appropriate treatment.

Partner treatment is essential, both from a public health perspective and to protect the infected patient from reinfection. Sexual partners during the past 60 days should be informed of exposure to the infection and encouraged to seek comprehensive STI evaluation and treatment. Health departments typically attempt to notify sex partners of patients infected with HIV or syphilis and arrange for treatment. Depending on health department resources, partner services may be offered for some gonorrhea cases and occasionally for chlamydia. If it appears unlikely that partners of patients treated for gonococcal, chlamydial, or trichomonas infections will seek care, pediatricians may consider providing expedited partner therapy (EPT) to patients in states where EPT is permissible.¹ EPT is the clinical practice of treating the sex partners of patients with diagnosed chlamydia or gonorrhea by providing prescriptions or medications to the patient to take to their partner without the health care professional first examining the partner. Information should include warning about the low risk of potential adverse events with EPT, with instructions to seek medical attention in the event that an adverse reaction occurs. Published studies suggest that in certain settings, >5% of MSM without previously diagnosed HIV infection will be diagnosed with HIV infection when evaluated as a partner of patients with gonorrhea or chlamydia. Considering limited data and the potential for other bacterial STIs among MSM partners, shared clinical decision-making regarding EPT is recommended among MSM. Guidance on the legal status of EPT by jurisdiction is available from the CDC (www.cdc.gov/std/ept/legal/).

PREVENTION OF STIs IN ADOLESCENTS

Pediatricians and other health care professionals can contribute to primary STI prevention by encouraging and supporting a teenager's decision to postpone sexual debut. For teenagers who become sexually active or are planning to be sexually active in the near future, pediatricians should discuss methods of protecting against STIs and pregnancies, including the correct and consistent use of external and internal condoms with all forms of sexual activity (vaginal, oral, and anal). Enhanced risk counseling should be targeted for teenagers who engage in illicit drug use or who are in juvenile detention or other state/county facilities, for whom consent abilities may be compromised or absent and risk of assault may be increased. Teenagers should be specifically counseled to consider the association between alcohol or drug use and failure to appropriately use barrier methods correctly when either partner is impaired. Health care

¹ Centers for Disease Control and Prevention. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(RR-4):1-187. Available at: www.cdc.gov/std/treatment-guidelines/clinical-EPT.htm

professionals should discuss other ways to decrease risk of acquiring STIs, including limiting the number of sex partners and choosing to abstain even if initiation of sexual intercourse already has occurred. Pediatricians should educate parents and adolescents how to recognize symptoms of STIs and to contact their provider for evaluation and treatment when symptoms occur. Adolescents and young adults who have not previously been vaccinated against HPV or hepatitis A or B viruses (HAV or HBV) should complete those immunization series.

Pediatricians should counsel their adolescent and young adult patients at substantial risk for HIV infection about preexposure prophylaxis (PrEP) as an effective strategy to prevent HIV infection. Three medications have been FDA approved for use as PrEP to help prevent an HIV-negative person from acquiring HIV from an HIV-positive sexual partner: emtricitabine with tenofovir disoproxil fumarate, emtricitabine with tenofovir alafenamide, and cabotegravir, which is the first long-acting injectable. The indications for PrEP, initial and follow-up prescribing, and laboratory testing recommendations are the same for adolescents and adults. Guidelines for PrEP are available from the US Public Health Service (www.cdc.gov/hiv/pdf/risk/prep/cdc-hiv-prep-guidelines-2021.pdf). When taken consistently, PrEP has been shown to significantly reduce the risk of HIV infection in people who are at risk. For sexual transmission, those considered at substantial risk for acquiring HIV include those who have engaged in anal or vaginal sex in the past 6 months AND IN ADDITION have 1 or more of the following: have an HIV-positive sexual partner; had a bacterial STI in the past 6 months; or report inconsistent or no condom use with sexual partner(s).

Sexual Assault and Abuse in Children and Adolescents/Young Adults

SUSPECTED SEXUAL ASSAULT

When the suspicion of sexual abuse or assault is raised, pediatricians should know how to respond to and evaluate the child or adolescent/young adult, when to refer the patient for evaluation by other professionals, when to report the case to the appropriate investigative agency, and how to counsel parents to decrease long-term deleterious effects of the abuse.^{1,2} Factors to be considered in assessing the likelihood of sexual abuse in a child with an STI include the biological characteristics of the STI in question, the age and developmental status of the child or adolescent, and whether the child reports a history of sexual contact (see Table 2.5). Preferably, children with concerns about possible sexual abuse would be referred for evaluation and management to a specialized clinic or child advocacy center. In areas without specialized abuse-related services, pediatricians can educate themselves about childhood genital and anal examinations and about how to gather the medical history to make appropriate decisions about reporting to child protective service or law enforcement agencies, referring to

Table 2.5. Implications of Commonly Encountered Sexually Transmitted (ST) or Sexually Associated (SA) Infections for Diagnosis and Reporting of Sexual Abuse Among Infants and Prepubertal Children

ST/SA Confirmed	Evidence for Sexual Abuse	Suggested Action
<i>Neisseria gonorrhoeae</i> ^a	Diagnostic	Report ^b
Syphilis ^a	Diagnostic	Report ^b
Human immunodeficiency virus ^c	Diagnostic	Report ^b
<i>Chlamydia trachomatis</i> ^a	Diagnostic	Report ^b
<i>Trichomonas vaginalis</i> ^a	Diagnostic	Report ^b
Anogenital herpes	Suspicious	Consider report ^{b,d}
<i>Condylomata acuminata</i> (anogenital warts) ^a	Suspicious	Consider report ^{b,d,e}
Anogenital molluscum contagiosum	Inconclusive	Medical follow-up
Bacterial vaginosis	Inconclusive	Medical follow-up

^aIf not likely to be perinatally acquired and rare vertical transmission is excluded.

^bReports should be made to the local or state agency mandated to receive reports of suspected child abuse or neglect.

^cIf not likely to be acquired perinatally or through transfusion.

^dUnless a clear history of autoinoculation exists.

^eReport if evidence exists to suspect abuse, including history, physical examination, or other identified infections. Lesions appearing for first time in child >5 years of age are more likely attributable to sexual transmission.

Table adapted from Kellogg N; American Academy of Pediatrics, Committee on Child Abuse and Neglect. The evaluation of sexual abuse in children. *Pediatrics*. 2005;116(2):506–512 (Updated 2013 clinical report [reaffirmed August 2018] available at <https://doi.org/10.1542/peds.2013-1741>) and Centers for Disease Control and Prevention. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(RR-4):1-187. Available at: www.cdc.gov/std/treatment-guidelines/sexual-assault-children.htm.

counseling facilities, or referring to pediatric clinics specializing in abuse evaluations. The AAP offers a variety of educational materials on child abuse to physicians.¹

WHEN TO SCREEN FOR STIs AFTER POSSIBLE SEXUAL ASSAULT OF A PREPUBERTAL CHILD

Symptoms are uncommon even in children with proven STIs; therefore, testing all sites for all pathogens is standard of care in child abuse evaluations. Examinations and collection of genital specimens in prepubertal children should be performed by an experienced clinician. Factors that would lead clinicians to consider testing for STI include:

1. Child reports sexual abuse, regardless of the acts involved.
2. Child has a sibling, other relative, or another person in the household with an STI.
3. Child has signs or symptoms of STIs (eg, vaginal discharge or pain, genital itching or odor, urinary symptoms, or genital lesions or ulcers).
4. Child or parent requests STI testing.
5. Child is unable to verbalize details of assault.

¹ www.aap.org/en-us/advocacy-and-policy/aap-health-initiatives/Child-Abuse-and-Neglect/Pages/Child-Abuse-and-Neglect.aspx

STI EVALUATION AFTER SEXUAL ASSAULT OF A PREPUBERTAL CHILD

A chaperone who is not the parent or guardian of the child should be present at the time of evaluation. In the evaluation of prepubertal children for suspected sexual abuse/assault, the CDC offers the following recommendations¹:

- Physical examination: Visually inspect the genital, perianal, and oropharyngeal areas for genital discharge, odor, bleeding, irritation, warts, and ulcerative lesions. In addition, if STI testing is indicated, then the following laboratory assessments should be performed.
 - ♦ Testing for *N gonorrhoeae* and *C trachomatis* should be performed with specimens collected from the pharynx and anus, as well as the vagina, and urine from the penile urethra. Cervical specimens are not recommended for prepubertal patients. For patients with a urethral discharge, a penile meatal specimen is an adequate substitute for an intraurethral swab specimen. Culture or a nucleic acid amplification test (NAAT) can be used to test for *N gonorrhoeae* and *C trachomatis*. Only an FDA-cleared NAAT should be used. Consultation with an expert is necessary before using a NAAT in this context, both to minimize the possibility of cross-reaction with nongonococcal *Neisseria* species and other commensals (eg, *Neisseria meningitidis*, *Neisseria sicca*, *Neisseria lactamica*, *Neisseria cinerea*, and *Moraxella catarrhalis*) and to ensure appropriate interpretation of results. If culture for isolation of *N gonorrhoeae* or *C trachomatis* is performed, only standard culture procedures should be performed. Specimens from the vagina, urethra, pharynx, or rectum should be streaked onto selective media for isolation of *N gonorrhoeae*, and all presumptive isolates of *N gonorrhoeae* should be identified definitively by at least 2 tests that involve different approaches (eg, biochemical, enzyme substrate, or molecular probes). Gram stains are inadequate to evaluate prepubertal children for gonorrhea and should not be used to diagnose or exclude gonorrhea. Every effort should be made to preserve specimens (either NAAT or culture including any isolates) obtained before treatment for further validation if needed. In the case of a positive specimen, the result should be confirmed either by retesting the original specimen or obtaining another. Given the overall low prevalence of *N gonorrhoeae* and *C trachomatis* in children, false-positive results may occur, and all specimens that are initially positive should be confirmed.
 - ♦ Testing for *Trichomonas vaginalis* should not be limited to patients with vaginal discharge if other indications for vaginal testing exist, because there is some evidence to indicate that asymptomatic sexually abused children could be infected with *T vaginalis* and might benefit from treatment. A NAAT can be used as an alternative or in addition to culture and wet mount, especially in situations in which culture and wet mount of vaginal swab specimens are not obtainable. Consultation with an expert is necessary before using a NAAT in this context to ensure appropriate interpretation of results. Because of the implications of a diagnosis of *T vaginalis* infection in a child, only a CLIA-validated, FDA-cleared NAAT should be used. Point-of-care tests for *T vaginalis* have not been validated for prepubertal children and should not be used. In the case of a positive specimen, the result should be

¹ Centers for Disease Control and Prevention. Sexually transmitted infection treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(RR-4):1-187. Available at: www.cdc.gov/std/treatment-guidelines/sexual-assault-children.htm

confirmed either by retesting the original specimen or obtaining another. Given the overall low prevalence of *T vaginalis* in children, false-positive results may occur, and all specimens that are initially positive should be confirmed.

- Because herpes simplex virus (HSV) can be indicative of sexual abuse, specimens should be obtained from all vesicular or ulcerative genital or perianal lesions and then sent for NAAT or viral culture.
- Wet mount or NAAT of a vaginal swab specimen for bacterial vaginosis (BV) should be performed, if discharge is present.
- Serum samples should be collected to be evaluated, preserved for subsequent analysis, and used as a baseline for comparison with follow-up serologic tests. Sera can be tested for antibodies to *Treponema pallidum*, HIV, and HBV. Decisions regarding the infectious agents for which to perform serologic tests should be made on a case-by-case basis.

TESTING SEXUALLY ABUSED POSTPUBERTAL PATIENTS FOR STIs

In the evaluation of the sexual assault patient of **postpubertal** age, if a decision to perform STI testing is made, gonorrhea and chlamydia diagnostic evaluation from any sites of penetration or attempted penetration should be performed, per CDC guidance.¹ *C trachomatis* and *N gonorrhoeae* NAATs from specimens should be obtained at the sites of penetration as the preferred diagnostic evaluation of the **postpubertal** person who has been sexually assaulted (Table 2.6). Testing for *T vaginalis* should be offered using a provider-collected vaginal specimen or NAATs from that patient's urine. Point-of-care testing and/or wet mount with measurement of vaginal pH and KOH application for the whiff test from vaginal secretions should be performed for evidence of BV and candidiasis, especially if vaginal discharge, malodor, or itching is present. Screening for *C trachomatis* and *N gonorrhoeae* should be offered to MSM who report receptive oral or anal sex during the preceding year, regardless of whether there was sexual contact with these anatomic sites during the assault. Baseline and follow-up serum samples for evaluation for HIV infection, HBV, and syphilis should be obtained (Table 2.7). In addition to STI testing, a pregnancy test should also be performed for patients capable of pregnancy, and the need for emergency contraception should be considered.

PROPHYLAXIS OF CHILDREN AND ADOLESCENTS AFTER SEXUAL ASSAULT

Antimicrobial therapy should be withheld until the STI diagnostic testing has been performed in cases of suspected sexual abuse/assault. Presumptive treatment for **prepubertal** children who have been sexually assaulted or abused is not recommended, because their incidence of STIs is low after abuse or assault, the risk of spread to the uterus, fallopian tubes, and ovaries is low, and follow-up usually can be ensured. If the result of an STI test is positive and confirmed with additional testing, treatment then should be given. Factors that may increase the likelihood of infection or that constitute an indication for prophylaxis are as listed under When to Screen for STIs After Possible Sexual Assault of a Prepubertal Child (p 183).

¹ Centers for Disease Control and Prevention. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(RR-4):1-187. Available at: www.cdc.gov/std/treatment-guidelines/sexual-assault-children.htm

Table 2.6. Sexually Transmitted Infection (STI) Testing^a When Sexual Abuse or Assault Is Suspected

Organism/Syndrome	Specimens
<i>Neisseria gonorrhoeae</i> and <i>Chlamydia trachomatis</i>	Prepubertal: Culture or NAAT from pharynx, anus, urine from penile urethra, vagina. For patients with a urethral discharge, a penile meatal specimen is an adequate substitute for an intraurethral swab specimen. Postpubertal: NAAT from sites of penetration or attempted penetration. May include rectum, throat, urine, vagina or cervix, and penile urethra or meatus.
Syphilis	Darkfield examination (if available) of chancre fluid; nontreponemal and treponemal serologic tests at time of abuse and approximately 6 weeks and <3 months after the last suspected sexual exposure.
Human immunodeficiency virus	Fourth-generation HIV antibody/antigen testing of abuser (if possible); serologic testing of child at time of abuse and approximately 6 weeks and <3 months after the last suspected sexual exposure.
Hepatitis B virus	Serum hepatitis B surface antigen testing of abuser or hepatitis B surface antibody testing of child, unless the child has received 3 doses of hepatitis B vaccine. See Table 3.23 (p 456) for management.
Herpes simplex virus (HSV)	Culture or NAAT of lesion specimen; all virologic specimens should be typed (HSV-1 vs HSV-2).
Bacterial vaginosis (BV)	Prepubertal: Vaginal specimen wet mount or NAAT for BV, if discharge is present. Postpubertal: Vaginal point-of-care testing and/or wet mount or NAAT with measurement of vaginal pH and KOH application for the whiff test from vaginal secretions should be performed for evidence of BV, especially if vaginal discharge, malodor, or itching is present.
Human papillomavirus	Clinical examination, with biopsy of lesion specimen, if diagnosis unclear.
<i>Trichomonas vaginalis</i>	Prepubertal: Vaginal specimen NAAT and/or culture and wet mount. Testing for <i>T vaginalis</i> should not be limited to patients with vaginal discharge if other indications for vaginal testing exist. Postpubertal: Vaginal or urine NAAT.
<i>Pediculus pubis</i>	Identification of eggs, nymphs, and lice with naked eye or using hand lens.

NAAT indicates nucleic acid amplification test.

^aSee text for examples of indications for testing for STIs.

Table 2.7. Prophylaxis After Sexual Victimization: Postpubertal Patients

Antimicrobial prophylaxis is recommended to include an empiric regimen to prevent chlamydia, gonorrhea, and trichomoniasis. Vaccination against hepatitis B and HPV is recommended if not fully immunized.	
For chlamydia, gonorrhea, and trichomoniasis	Ceftriaxone, 500 mg, ^a intramuscularly, in a single dose PLUS Doxycycline, 100 mg, orally, twice daily for 7 days PLUS (IF FEMALE) Metronidazole, 500 mg, orally, twice daily for 7 days
For hepatitis B virus infection	See Table 3.23, p 456
For human immunodeficiency virus (HIV) infection	See Fig 2.1 and text
For HPV	HPV vaccine series should be initiated at ≥ 9 y if not already begun or completed if not fully immunized (2 or 3 doses depending on age of initiation of vaccine)

HPV, human papillomavirus.

^aFor persons weighing ≥ 150 kg, 1 g of ceftriaxone should be administered.

Source: Centers for Disease Control and Prevention. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(RR-4):1-187. Available at: www.cdc.gov/std/treatment-guidelines/sexual-assault-children.htm.

In contrast, many experts believe that STI prophylaxis, after baseline testing has been performed, is warranted for **postpubertal** patients who seek care after an episode of sexual victimization. This is recommended in this population because of the greater possibility of a preexisting asymptomatic infection, the potential risk for acquisition of new infections with the assault, the substantial risk of pelvic inflammatory disease after untreated STIs in this age group, and established data demonstrating poor compliance with follow-up visits after sexual assault.¹ Regimens for prophylaxis are presented in Table 2.7. The need for emergency contraception should be considered as well.

Completion of the HPV, HBV, and HAV immunization series for children and adolescents 9 years and older should be documented. For more detailed diagnosis and treatment recommendations for specific STIs, see the disease-specific chapters in Section 3 and Tables 4.4 (p 1007) and 4.5 (p 1014).

HIV infection has been reported in children and adolescents for whom sexual abuse was the only known risk factor. Because of the demonstrated effectiveness of nonoccupational postexposure prophylaxis (PEP) to prevent HIV infection, the question arises whether HIV prophylaxis is warranted for children and adolescents after sexual assault (see Fig 2.1). The risk of HIV transmission from a single sexual assault that involves transfer of secretions and/or blood is low. Prophylaxis may be considered for patients who seek care within 72 hours after an assault if the assault

or other mucous membrane,
intact or nonintact skin,
or percutaneous contact

With
urine, nasal secretions, saliva, sweat,
or tears if not visibly contaminated
with blood

Regardless
of the known or suspected HIV status
of the source

nPEP indicates nonoccupational postexposure prophylaxis.

^aDominguez, KL, Smith DK, Thomas V, Crepaz N, Lang KS, et al. Updated Guidelines for Antiretroviral Postexposure Prophylaxis After Sexual, Injection Drug Use, or Other Nonoccupational Exposures to HIV—United States, 2016. Atlanta, GA: Centers for Disease Control and Prevention; 2016. Available at: <https://stacks.cdc.gov/view/cdc/38856>

involved mucosal exposure to secretions; repeated abuse; multiple assailants; and oral, vaginal, and/or anal trauma and particularly if the alleged perpetrator(s) is known to have or is at high risk of having HIV infection (see Human Immunodeficiency Virus Infection, p 489).¹

¹Centers for Disease Control and Prevention. Preexposure prophylaxis for the prevention of HIV infection in the United States-2021 Update. Available at: www.cdc.gov/hiv/pdf/risk/prep/cdc-hiv-prep-guidelines-2021.pdf

The following are recommendations for postexposure HIV assessment within 72 hours of sexual assault¹:

- Assess risk for HIV infection in the assailant, and test that person for HIV whenever possible.
- Use Fig 2.1 to evaluate the survivor for the need for HIV PEP.
- Consult with a specialist in HIV treatment if PEP is being considered.
- If the survivor appears to be at risk for acquiring HIV from the assault, discuss PEP, including benefits and risks.
- If the survivor chooses to start PEP, provide an initial course of 3 to 7 days of medication (ie, a starter pack) with a prescription for the remainder of the course, or provide a prescription for an entire 28-day course. Schedule an early follow-up visit to discuss test results and provide additional counseling.
- Before initiating PEP, order baseline serum creatinine, aspartate transaminase (AST), and alanine transaminase (ALT).
- Perform an HIV antibody test at original assessment; repeat at approximately 6 weeks and <3 months after the last suspected sexual exposure.
- Counsel individuals with ongoing risk of HIV acquisition about HIV PrEP and provide referrals to a PrEP provider.

Assistance with PEP-related decisions can be obtained by calling the National Clinician's Post Exposure Prophylaxis Hotline (PEP Line) (telephone: 888-448-4911).

A follow-up visit approximately 4 to 6 weeks after the most recent sexual exposure may include a repeat physical examination and collection of additional specimens. Additional follow-up visits at 3 and 6 months after the most recent sexual exposure may be necessary to obtain convalescent sera to test for HBV (if indicated), HCV (if indicated), syphilis, and HIV infection.

MEDICAL EVALUATION FOR INFECTIOUS DISEASES FOR INTERNATIONALLY ADOPTED, REFUGEE, AND OTHER IMMIGRANT CHILDREN^{2,3}

Every year, thousands of children arrive in the United States from other countries. They arrive as immigrants, adoptees, refugees, asylum seekers, or as other migrants including undocumented children. The medical evaluation of these children is a challenging and important task and is influenced by multiple factors, including the child's

¹ Centers for Disease Control and Prevention. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(RR-4):1-187. Available at: www.cdc.gov/std/treatment-guidelines/sexual-assault-children.htm

² For additional information, see Canadian Paediatric Society (www.kidsnewtocanada.ca), the Centers for Disease Control and Prevention (wwwnc.cdc.gov/travel/yellowbook/2024/family/international-adoption and wwwnc.cdc.gov/travel/yellowbook/2024/posttravel-evaluation/newly-arrived-immigrants-refugees-and-other-migrants), and World Health Organization (www.who.int) websites.

³ Information for parents can be found at www.cdc.gov/immigrantrefugeehealth/adoption/index.html/.

country of origin, socioeconomic status, and health history; availability of reliable health care in the country of origin; and the migration route, including type of travel (eg, by foot or by air), countries passed through, and the conditions during the journey.

Children arriving in the United States should be evaluated as soon as possible after arrival to begin medical assessment and preventive health services, including immunizations. Screening for infectious diseases is important to identify infections with a long latency period. Each of the groups mentioned previously has its own characteristics and special needs.

Internationally Adopted Children

There is a great deal of information available to guide management of children adopted internationally. Some health concerns may be addressed before adoption, although some are apparent to the adoptive family only after arrival. Many adoptive families interact with the health care system before the child arrives and make arrangements for the child to have health insurance at the time of arrival in the United States. There often are opportunities to provide advice to the family and to optimize immunizations that the family may need before traveling to receive their child and for family members and caregivers who will interact with the child after arrival. These immunizations serve to protect the child from diseases that might be transmitted from family and community members (eg, pertussis, influenza) and to protect the family and community from diseases that might be transmitted from the child (eg, hepatitis A, measles). Access to and quality of medical care for international adoptees before arrival in the United States can be variable. Internationally adopted children are required to have a medical examination performed by a physician designated by the US Department of State in their country of origin. This examination usually is limited to completing legal requirements for screening for certain communicable diseases of public health significance and to examine for serious physical or mental disorders that would prevent issuance of an immigrant visa. Such an evaluation is not a comprehensive assessment of the child's health. During preadoption visits, pediatricians should stress to prospective parents the importance of acquiring immunization and other health records. Parents who have not met with a physician before adoption should notify their physician when their child arrives so that a timely medical evaluation can be arranged. Guidance on comprehensive assessment of a newly adopted child is available from the American Academy of Pediatrics (AAP).¹

Refugees

Refugees have legal status in the United States and are required to undergo medical examination before arrival. The Centers for Disease Control and Prevention (CDC) has issued recommendations for screening of refugees after arrival, and various states have different protocols for initial evaluation of refugees (**www.cdc.gov/immigrantrefugeehealth/guidelines/domestic-guidelines.html**). Immunizations are not required before travel for US-bound refugees, although most receive some age-appropriate vaccinations during the overseas medical examination.

¹Jones VF, Schulte EE; American Academy of Pediatrics, Council on Foster Care, Adoption, and Kinship Care. Comprehensive health evaluation of the newly adopted child. *Pediatrics*. 2019;143(5):e20190657

Immigrants

Immigrant children and children in immigrant families represent the largest and most diverse group of new arrivals to the United States. Most pediatricians will encounter immigrant children in their practice. Evaluation is individual to each case, depending on whether the child is documented or has insurance coverage, the circumstances of immigration, country of origin and migration route, medical history, and socioeconomic status. Resources such as the toolkit developed by the AAP can guide the pediatrician in evaluating new immigrants. (https://downloads.aap.org/AAP/PDF/cocp_toolkit_full.pdf).

Most immigrant children have received some immunizations but may have received them on schedules different from those used in the United States or may have missed essential immunizations. Written documentation of immunizations that includes month and year of administration is accepted as valid if the vaccinations conform to the US schedule. See *Children Who Received Immunizations Outside the United States or Whose Immunization Status Is Unknown or Uncertain* (p 119) for recommendations regarding immunizations.

Consideration for Testing for Infectious Agents

Infectious diseases are among the most common medical diagnoses identified in immigrant, refugee, and internationally adopted children after arrival in the United States, including diseases of long latency in asymptomatic children. Because of inconsistent use of the birth dose of hepatitis B vaccine (HepB); inconsistent perinatal screening for hepatitis B virus (HBV), syphilis, and human immunodeficiency virus (HIV); and the high prevalence of certain intestinal parasites and tuberculosis (TB), screening for these diseases should be considered for all immigrant children. Screening for other diseases can be considered on an individual basis, as discussed in the following paragraphs (see Table 2.8) and in the disease-specific chapters in Section 3.

HEPATITIS A

Hepatitis A virus (HAV) is endemic in most countries of origin of internationally adopted, refugee, and immigrant children. Some children may have acquired HAV infection early in life and may be immune, but others may be incubating HAV or remain susceptible at the time of entry into the United States. Serologic testing for acute infection (hepatitis A immunoglobulin [Ig] M) is appropriate for symptomatic children. Testing children 12 months of age and older for hepatitis A IgG antibody or total hepatitis A antibody (IgG plus IgM) can be considered at the initial visit to determine whether the child is immune and does not require immunization. Children 12 months of age and older without HAV immunity or documentation of 2 hepatitis A vaccine doses ≥ 6 months apart should receive HepA vaccine according to routine immunization schedules.

The preferred management strategy for the possibility of a child incubating HAV infection and transmitting the virus to others on arrival in the United States is to recommend hepatitis A vaccine (HepA) for all previously unvaccinated people who anticipate close personal contact (eg, household contact or other regular caregiver) with the child during the first 60 days after arrival from a country with high or intermediate HAV prevalence. Adoptive parents and accompanying family members traveling to adopt the child should ensure that they themselves are immunized or otherwise immune to HAV infection before traveling to a country of high or intermediate prevalence.

Table 2.8. Suggested Possible Screening Tests for Infectious Diseases in International Adoptees, Refugees, and Immigrants^a (see text for detail)

Hepatitis B virus serologic testing:
Hepatitis B surface antigen (HBsAg), hepatitis B surface antibody (anti-HBs), and total hepatitis B core antibody (anti-HBc) ^b
Hepatitis C virus NAAT for children <18 mo, or serologic testing for children ≥18 mo, when indicated (see text)
Syphilis serologic testing:
Nontreponemal test (eg, RPR or VDRL)
Treponemal test (eg, EIA, CIA, TPPA, MHA-TP, or FTA-ABS)
Human immunodeficiency virus (HIV) 1 and 2 serologic testing; consider fourth-generation HIV antibody/antigen testing
Complete blood cell count with red blood cell indices and differential
Stool examination for ova and parasites (1–3 specimens) with specific request for <i>Giardia duodenalis</i> and <i>Cryptosporidium</i> species testing by direct fluorescent antibody or EIA testing
Interferon-gamma release assay (IGRA) or tuberculin skin test (TST)
In children from countries with endemic infection ^c :
<i>Trypanosoma cruzi</i> serologic testing
In children with eosinophilia (absolute eosinophil count exceeding 450 cells/mm ³) and negative stool ova and parasite examinations ^d can consider:
<i>Toxocara canis</i> serologic testing
<i>Strongyloides</i> species serologic testing ^e
<i>Schistosoma</i> species serologic testing for children from sub-Saharan African, Southeast Asian, and certain Latin American countries
Lymphatic filariasis serologic testing for children older than 2 years from countries with endemic infection

CIA indicates chemiluminescence assay; EIA, enzyme immunoassay; FTA-ABS, fluorescent treponemal antibody absorption; MHA-TP, microhemagglutination test for *Treponema pallidum*; NAAT, nucleic acid amplification test; RPR indicates rapid plasma reagin; TPPA, *T. pallidum* particle agglutination; VDRL, Venereal Disease Research Laboratories.

^aFor evaluation of noninfectious disease conditions, see Linton JM, Green A; American Academy of Pediatrics, Council on Community Pediatrics. Providing care for children in immigrant families. *Pediatrics*. 2019;144(3):e20192077.

^bPassively acquired maternal anti-HBc may be detected in infants born to HBV-infected mothers up to age 24 months.

^cArgentina, Belize, Bolivia, Brazil, Chile, Colombia, Costa Rica, Ecuador, El Salvador, French Guiana, Guatemala, Guyana, Honduras, Mexico, Nicaragua, Panama, Paraguay, Peru, Suriname, Uruguay, and Venezuela.

^dSome experts would perform serologic tests for schistosomiasis in children from areas with high endemicity regardless of eosinophil count because of its poor positive- and negative-predictive values.

^eCDC recommends *Strongyloides* testing or presumptive treatment for all refugees.

HEPATITIS B

Studies conducted primarily during the 1990s identified prevalence of hepatitis B surface antigen (HBsAg) from 1% to 5% in internationally adopted children and from 4% to 7% in refugee children, depending on the country of origin and the year studied. HBV infection was associated with country of origin and was most common in children from Asia and Africa and from some countries of central and eastern Europe (eg, Romania, Bulgaria, Russia, and Ukraine). The number of countries with routine infant hepatitis B immunization programs has increased markedly in the past decade, and many countries have introduced a birth dose of hepatitis B vaccine (HepB).

Despite the number of countries that have added the birth dose of HepB, vaccination coverage among infants can be suboptimal. Even when a birth dose of HepB is administered, efficacy of postexposure prophylaxis is lower among infants whose birthing parent had a high HBV viral load and hepatitis B e antigen (HBeAg) positivity. All children who were born in or have lived in countries with intermediate (2%–7%) or high ($\geq 8\%$) prevalence (see Fig 3.2, p 440) should be tested to identify cases of chronic infection, regardless of immunization status (see Hepatitis B, p 437). Even if a child has had HBV serologic tests performed before arrival in the United States, testing may be incomplete or children may become infected after testing, so testing should be repeated. Appropriate screening tests are those for hepatitis B surface antigen (HBsAg), hepatitis B surface antibody (anti-HBs), and total hepatitis B core antibody (anti-HBc). People with chronic HBV infection have circulating HBsAg and circulating total anti-HBc; in a minority of chronically infected individuals, anti-HBs also is present. Both anti-HBs and total anti-HBc are present in people with resolved infection, whereas anti-HBs alone is present in people immunized with hepatitis B vaccine. Antibody tests should be interpreted with caution for children in the first 1 to 2 years of life because of the potential for transplacentally transferred antibody. Unimmunized children with negative HBsAg and negative hepatitis B surface antibody (HBsAb) test results should be immunized according to the recommended childhood and adolescent immunization schedules (also see Children Who Received Immunizations Outside the United States or Whose Immunization Status Is Unknown or Uncertain, p 119).

Children testing positive for HBsAg should be evaluated further to distinguish between acute and chronic HBV infection. Persistence of HBsAg for at least 6 months indicates chronic HBV infection (www.cdc.gov/hepatitis/hbv/interpretationOfHepBSerologicResults.htm; see Hepatitis B, p 437). Children with chronic HBV infection should be tested for biochemical evidence of liver disease and followed by a specialist who cares for patients with chronic HBV infection (see Hepatitis B, p 437). Transient presence of HBsAg can occur following hepatitis B immunization, from within the first 24 hours of immunization up to 3 weeks after immunization, so preimmunization assessment is important. All unimmunized household contacts of children with chronic HBV infection should be immunized (see Hepatitis B, p 437).

HEPATITIS C

Hepatitis C virus (HCV) screening for refugee and immigrant children is not recommended routinely during the new arrival medical examination unless individuals have risk factors, including a birthing parent with hepatitis C, overseas surgery, transfusion, major dental work, intravenous drug use, tattoos, sexual activity/abuse, female genital cutting, and other traditional cutting. Testing for HCV infection also can be considered for unaccompanied children and for internationally adopted children, given that most international adoptees in recent years have been adopted from countries with elevated prevalence (eg, China, Russia, southeast Asia) and because risk factors for infection rarely are known. An HCV antibody screen should be used as the initial screening test for children ≥ 18 months of age, with reflex testing for HCV RNA for positive antibody specimens.

A nucleic acid amplification test (NAAT) for HCV RNA detection can be performed, ideally from 2 through 6 months of age but also from 7 through 17 months of age if the child has not previously been tested by NAAT for HCV RNA. If the NAAT result at 2 through 17 months is negative, no further follow-up or additional testing is

needed. If the child is 18 months of age or older, serologic testing should be performed for diagnosis (see Hepatitis C, p 458).

INTESTINAL PATHOGENS

Serial fecal examinations for ova and parasites tested in a laboratory experienced in parasitology will identify a pathogen in 15% to 35% of internationally adopted and refugee children. Gastrointestinal pathogen nucleic acid amplification testing (NAAT) is not recommended, because it does not detect the full array of parasites these children can have. Presence or absence of symptoms is not predictive of parasitosis. Prevalence of intestinal parasites varies by age of the child and by country of origin. For refugees, guidelines differ depending on whether the child received presumptive therapy before departure (www.cdc.gov/immigrantrefugeehealth/guidelines/overseas-guidelines.html). The most common pathogens identified are *Giardia duodenalis*, *Dientamoeba fragilis*, *Hymenolepis* species, some *Schistosoma* species, *Strongyloides stercoralis*, and other soil-transmitted helminths including *Ascaris lumbricoides*, *Trichuris trichiura*, and hookworm (*Necator americanus*). *Entamoeba histolytica* and *Cryptosporidium* species are recovered less commonly. Regardless of nutritional status or presence of symptoms, 1 to 3 stool specimens collected on separate days (the CDC recommends 2 or more specimens for asymptomatic refugees from Asia, the Middle East, and Africa if they received no or incomplete predeparture treatment) may be examined for ova and parasites, and direct fluorescent antibody testing or enzyme immunoassay (EIA) may be performed for *Giardia* species and *Cryptosporidium* species.

Some clinicians prefer to administer albendazole for presumptive therapy for helminth infection. Therapy for intestinal parasites generally is successful, but complete eradication may not occur. Proof of eradication is not recommended for individuals who are asymptomatic following therapy. If symptoms persist after treatment, however, ova and parasite testing should be repeated to ensure successful elimination of parasites.

Children who fail to demonstrate adequate catch-up growth, who have unexplained anemia, or who have gastrointestinal tract symptoms or signs that occur or recur months or even years after arrival in the United States should be reevaluated for intestinal parasites. When newly arrived children have acute onset of bloody diarrhea, stool specimens should be tested for *Salmonella* species, *Shigella* species, *Campylobacter* species, Shiga toxin-producing *Escherichia coli* including *E coli* O157:H7, and *Entamoeba histolytica*. If a bacterial pathogen is detected by a nonculture method, confirmation with culture and antimicrobial susceptibility testing are helpful for informing decisions regarding possible treatment and public health measures.

TISSUE PARASITES/EOSINOPHILIA

Eosinophilia is commonly but not universally present in people with tissue parasites. Refugee children may have received presumptive treatment of intestinal helminths overseas before departure to the United States (www.cdc.gov/immigrantrefugeehealth/guidelines/overseas-guidelines.html#ipg). In children who did not receive albendazole or ivermectin for presumptive therapy of intestinal helminths, who have negative stool ova and parasite test results, and in whom eosinophilia (absolute eosinophil count exceeding 450 cells/mm³) is found on review of complete blood cell count, serologic testing for *Toxocara canis*, strongyloidiasis, schistosomiasis, and lymphatic filariasis should be considered, depending on country of birth

and migration route (see Table 2.8). Although logistically attractive to perform all tests at the first encounter, predictive values of many serologic tests for parasites are suboptimal; therefore, common treatable causes of eosinophilia usually should be considered first. Because *T canis* is prevalent worldwide, screening is warranted in children who have no identified cause of eosinophilia. For all immigrant children with eosinophilia and no identified pathogen commonly associated with an increased eosinophil count, serologic testing for *S stercoralis* is reasonable regardless of country of origin, and testing for *Schistosoma* species should be performed for all children who are from sub-Saharan Africa, Southeast Asia, or areas of the Caribbean and South America where schistosomiasis is endemic. Serologic testing for lymphatic filariasis should be considered in children older than 2 years with eosinophilia who are from countries with endemic lymphatic filariasis (www.cdc.gov/parasites/lymphaticfilariasis/index.html). A positive serologic result should be confirmed by testing in a reference laboratory (CDC or National Institutes of Health) for release of drugs for treatment of lymphatic filariasis. Screening for loiasis should be performed for any child coming from a region of Africa with coendemic *Loa loa* before treatment for lymphatic filariasis or onchocerciasis, as there is a risk of encephalopathy resulting in death in children with *L loa* infection following treatment with diethylcarbamazine or ivermectin (www.cdc.gov/parasites/loiasis/health_professionals/index.html).

SEXUALLY TRANSMITTED INFECTIONS

Congenital syphilis, including with involvement of the central nervous system, may not have been diagnosed or may have been inadequately treated in children from some resource-limited countries. Individuals applying for US immigrant or refugee status or nonimmigrants required to have an overseas examination are required to have testing for syphilis if 18 through 44 years of age, and this group of individuals 18 through 24 years of age also are required to have testing for gonorrhea; people outside these age ranges (including children, as they are <18 years of age) are required to have testing only if there is reason to suspect or a history of syphilis (www.cdc.gov/immigrantrefugeehealth/panel-physicians/syphilis.html) or gonorrhea (www.cdc.gov/immigrantrefugeehealth/panel-physicians/gonorrhea.html) infection (see Gonococcal Infections, p 394). Those who have positive test results are required to complete treatment before arrival in the United States (www.cdc.gov/immigrantrefugeehealth/guidelines/domestic/sexually-transmitted-diseases/index.html).

Children adopted internationally and other immigrant children with risk factors should be tested for syphilis after arrival in the United States by reliable nontreponemal and treponemal serologic tests (see Syphilis, p 825). Children with positive nontreponemal or treponemal serologic test results should be evaluated by a health care professional with specific expertise to assess the differential diagnosis of pinta, yaws, and syphilis and to determine the stage of infection so that appropriate treatment can be administered (see Syphilis, p 825). Assessment for other STIs can be considered on the basis of sexual history, past medical history, history of sexual assault, and physical examination findings.

TUBERCULOSIS

Infection with an organism of the *Mycobacterium tuberculosis* complex commonly is encountered in immigrant and refugee children, although incidence rates of tuberculosis (TB) vary by country and by age within countries. Predeparture screening

requirements for immigrants, adoptees, refugees, and other applicants depend on age and the TB burden in the country of birth and the migration route (www.cdc.gov/immigrantrefugeehealth/guidelines/domestic/tuberculosis-guidelines.html#fig-2). For those from countries with tuberculosis incidence ≥ 20 cases per 100 000 population (www.who.int/tb/publications/global_report/en/) who are ≥ 15 years of age, screening and treatment requirements include: chest radiograph; 3 sputum smears and cultures for people with an abnormal chest radiograph, signs and symptoms of tuberculosis disease, or known HIV infection; drug susceptibility testing for people with positive cultures; and, for people with tuberculosis disease, treatment with a standard CDC-recommended regimen delivered as directly observed therapy to cure before travel to the United States. This treatment requirement may result in unanticipated delays in travel to the United States for adoptive children or refugee families. Refugees and immigrant children are screened with an interferon-gamma release assay (IGRA) if IGRA is licensed in the country. Children with a positive IGRA result are required to undergo chest radiography before departure. Children younger than 2 years are not tested unless it is brought to attention of screening physicians outside the United States that they are a known contact of an active case, have HIV infection, or have signs or symptoms suggestive of TB disease. Information about the screening and implementation requirements is available at www.cdc.gov/immigrantrefugeehealth/panel-physicians/tuberculosis.html.

Testing for *M tuberculosis* infection after arrival in the United States in immigrants, adoptees, and refugees is important, because TB can be more severe in young children and can reactivate in later years. Presence or absence of a bacille Calmette-Guérin (BCG) vaccine scar should be noted, but approximately 10% of children who received BCG vaccine as infants will not have a scar. BCG coverage in most countries where the vaccine is used is very high, but BCG vaccination has limitations. Efficacy of BCG vaccine against lethal forms of TB (eg, meningitis) in children is approximately 80%, but efficacy against pulmonary TB disease or TB infection is much lower. Receipt of BCG vaccine is not a contraindication to a tuberculin skin test (TST). Either TST or IGRA can be used for detection of *M tuberculosis* infection children of any age, but in children previously vaccinated with BCG, IGRA is preferred to avoid a false-positive TST result caused by a previous vaccination with BCG (see Tuberculosis, p 888, for further guidance). Some immigrants may be anergic initially because of malnutrition, stress, or untreated HIV infection, producing falsely negative TST results or indeterminate or falsely negative IGRA test results; repeat testing may be required. Routine chest radiography is not indicated in asymptomatic children in whom the IGRA or TST result is negative. In children with a positive IGRA or TST, further investigation, including chest radiography and a complete physical examination, is necessary to determine whether tuberculosis disease is present (see Tuberculosis, p 888). When tuberculosis disease is suspected in an immigrant child, efforts to isolate and test the organism for drug susceptibilities are imperative because of the high prevalence of drug resistance in many countries. TB disease, whether suspected or confirmed, is a reportable condition in all US jurisdictions regardless of a patient's immigration status; TB infection is reportable in some states. Physicians who are experts in the management of TB should be consulted when therapy for TB infection or disease is indicated for children from countries with prevalent isoniazid resistance (see Table 3.86, p 909, and www.who.int/publications/i/item/9789240037021).

HIV INFECTION

The risk of HIV infection in newly arrived children depends on the country of origin and on individual risk factors. Screening for HIV should be performed for all internationally adopted children, because adoptees may come from populations at high risk of infection and details of their history often are unknown. Although some children will have HIV test results documented in their referral information, test results from the child's country of origin may not be reliable.

Refugees and immigrants have not been required to have HIV testing routinely as part of the predeparture immigration medical assessment since 2010. HIV testing still is recommended for people who are diagnosed with TB disease as part of this medical assessment, and for any refugee diagnosed with another STI. HIV testing after arrival in the United States is recommended for refugees 13 through 64 years of age and is encouraged for refugees 12 years or younger and older than 64 years of age (www.cdc.gov/immigrantrefugeehealth/guidelines/domestic/screening-hiv-infection-domestic.html). The decision to screen immigrant children for HIV after arrival in the United States should depend on history and risk factors (eg, receipt of blood products, prenatal drug use), sexual activity (consensual or nonconsensual), physical examination findings, and prevalence of HIV infection in the child's country of origin. If there is a suspicion of HIV infection, testing should be performed before administration of live vaccines. Some experts believe HIV testing may be appropriate for most immigrant children. Repeat screening 3 to 6 months following resettlement is recommended for refugees with a recent exposure or high-risk activity to identify individuals who may be in the "window period" when they arrive in the United States.

CHAGAS DISEASE (AMERICAN TRYPANOSOMIASIS)

Chagas disease is found throughout much of Central and South America (see American Trypanosomiasis [Chagas Disease], p 884). Countries with endemic Chagas disease include Argentina, Belize, Bolivia, Brazil, Chile, Colombia, Costa Rica, Ecuador, El Salvador, French Guiana, Guatemala, Guyana, Honduras, Mexico, Nicaragua, Panama, Paraguay, Peru, Suriname, Uruguay, and Venezuela. Transmission within countries with endemic infection is focal, but if a child comes from, or received a blood transfusion in, a country with endemic Chagas disease, testing for *Trypanosoma cruzi* should be considered; see Fig 3.20 (p 886) and 3.21 (p 887). Treatment of children with Chagas disease is highly effective.

OTHER INFECTIOUS DISEASES

Skin infections that may occur in immigrant children include bacterial (eg, impetigo), fungal (eg, candidiasis and tinea corporis and capitis), and viral (molluscum contagiosum) infections, and ectoparasitic infestations (eg, scabies and pediculosis). New adoptive parents may need to be instructed on how to examine their child for signs of scabies, pediculosis, and tinea so that treatment can be initiated and transmission to others can be prevented (see Scabies, p 750, and Pediculosis chapters, p 644–652).

Diseases such as typhoid fever, leprosy, or melioidosis are encountered infrequently in immigrant children; routine screening for these diseases is not recommended. Findings of fever, splenomegaly, respiratory tract infection, anemia, or

eosinophilia should prompt an appropriate evaluation on the basis of the epidemiology of infectious diseases that occur in the child's country of origin or along their migration route.

Routine screening for malaria is not recommended for immigrants, refugees, or internationally adopted children. Testing for malaria (thick and thin blood films) should be performed immediately for any febrile child who has arrived from an area with endemic malaria (see Malaria, p 561). Malaria also should be considered as a cause of asymptomatic splenomegaly in a child from an area with endemic malaria; evaluation should include nucleic acid amplification testing (NAAT) for malaria, because asymptomatic children with splenomegaly attributable to a history of repeated malaria infections may have a positive NAAT assay results but negative smears. If the malaria NAAT assay result is positive, the child should be treated with antimalarial drugs.

Refugee children from Sub-Saharan Africa may have received presumptive treatment for malaria before departure to the United States (www.cdc.gov/immigrantrefugeehealth/guidelines/overseas-guidelines.html#malaria-guidance; see Malaria, p 561). Refugees originating from Sub-Saharan Africa who have not received predeparture presumptive treatment should receive presumptive treatment or screening if seen within 3 months of arrival; pregnant people in the first trimester and infants weighing <5 kg should not receive presumptive treatment (www.cdc.gov/immigrantrefugeehealth/guidelines/domestic/malaria-guidelines-domestic.html).

In the United States, multiple outbreaks of measles have been reported in children adopted from China and in their US contacts. Measles transmission continues in many parts of the world. Prospective parents who are traveling internationally to adopt children, as well as their household contacts, should ensure that they have a history of measles disease or have been immunized adequately for measles according to US recommendations. If born in the United States after 1956, and in the absence of documented measles infection or contraindication to the vaccine, prospective parents and household contacts of adopted children should receive 2 doses of measles-containing vaccine after the age of 12 months and separated by at least 28 days (see Measles, p 570).

Although one of the major purposes of screening is to identify asymptomatic diseases with long latency, screening need not be performed for all such diseases; an example is neurocysticercosis, which may not be clinically apparent for many years.

For all immigrant children, establishing a medical home with a primary care provider is of prime importance. Country of birth and migration history will remain an important health determinant throughout the child's life.

INJURIES FROM NEEDLES DISCARDED IN THE COMMUNITY

Contact with and injuries from hypodermic needles and syringes improperly discarded in public places pose a risk of transmission of bloodborne pathogens, including human immunodeficiency virus (HIV), hepatitis B virus (HBV), and hepatitis C

virus (HCV). However, a review of 14 studies of children exposed to needlesticks in the community documented no transmissions with follow-up of 613 children for HIV, 575 children for HBV, and 394 children for HCV, although many of these children had received postexposure prophylaxis (PEP) for HIV and/or HBV. Infection risks and options for PEP vary depending on the virus and type and extent of exposure. Risk of infection also depends on the nature of the wound, the ability of the pathogens to survive on environmental surfaces, the volume of source material, the concentration of virus in the source material, infection prevalence rates among local injection drug users, the probability that the syringe and needle were used by a person with a substance use disorder, and the immunization status of the person with the needlestick. Although nonoccupational needlestick injuries may pose a lower risk of infection transmission than occupational needlestick injuries, a person injured by a needle in a nonoccupational setting should be evaluated and counseled and, in some cases, should receive PEP. A person who was injured by or exposed to a needlestick should be assessed even if the potential for the discarded syringe to contain a specific bloodborne pathogen is estimated to be low from the background prevalence rates of these infections in the local community.

Wound Care and Tetanus Prophylaxis

Management of people with needlestick injuries includes acute wound care and consideration of the need for antimicrobial prophylaxis. Standard wound care and cleansing with soap and water is indicated; such wounds rarely require closure. A tetanus toxoid-containing vaccine, with or without Tetanus Immune Globulin, should be considered as appropriate for the patient's age, severity of injury, immunization status, and potential for dirt or soil contamination of the needle (see Tetanus, p 848). Tetanus and diphtheria toxoids (Td) or tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine (Tdap) may be used. If the patient's pertussis vaccination status is not current or is unknown, Tdap should be used (see Pertussis, p 656).

Bloodborne Pathogens

Bloodborne pathogens of primary concern in needlestick exposure are HIV, HBV, and HCV. Consideration of the need for PEP for HBV and HIV is the next step in exposure management; currently, there is no recommended PEP for HCV. Unlike an occupational blood or body fluid exposure, in which the status of the exposure source for HBV, HCV, and HIV often is known, these data usually are not available to help in the decision-making process in a nonoccupational exposure.

HEPATITIS B VIRUS

HBV retains infectivity when held at room temperature for at least 7 days after drying. Transmission to health care personnel with needlestick injury occurs at a rate of 23% to 62% from hepatitis B surface antigen (HBsAg)-positive and hepatitis B envelope antigen (HBeAg)-positive sources, and at a rate of 1% to 6% for HBsAg-positive and HBeAg-negative sources. Prompt and appropriate PEP intervention reduces

this risk.¹ The effectiveness of PEP diminishes the longer it is delayed after exposure. Management following a needlestick is predicated on whether the source of the needle is known to be HBsAg-positive and on the HBV immunization status of the person receiving the needlestick and is detailed in Table 3.23 (p 456).

HUMAN IMMUNODEFICIENCY VIRUS

The risk of HIV transmission from a needle discarded in public is lower than the 0.3% risk of HIV transmission by needlestick from a person with known HIV infection to a health care worker, and no cases of HIV transmission by needlestick outside of health care settings have been reported in the United States. HIV is susceptible to drying. When HIV is exposed to air, the 50% tissue culture infective dose decreases by approximately 1 log every 9 hours. In injuries from discarded needles in public, viruses that may have been present have been exposed to drying and environmental temperatures. In addition, injury does not generally occur immediately after the needle was used, needles rarely contain fresh blood, and injuries are usually superficial.

Testing for HIV, if indicated, is performed at baseline and 4 to 6 weeks and again 3 months after the injury (see Human Immunodeficiency Virus Infection, p 489, <https://stacks.cdc.gov/view/cdc/38856>, and <https://nccc.ucsf.edu/clinician-consultation/pep-post-exposure-prophylaxis/>). The decision to test for HIV does not compel the initiation of PEP, with treatment decisions based on a case-by-case consideration as detailed below. Because concurrent infection with HCV and HIV may be associated with delayed HIV seroconversion, a person whose HCV antibody test result is negative at baseline but seroconverts to positive after exposure should undergo an additional HIV test at 6 months. Testing also is indicated if an illness consistent with acute HIV-related syndrome develops before the 4- to 6-week testing and should include HIV RNA viral load. An alternative is to save a baseline serum specimen to be tested later for HIV if indicated. Counseling is necessary before and after testing (see Human Immunodeficiency Virus Infection, p 489). A positive initial test result in a pediatric patient requires further investigation of the cause, such as perinatal transmission, sexual abuse or activity, or drug use.

With needlestick injuries, a case-by-case assessment of risk of HIV transmission and of risks and benefits of PEP is indicated. In deciding whether or not to initiate PEP, higher-risk situations in which PEP should be recommended include the source being known to be living with HIV, detectable HIV viral load of the person living with HIV, the injury occurring in an area with a high prevalence of HIV infection and injection drug use (some sources suggest >15% prevalence as a threshold), the needle being a large lumen device with visible blood on it or in the syringe, or the injury involving deeper penetration of the needle or involving a mucosal membrane. In some lower-risk situations, it still may be appropriate to consider PEP on the basis of the specifics of a given case. Fig 2.1 (p 188) provides a framework for decision making on PEP utilization.

An HIV specialist should be consulted before deciding whether to initiate PEP. Other consultation services such as the National Clinical Consultation Center (PEP consultation line 888-448-4911; <https://nccc.ucsf.edu/about-the-center/history/>)

¹ Schillie S, Murphy TV, Sawyer M, et al. CDC guidance for evaluating health-care personnel for hepatitis B virus protection and for administering postexposure management. *MMWR Recomm Rep*. 2013;62(RR-10):1-19

or the New York City PEP Hotline (844-373-7692) are also available. For a needlestick with high risk for HIV exposure, PEP should begin within 72 hours. If the needlestick is determined to warrant PEP, a 28-day combination antiretroviral regimen that is appropriate for the patient's age and medical conditions should be selected, and the recommended schedule of laboratory tests should be followed¹ (see Human Immunodeficiency Virus Infection, p 489). Testing the needle for HIV is not recommended.

HEPATITIS C VIRUS

HCV retains infectivity in blood in syringes for days to weeks, depending on syringe residual volume and ambient temperature. Although HCV transmission by sharing syringes and needles among injection drug users is efficient, the risk of transmission from a discarded needle or syringe is likely low. If testing is indicated, anti-HCV antibody testing with reflex to HCV RNA viral load should be performed at baseline and 6 or more months after exposure. Anti-HCV antibody can be detected in 80% of newly infected patients within 15 weeks after exposure and in 97% by 6 months after exposure. Coinfection with HIV and HCV can delay HCV seroconversion. For earlier diagnosis, testing for HCV viral load may be performed at 3 to 6 weeks after exposure. However, a negative HCV viral load does not preclude the need for anti-HCV antibody testing 6 months or later after exposure. To confirm infection, positive anti-HCV antibody results should be accompanied by HCV viral load (see Hepatitis C, p 458). Although treatment for hepatitis C infection is highly effective (www.hcvguidelines.org/unique-populations/children), there is no recommended PEP for HCV exposure. Immune globulin preparations for HCV are not available, because anti-HCV antibody-positive donors are excluded from the pool from which immune globulin products are prepared.

Preventing Needlestick Injuries

Needlestick injuries can be minimized by implementing public health programs on safe needle disposal and comprehensive syringe services programs including sterile needle access or exchange for used syringes and needles from people who inject drugs. Nearly 30 years of research has shown that comprehensive syringe services programs are safe, effective, and cost-saving; do not increase illegal drug use or crime; and play an important role in reducing the transmission of viral hepatitis, HIV, and other infections. On that basis, the American Academy of Pediatrics supports syringe service programs in conjunction with drug treatment and ongoing evaluation to ensure their effectiveness.

Children should be cautioned to avoid playing in areas known to be frequented by people who inject drugs and to notify a responsible adult parent, teacher, or other caregiver if a discarded syringe or needle is found. Adults should handle used injection paraphernalia with caution; guidance on safe disposal of discarded syringes and needles can be obtained from the local health department.

¹ Dominguez KL, Smith DK, Vasavi T, et al. Updated guidelines for antiretroviral postexposure prophylaxis after sexual, injection drug use, or other nonoccupational exposure to HIV—United States, 2016. Atlanta, GA: Centers for Disease Control and Prevention; 2016. Available at: <https://stacks.cdc.gov/view/cdc/38856>

..... BITE WOUNDS

An estimated 5 million human or animal bite wounds occur annually in the United States; dog bites account for approximately 90% of those wounds. The rate of infection after a bite varies but can be as high as 50% after a cat bite and 5% to 20% after a dog or human bite. Although postinjury rates of infection can be minimized through early administration of proper wound care, the bites of humans, wild animals, or nontraditional pets are potential sources of serious morbidity. Parents should teach children to avoid contact with wild animals and to secure garbage containers so that raccoons and other animals will not be attracted to the home and places where children play. Nontraditional pets, including ferrets, iguanas and other reptiles, and wild animals also pose infection and injury risks for children, and their ownership should be discouraged in households with young children. Health care professionals should be knowledgeable about and offer counseling to parents whose children will have animal contact at petting zoos and exotic animal summer camps. The Centers for Disease Control and Prevention (CDC) has websites that provide information on healthy interactions with pets and other animals.¹ Potential transmission of rabies is increased when a bite is from a wild animal (especially a bat or a carnivore) or from a domestic animal with uncertain immunization status that cannot be captured for adequate quarantine (see Rabies, p 702). Dead animals should be avoided because saliva from recently deceased mammals can contain active rabies virus, which can be transmitted via physical contact with virus-containing saliva.

Recommendations for bite wound management are provided in Table 2.9. Current guidelines from the Infectious Diseases Society of America (IDSA) state that primary wound closure is not recommended for most animal bite wounds.² Bite wounds on the face carry a relatively low rate of secondary infection, perhaps because of the generous vascular supply to the area or because these wounds likely receive prompt medical attention, and should be managed with copious irrigation, cautious debridement, and preemptive antibiotics; primary closure is acceptable. Cranial penetrating bite wounds to the scalp and skull sustained from large dogs or other large animals pose an increased risk for intracranial infection. Head imaging is recommended to examine possible skull penetration for these bite wounds. Reports of infection following primary closure on regions other than the face have major limitations including lack of a control group; lack of standardization of the type, severity, and location of the wound; and circumstances surrounding the injury. In addition, thorough wound cleansing before surgical closure has brought the rate of secondary infection of these wounds to well below 10%, no matter the species of animal that inflicted the wound. These factors combine to suggest that, although approximation of margins and closure by delayed primary or secondary intention is prudent for most infected nonfacial wounds, primary closure (or delayed primary closure following a brief antibiotic course) may be considered in some cases. High-pressure irrigation should be avoided because it might drive infectious agents into deeper tissue locations. Smaller, cosmetically unimportant

² Stevens DL, Bisno AL, Chambers HF, et al. Practice guidelines for the diagnosis and management of skin and soft tissue infections: 2014 update by the Infectious Diseases Society of America. *Clin Infect Dis*. 2014;59(2):e10–e52

Table 2.9. Management of Human or Animal Bite Wounds

Category of Management	Management
Cleansing	Remove visible foreign material. Cleanse the wound surface with clean water or saline. Cleansers such as 1% povidone–iodine or 1% benzalkonium chloride can be used for particularly soiled wounds. Irrigate open wounds with a copious volume of sterile water or saline solution by moderate-pressure irrigation.^a Avoid blind high-pressure irrigation of puncture wounds.
Wound culture	No, for fresh wounds,^b unless signs of infection exist. Yes, for wounds that appear infected.^c
Diagnostic imaging	Indicated for penetrating injuries overlying bones (including skull) or joints, for suspected fracture, or to assess foreign body inoculation.
Débridement	Remove superficial devitalized tissue and foreign material.
Operative débridement and exploration	Yes, if any of the following: • Extensive wounds with devitalized tissue or mechanical dysfunction. • Penetration of joints (eg, clenched fist injury) or cranium. • Plastic or other repairs requiring general anesthesia.
Assess mechanical function	Assess and address mechanical function of injured structures.
Wound closure	Yes, for selected (see text) fresh, ^b nonpuncture bite wounds.
Assess tetanus immunization status ^d	Yes, for all wounds.
Assess risk of rabies	Yes, if bite by any rabies-prone, unobservable wild or domestic animal with unknown immunization status. ^e
Assess risk of hepatitis B virus infection	Yes, for human bite wounds. ^f
Assess risk of human immunodeficiency virus (HIV) infection	Yes, for human bite wounds.^g An HIV test in the person bitten or in the person who bit should be considered if bloody saliva from the biter came into contact with abraded or broken skin or if either person involved in the bite incident has HIV infection or is at risk for HIV infection. Guidance on initiating nonoccupational HIV postexposure prophylaxis (PEP) as soon as possible but no later than 72 hours after a potential HIV exposure is available.^h

Table 2.9. Management of Human or Animal Bite Wounds, continued

Category of Management	Management
Initiate antimicrobial therapy ⁱ	Yes, for: • Moderate or severe bite wounds, especially if edema or crush injury is present. • Puncture wounds, especially if penetration of bone, tendon sheath, or joint has occurred. • Deep or surgically closed facial bite wounds. • Hand and foot bite wounds. • Genital area bite wounds. • Wounds in immunocompromised and asplenic people. • Wounds with signs of infection. • Cat bite wounds.
Follow-up	Inspect wound for signs of infection within 48 hours.

^aUse of an 18-gauge needle with a large-volume syringe is effective. Antimicrobial or anti-infective solutions offer no advantage and may increase tissue irritation.

^bWounds less than 12 hours old.

^cBoth aerobic and anaerobic bacterial culture should be performed.

^dSee Tetanus, p 848.

^eSee Rabies, p 702.

^fSee Hepatitis B, p 437.

^gSee Human Immunodeficiency Virus Infection, p 489.

^hDominguez KL, Smith DK, Vasavi T, et al. Updated Guidelines for Antiretroviral Postexposure Prophylaxis After Sexual, Injection Drug Use, or Other Nonoccupational Exposure to HIV—United States, 2016. Atlanta, GA: Centers for Disease Control and Prevention; 2016. Available at: <https://stacks.cdc.gov/view/cdc/38856>; and National Clinician Consultation Center, University of California, San Francisco. PEP: Post-Exposure Prophylaxis. Available at: <https://nccc.ucsf.edu/clinician-consultation/pep-post-exposure-prophylaxis/>.

ⁱ See Table 2.10 (p 206) for suggested drug choices.

wounds can be cleansed and allowed to heal by secondary intention. Hand and foot wounds have a higher risk of infection. This is especially true of deeper wounds that penetrate multiple tissue planes and are more difficult to clean effectively. Injuries that are more complicated should be managed in consultation with an appropriate surgical specialist. To minimize infection risk, bite wounds should not be sealed with a tissue adhesive.

Most infected mammalian bite wound infections are polymicrobial, often involving a mixture of mouth flora from the biting animal and skin flora from the victim (gram-positive and gram-negative aerobes and anaerobes) (see Table 2.10). It usually takes at least 12 hours for signs of infection to manifest clinically. Patients with mild injuries in which the skin is abraded do not need to be treated with antimicrobial agents. For those injuries, cleansing is sufficient.

Specimens for both aerobic and anaerobic culture should be obtained from wounds that appear infected. Limited data exist to guide short-term antimicrobial therapy for patients with wounds that do not appear infected. Preemptive early antimicrobial therapy for 3 to 5 days is recommended for patients who (a) are immunocompromised; (b) are asplenic; (c) have advanced liver disease; (d) have preexisting or resultant edema of the affected area; (e) have moderate to severe injuries, especially

to the hand or face; or (f) have injuries that may have penetrated the periosteum or joint capsule.¹ Antimicrobial therapy is recommended following cat bites, given the frequency of associated infection. In certain cases, postexposure prophylaxis for rabies may be indicated. Always assume that bats, skunks, raccoons, foxes, and woodchucks are rabid unless the geographic area is known to be rabies-free or until the animal tests negative (see Rabies, p 702). Tetanus toxoid should be administered to patients with animal bite wounds who have not had toxoid vaccination within the prior 5 years (see Tetanus, p 848). Humans exposed to macaque bites or secretions are at risk for B virus (*Cercopithecine herpesvirus 1*) infection and could be considered for postexposure antiviral prophylaxis (valacyclovir) in certain situations.² Routine antiviral prophylaxis following most animal bite wounds is not indicated, although risks for transmission of hepatitis B virus and human immunodeficiency virus (HIV) should be assessed in human bite injuries (see Table 2.9).

Suggestions for initial choice of antimicrobial therapy for human and animal bites are provided in Table 2.10. The treatment of choice following most bite wounds for which therapy is indicated is amoxicillin-clavulanic acid. For a child who cannot take penicillin, alternative options include oral or parenteral treatment with trimethoprim-sulfamethoxazole, which is effective against *Staphylococcus aureus* (including methicillin-resistant *S aureus* [MRSA]), *Pasteurella multocida*, and *Eikenella corrodens*, in conjunction with clindamycin, which is active in vitro against anaerobic bacteria, streptococci, and many strains of *S aureus*. Extended-spectrum cephalosporins, such as parenteral ceftriaxone or oral cefpodoxime, do not have good anaerobic activity but can be used in conjunction with clindamycin as alternative therapy for penicillin-allergic patients who can tolerate cephalosporins. Doxycycline is an alternative agent that has activity against *P multocida* and can be used regardless of patient age (see Antimicrobial Agents and Related Therapy, p 973). Azithromycin and fluoroquinolones display good in vitro activity against organisms that commonly cause bite wound infections, but clinical data are lacking. Carbapenems are also an option for children with penicillin allergy. A 5-day course of treatment usually is sufficient for soft tissue infections, but the duration of treatment for bite wound-associated bone infections is based on location, severity, and pathogens isolated.

In the child with a confirmed bite wound-associated infection, initial therapy should be optimized when culture results become available. MRSA is a potential but uncommon bite wound pathogen; empiric therapy may require modification in cases of known colonization, severe infections, or when MRSA is isolated from an infected wound (see *Staphylococcus aureus*, p 767).

Bites from some animals may lead to infections with unusual microbes such as *Salmonella* species (eg, many reptiles), *Aeromonas* species (eg, alligators), or *Vibrio* species (eg, sharks). *Bartonella henselae* infections may be a late manifestation of cat, and sometimes dog, bites.

¹ Stevens DL, Bisno AL, Chambers HF, et al. Practice guidelines for the diagnosis and management of skin and soft tissue infections: 2014 update by the Infectious Diseases Society of America. *Clin Infect Dis*. 2014;59(2):e10–e52

² Cohen JI, Davenport DS, Steward JA, et al. Recommendations for prevention of and therapy for exposure to B virus (*Cercopithecine herpesvirus 1*). *Clin Infect Dis*. 2002;35(10):1191–1203

Table 2.10. Antimicrobial Agents for Human or Animal Bite Wounds

Source of Bite	Organism(s) Likely to Cause Infection	First-Line Therapy ^a	Alternatives for Penicillin-Allergic Patients ^{a,b}
Dog, cat, or mammal ^c	<i>Pasteurella</i> species, <i>Staphylococcus aureus</i> , streptococci, anaerobes, <i>Capnocytophaga</i> species, <i>Moraxella</i> species, <i>Corynebacterium</i> species, <i>Neisseria</i> species	Amoxicillin-clavulanate (oral) OR Ampicillin-sulbactam (IV)	Oral or IV: Extended-spectrum cephalosporin or trimethoprim-sulfamethoxazole ^d PLUS Clindamycin
Reptile ^e	Enteric gram-negative bacteria (including <i>Salmonella</i> species), anaerobes	Amoxicillin-clavulanate (oral) OR Ampicillin-sulbactam (IV)	Oral: Extended-spectrum cephalosporin or trimethoprim-sulfamethoxazole ^d PLUS Clindamycin OR IV: Extended-spectrum cephalosporin or gentamicin or aztreonam or quinolone PLUS Clindamycin
Human	Streptococci, <i>S aureus</i> , <i>Eikenella corrodens</i> , <i>Haemophilus</i> species, anaerobes	Amoxicillin-clavulanate (oral) OR Ampicillin-sulbactam (IV)	Oral or IV: Extended-spectrum cephalosporin or trimethoprim-sulfamethoxazole ^d PLUS Clindamycin

^aCoverage for methicillin-resistant *Staphylococcus aureus* (MRSA) can be considered for severe bite wounds. Note that neither amoxicillin-clavulanate nor ampicillin-sulbactam will provide MRSA coverage.

^bFor patients with history of suspected IgE-mediated allergy or severe drug reaction to penicillin, alternative drugs are recommended (see text).

^cData are lacking to guide antimicrobial use for bites that are not overtly infected from small mammals, such as guinea pigs and hamsters.

^dDoxycycline provides alternative coverage for *Pasteurella multocida* and MRSA.

^eThe role of empirical antimicrobial use for noninfected snake bite wounds is not well-defined. Therapy should be chosen based on results of cultures from infected wounds.

PREVENTION OF MOSQUITO-BORNE AND TICK-BORNE INFECTIONS

Mosquito-borne diseases in the continental United States are caused by arboviruses (eg, West Nile, La Crosse, Jamestown Canyon, St. Louis encephalitis, and eastern equine encephalitis [see Arboviruses, p 237, and Table 2.11]). Several mosquito species in the *Culex* genus transmit West Nile and St. Louis encephalitis viruses to

Table 2.11. Diseases Transmitted by Mosquitoes and Ticks in the United States^a

Organism/Disease	Primary Vector	Geographic Region
Mosquito-borne Infections		
West Nile virus	<i>Culex</i> species	Across continental United States
La Crosse encephalitis virus	<i>Aedes triseriatus</i>	Upper midwestern, mid-Atlantic, and southeastern states
Jamestown Canyon virus	Unknown	Upper midwestern states
St. Louis encephalitis virus	<i>Culex</i> species	Midwestern and western states
Eastern equine encephalitis virus	<i>Aedes</i> , <i>Coquillettidia</i> , and <i>Culex</i> species	Midwestern and eastern states
Dengue virus	<i>Aedes aegypti</i> and <i>Aedes albopictus</i>	US territories (Puerto Rico, US Virgin Islands, American Samoa)
Chikungunya virus	<i>A. aegypti</i> and <i>A. albopictus</i>	US territories (Puerto Rico, US Virgin Islands, American Samoa)
Zika virus	<i>A. aegypti</i> and <i>A. albopictus</i>	US territories (Puerto Rico, US Virgin Islands, American Samoa)
Tick-borne Infections		
<i>Rickettsia rickettsii</i> (Rocky Mountain spotted fever)	<i>Dermacentor variabilis</i> (American dog tick), <i>Dermacentor andersoni</i> (Rocky Mountain wood tick), <i>Rhipicephalus sanguineus</i> (brown dog tick)	Throughout the United States but most common in midwestern and southeastern states
Colorado tick fever	<i>Dermacentor andersoni</i>	Western states
<i>Borrelia burgdorferi</i> , <i>Borrelia mayonii</i> (Lyme disease)	<i>Ixodes scapularis</i> , <i>Ixodes pacificus</i>	Northeastern and upper midwestern states

Table 2.11. Diseases Transmitted by Mosquitoes and Ticks in the United States,^a continued

Organism/Disease	Primary Vector	Geographic Region
<i>Anaplasma phagocytophilum</i> (anaplasmosis)	<i>I scapularis</i> , <i>I pacificus</i>	Northeastern and upper midwestern states
<i>Babesia microti</i> (babesiosis)	<i>Ixodes</i> species	Northeastern and midwestern states
<i>Borrelia miyamotoi</i> (hard tick relapsing fever)	<i>Ixodes</i> species	Upper midwestern, northeastern, and mid-Atlantic states
Powassan virus	<i>Ixodes</i> species	Northeastern and upper midwestern states
<i>Ehrlichia muris eauclairensis</i>	<i>Ixodes</i> species	Cases have been reported in Minnesota and Wisconsin
<i>Ehrlichia chaffeensis</i> , <i>Ehrlichia ewingii</i> (ehrlichiosis)	<i>Amblyomma americanum</i> (lone star tick)	Southeastern and south-central states
Heartland virus	<i>A americanum</i> (lone star tick)	Southeastern and south-central states
Southern tick-associated rash illness (STARI)	<i>A americanum</i> (lone star tick)	Southeastern and eastern states
<i>Borrelia hermsii</i> , <i>Borrelia turicatae</i> (tick-borne relapsing fever)	<i>Ornithodoros</i> species	Western mountainous states
<i>Rickettsia parkeri</i> (spotted fever)	<i>Amblyomma maculatum</i>	Southeastern states
<i>Francisella tularensis</i> (tularemia)	<i>D andersoni</i> , <i>D variabilis</i> , or <i>A americanum</i>	Reported in all states

^aMosquito-borne and tick-borne infections that are transmitted primarily in other countries are not included here (eg, malaria, yellow fever virus, Japanese encephalitis virus, tick-borne encephalitis virus).

humans (primarily *Culex pipiens*, *Culex quinquefasciatus*, and *Culex tarsalis*). Eastern equine encephalitis virus can be transmitted by *Aedes*, *Coquillettidia*, and *Culex* species. The main mosquito vector of La Crosse virus is the treehole-inhabiting species *Aedes triseriatus*. Primary vector species of Jamestown Canyon virus have not been identified. Local transmission of other mosquito-borne viruses (eg, dengue, chikungunya, and Zika viruses) occurs in US territories (eg, Puerto Rico, US Virgin Islands, American Samoa) and occasionally in the continental United States. Chikungunya, dengue, and Zika viruses are primarily transmitted by 2 container-inhabiting mosquito species, *Aedes aegypti* and *Aedes albopictus*. International travelers may encounter similar or different arboviruses (eg, yellow fever, Japanese encephalitis, tick-borne encephalitis) or other mosquito-borne infections (eg, malaria) during travel (also see disease-specific chapters in Section 3).

Tick-borne infectious diseases in the United States include those caused by bacteria (spirochetes and rickettsia), protozoa, and viruses. Different species of ticks transmit different infectious agents. *Dermacentor variabilis* (American dog tick), *Dermacentor andersoni* (Rocky Mountain wood tick), and *Rhipicephalus sanguineus* (brown dog tick) are the

primary vectors of *Rickettsia rickettsii* (Rocky Mountain spotted fever). *Dermacentor andersoni* also transmits Colorado tick fever virus. *Ixodes scapularis* (deer or blacklegged tick) and *Ixodes pacificus* (western blacklegged tick) transmit *Borrelia burgdorferi* (Lyme disease) and *Anaplasma phagocytophilum* (anaplasmosis). *Ixodes* ticks also transmit *Babesia microti* (babesiosis), *Borrelia miyamotoi* (hard tick relapsing fever), *Borrelia mayonii* (Lyme disease), *Ehrlichia muris euclairensis*, and Powassan virus. *Amblyomma americanum* (lone star tick) transmits *Ehrlichia chaffeensis*, *Ehrlichia ewingii* (ehrlichiosis), and Heartland virus, and is associated with southern tick-associated rash illness (STARI). *Francisella tularensis* (tularemia) can be transmitted by *D andersoni*, *D variabilis*, or *A americanum*. Soft-bodied ticks (*Ornithodoros* species) transmit *Borrelia hermsii* and *Borrelia turicatae* to cause tick-borne relapsing fever. *Amblyomma maculatum* (the Gulf Coast tick) can transmit *Rickettsia parkeri*, a form of spotted fever rickettsiosis.

Prevention of infection depends on avoiding known areas of disease, reducing arthropod habitats, using repellents and clothing to protect against biting arthropods, and limiting the amount of time that ticks are attached to the skin.

Vaccines for yellow fever, Japanese encephalitis, and tick-borne encephalitis are licensed and available in the United States for use in travelers. A dengue vaccine is approved in the United States for use in children 6 through 16 years of age with laboratory-confirmed previous dengue infection living in areas where dengue is endemic. Chemoprophylactic drugs are available to protect against malaria.

General Protective Measures

Pediatricians can educate patients and families to take the following measures to reduce exposures to vectorborne diseases:

- **Understand which arthropod-related infections are common in your area.** Physicians need to be aware of the burden of arthropod-related infections in their local areas. Local health departments can provide information about domestic disease risks and patterns. Travelers, to the extent possible, should avoid known areas of disease transmission. The Centers for Disease Control and Prevention (CDC) Travelers' Health website provides updates on regional disease transmission patterns and outbreaks (wwwnc.cdc.gov/travel/). Climate change is affecting the geographic range of arthropod vectors.
- **Eliminate standing water sources that attract mosquitoes.** Mosquitoes lay eggs on or near standing water, and large numbers of mosquitoes can arise from sources of standing water at or near the home. Measures to limit places where mosquitoes can lay eggs around the home include drainage, cleaning, or removal of receptacles for standing water (eg, tires, toys, flower pots, cans, buckets, barrels, other containers that collect rain water); keeping swimming pools, decorative pools, and children's wading pools in working condition so that water does not become stagnant; replacing water in bird baths several times weekly; and clearing clogged rain gutters. Under certain circumstances, large-scale mosquito-control measures may be conducted by community or public health officials. These efforts include drainage of standing water; use of larvicides in waters that are sources of mosquitoes, and use of adulticides to control adult mosquitoes. More information on integrated pest management is available from the US Environmental Protection Agency (EPA) at www.epa.gov/ipm/introduction-integrated-pest-management.

- **Reduce exposure to mosquitoes.** Mosquitoes may bite at any time of day. Although different species of mosquitoes have different peak biting times, precautions should be taken anytime when outdoors. Peak biting time for vectors of malaria are from dusk to dawn, and peak biting times for vectors carrying West Nile, dengue, chikungunya, and Zika viruses are at dawn and dusk. Bed nets, screens, and nets tucked around strollers and other confined spaces where young children play are important barriers against mosquitoes. Mosquito traps, electrocutors (bug zappers), ultrasonic repellents, and other devices marketed to prevent mosquitoes from biting people should not be relied on to reduce mosquito bites.
- **Reduce exposure to ticks.** Ticks generally live in grassy, brushy, or wooded areas and on animals. People are more likely to come in contact with ticks while with animals or when camping, gardening, or hunting. The residential backyard is a primary environment where people are bitten by ticks that transmit pathogens that may cause disease. Tick-infested areas should be avoided whenever possible. When hiking, use the center of trails to reduce exposure to questing ticks on vegetation. Risk of exposure to some ticks can be reduced by locating play equipment in sunny, dry areas away from forest edges; creating a barrier of dry wood chips or gravel between recreation areas and forest; regularly mowing vegetation; and keeping leaves raked and underbrush cleared. The brown dog tick (*Rhipicephalus sanguineus*), a concern in the southwestern United States, can survive in more arid environments and can be introduced indoors where it may be found in cracks and crevices in the house; on walls, carpet, and furniture; or in animal housing or bedding. Control of tick populations in the community often is not practical but can be effective in more defined areas, such as around places where children play. Using acaricides (pesticides targeting ticks) on a property or on pets can reduce tick populations.
- **Wear appropriate protective clothing.** Whenever possible, clothing should be worn that covers the arms, legs, head, and other exposed skin areas when entering mosquito or tick habitats. Tucking in shirts and wearing closed-toe shoes instead of sandals may reduce opportunities for ticks to attach. Visualization of crawling arthropods is improved with light-colored clothing.
- **Consider treatment of clothing and gear.** Permethrin (a synthetic pyrethroid) is both a pesticide and a repellent that can be sprayed onto clothes and gear. Permethrin repels both mosquitoes and ticks. Clothing and gear should be treated with products containing 0.5% permethrin. Permethrin should not be sprayed directly onto skin, and treated clothing should be dried before wearing. The US EPA has registered the commercial sale of permethrin-treated outdoor clothing, hats, bed nets, and camping gear, which is safe for children and pregnant people when used according to the product label. Adverse reactions to permethrin are mild and transient and may include skin rash, burning, stinging, erythema, tingling, or numbness. Permethrin-treated clothing remains effective through multiple launderings but may need retreatment over time. Permethrin or repellents should not be used on clothing or mosquito nets where children may chew or suck on the material. More information on repellent treated clothing is available at www.epa.gov/insect-repellents/repellent-treated-clothing and www.epa.gov/mosquitocontrol/permethrin-resmethrin-d-phenothrin-sumithrin-synthetic-pyrethroids-mosquito.

Repellents for Use on Skin

The EPA regulates repellent products in the United States. The CDC, US Food and Drug Administration (FDA), and American Academy of Pediatrics (AAP) recommend that people use repellent products that have been registered by the EPA, which indicates that the materials have been reviewed for both efficacy and human safety when applied according to the instructions on the label.

Arthropods are attracted to people by body heat, odors on the skin, vibrations, and carbon dioxide and other volatile chemicals from the breath. The active ingredients in repellents, with the exception of permethrin-based repellents, help ward off mosquitoes or ticks but do not kill them. Repellents should be used during outdoor activities when mosquitoes or ticks are present and should always be used according to the label instructions. Protection times listed below generally are against mosquitoes; duration of protection generally is shorter against ticks. Protection also varies by type and concentration of active ingredient, product formulation, ambient temperatures, and types of activity (eg, protection time is reduced by perspiration, washing of skin, and involvement in water recreation). Product labels should be followed for application and reapplication recommendations. Repellents should not be reapplied more frequently than recommended on the label. More information on insect repellants is available from the EPA (www.epa.gov/insect-repellents/find-insect-repellent-right-you).

EPA-REGISTERED REPELLENTS

Several types of EPA-registered products provide repellent activity sufficient to help people reduce the bites of disease-carrying mosquitoes and ticks (www.epa.gov/insect-repellents and wwwnc.cdc.gov/travel/yellowbook/2024/environmental-hazards-risks/mosquitoes-ticks-and-other-arthropods).

Products containing the following active ingredients typically provide reasonably long-lasting protection from mosquitoes and ticks when applied directly to the skin. More information about these ingredients can be found at www.epa.gov/insect-repellents/skin-applied-repellent-ingredients.

DEET. Chemical name: N,N-diethyl-meta-toluamide or N,N-diethyl-3-methylbenzamide. Commercial products registered for direct application to human skin contain from 5% to 99% DEET (www.epa.gov/insect-repellents/deet). DEET repels both mosquitoes and ticks. In general, higher concentrations of active ingredient provide longer duration of protection. Protection times for DEET against mosquitoes range from 1 to 2 hours for products containing 5% concentrations (which may not protect against ticks) to 10 hours or more for products containing 40% or more DEET. There does not appear to be a meaningful increase in protection time for products containing >50% DEET. Time-released DEET formulations are available that provide 11 to 12 hours of protection with concentrations of 20% to 30% DEET.

DEET does not present a health problem if used appropriately. Adverse effects related to DEET are rare and most often are associated with ingestions or chronic or excessive use and do not appear to be related to DEET concentration used. Although rare, encephalopathy has been reported after excessive skin application in children and after unintentional ingestion. Urticaria and contact dermatitis have been reported in a small number of people. DEET is irritating to eyes and mucous membranes and

should not be applied to these areas. Highly concentrated formulations can damage plastic and certain synthetic fabrics.

PICARIDIN (KBR 3023). Chemical name: 2-(2-hydroxyethyl)-1-piperidinecarboxylic acid 1-methylpropyl ester. Picaridin has concentration-related efficacy and ages for use similar to DEET. Products containing 5% picaridin provide 3 to 4 hours of protection against mosquitoes and ticks, and products with 20% picaridin can provide protection for 8 to 12 hours. Although experience with this product is less than with DEET, no serious toxicity has been reported. Picaridin-containing compounds have been used as repellents for 2 decades in Europe and Australia and for more than 10 years in the United States as a 20% formulation with no serious toxicity reported.

OIL OF LEMON EUCALYPTUS. Chemical name: para-menthane-3,8-diol (PMD). PMD is the synthesized version of oil of lemon eucalyptus (OLE). Only EPA-registered repellent products containing the active ingredient OLE or PMD should be used. “Pure” oil of lemon eucalyptus has not been tested for safety and efficacy and is not registered with the EPA as an insect repellent. Products with 8% to 10% PMD protect for up to 2 hours, and products containing 30% to 40% OLE provide 6 hours of protection. These products should not be used on children younger than 3 years.

IR3535. Chemical name: 3-(N-butyl-N-acetyl)-aminopropionic acid. IR3535 is available in formulations ranging from 7.5% to 20%, with estimated protection times ranging from 2 hours to up to 10 hours depending on concentration.

2-UNDECANONE. Chemical name: methyl nonyl ketone. 2-undecanone is a synthetic version of an organic compound that can also be extracted from oil of rue, a perennial shrub. It can also be found naturally in wild-grown tomatoes, cloves, and other plant sources. 2-undecanone products contain 7.75% active ingredient and provides protection for up to 5 hours for mosquitoes and 2 hours for ticks.

NONREGISTERED PRODUCTS

Topical products based on citronella, catnip oil, and other essential plant oils provide minimal protection and are not recommended. Ingestion of garlic or vitamin B₁ and wearing devices that emit sounds or impregnated wristbands are ineffective.

APPLICATION OF REPELLENTS

The following are recommended precautions for use of repellents:

- Apply repellents only to exposed skin or clothing, as directed on the product label. Do not apply repellents under clothing.
- Never use repellents over cuts, wounds, or irritated skin.
- When using sprays, do not spray directly on face—spray on hands first and then apply to face. Do not apply repellents to eyes or mouth and apply sparingly around ears.
- Children should not handle repellents. Adults should apply repellents to their own hands first, and then gently spread on the child’s exposed skin. Adults should avoid applying directly to children’s hands, because children frequently put fingers and hands into their mouths. Children also may be exposed to the pesticides applied to their pets.
- Use just enough repellent to cover exposed skin or clothing.
- Sprays should not be applied in enclosed areas or near food.

- Wash hands after application to avoid accidental exposure to eyes or ingestion.
- Do not apply repellents for use on humans to pets.

REPELLENTS AND SUNSCREEN. Sunscreen should be applied first when using both products simultaneously. Repellents that are applied according to label instructions may be used with sunscreen with no reduction in repellent activity; limited data show a one-third decrease in the sun protection factor (SPF) of sunscreens when DEET-containing insect repellents are used after a sunscreen is applied. Reapplication of sunscreen or repellent may be needed depending on the duration of protection needed and type of activity. Products that combine sunscreen and repellent are not recommended.

Tick Inspection and Removal

Parents or caregivers should promptly inspect children's bodies, clothing, and equipment after possible tick exposure ("tick check"). When conducting tick checks, special attention should be given to the exposed regions of the body where ticks often attach, including the head, neck, around the ears, and inside the umbilicus, behind the knees, between the legs, and around the waist. Ticks also may attach at areas of tighter clothing (eg, sock line, belt line, axillae, groin). Timely tick checks at least daily increase the likelihood of finding and removing ticks before they can transmit an infectious agent. Longer periods of attachment significantly increase the probability of transmission of tick-borne pathogens, although certain pathogens (eg, Powassan virus) are believed to be transmitted in less than 15 minutes. It is important to remove clothes as soon as possible after potential tick exposure because they may harbor crawling ticks. Bathing or showering after coming indoors (preferably within 2 hours) can be an opportunity to locate attached or crawling ticks and has been shown to be an important personal protective measure against several tick-borne diseases. Unattached ticks can enter the home by hiding in clothing. Placing dry clothing in a dryer on high heat for at least 10 minutes (damp clothes can take up to 1 hour) has been used to kill unattached ticks on clothes.

TICK REMOVAL

Ticks should be removed from skin as soon as possible. Do not wait for the tick to detach itself from the skin by "painting" it with petroleum jelly or using heat. When possible, use fine-tipped forceps or tweezers to grasp the tick as close to the skin as possible and gently pull straight out without twisting motions. Be careful not to break mouthparts as the tick is removed. Tweezers should be cleaned of any potential tick body tissue or fluids that may have been left after pulling on the attached tick. Tweezers then can be used to remove mouthparts or cement (an adhesive secretion that anchors tick mouthparts to the skin) left on the skin. Avoid cutting or digging into skin to remove small remnants; if unable to remove the mouth parts easily, leave them alone and let the skin heal. If fingers are used to remove ticks, they should be protected with a barrier, such as tissue or plastic gloves, and washed after removal of the tick. The bite site should be washed with soap and water to reduce the risk of secondary skin infections.

TESTING TICKS

Testing ticks removed from animals or humans for infectious pathogens is unnecessary because it is not diagnostically informative.

Other Preventive Measures

PETS

Maintaining tick-free pets also will decrease tick exposure in and around the home. Daily inspection of pets, removal of ticks, and use of appropriate veterinary products to prevent ticks on pets are indicated. Consult a veterinarian for information on effective products. Apply recommended products as instructed.

CHEMOPROPHYLAXIS

In areas of high Lyme disease incidence, chemoprophylaxis with a single dose of doxycycline to prevent Lyme disease after an *Ixodes* tick bite may be considered under certain conditions (see www.cdc.gov/lyme/resources/FS-Guidance-for-Clinicians-Patients-after-TickBite-508.pdf and Lyme Disease, p 549). Doxycycline can be used regardless of patient age (see Antimicrobial Agents and Related Therapy, p 973). Chemoprophylaxis is not recommended for other tick-borne diseases, including those caused by rickettsiae. Following a tick bite, individuals should be on alert for signs or symptoms of tick-borne illnesses and consult a physician if a fever, rash, or other concerns develop.

Chemoprophylaxis is recommended for travelers to areas where malaria is endemic (see Malaria, p 561)

PREVENTION OF ILLNESSES ASSOCIATED WITH RECREATIONAL WATER USE

Recreational water-associated illness (RWI) can be caused by pathogens transmitted through ingestion, inhalation of aerosols, or contact with contaminated water in swimming pools, splash pads, water playgrounds, hot tubs, lakes, rivers, or oceans. RWI also can be caused by chemicals or toxins in recreational water via ingestion, inhalation, or contact. Illnesses associated with recreational water can involve the gastrointestinal tract, respiratory tract, central nervous system, skin, ears, or eyes. From 2015 through 2019, 208 outbreaks associated with treated recreational water (eg, in pools, splash pads, hot tubs) were reported to the Centers for Disease Control and Prevention (CDC).¹ These outbreaks resulted in more than 3600 cases of illness, including 13 deaths, and only represent a small fraction of the true disease burden as most RWI is unreported. The leading cause of these outbreaks was *Cryptosporidium* species. Cryptosporidiosis can cause life-threatening infection in immunocompromised persons (see Cryptosporidiosis, p 338). Another common cause in these outbreaks was *Legionella* species (see *Legionella pneumophila* Infections, p 531). Although not confirmed in this series, *Pseudomonas* species can cause folliculitis (“hot tub rash”) or acute otitis externa (“swimmer’s ear”). Among 140 outbreaks from 2000 to 2014 associated with untreated recreational water venues (eg, lakes, rivers),² common causes included norovirus (see Norovirus and Sapovirus

¹ Hlavsa MC, Aluko SA, Miller AD, et al. Outbreaks associated with treated recreational water—United States, 2015–2019. *MMWR Morb Mortal Wkly Rep.* 2021;70(20):733–738.

² Gracia DS, Cope JR, Roberts VA, et al. Outbreaks associated with untreated recreational water—United States, 2000–2014. *MMWR Morb Mortal Wkly Rep.* 2018;67(25):701–706

Infections, p 622), pathogenic *Escherichia coli* (see *Escherichia coli* Diarrhea, p 376), *Shigella* species (see *Shigella* Infections, p 756), *Cryptosporidium* (see Cryptosporidiosis, p 338), avian schistosomes (cercarial dermatitis), and algal toxins associated with harmful algal blooms. Leptospirosis (see Leptospirosis, p 542), although less common, also caused outbreaks. Two deaths were attributed to primary amoebic meningoencephalitis (PAM) caused by *Naegleria fowleri* (see Amebic Meningoencephalitis and Keratitis, p 228), a free-living amoeba found in natural or ambient bodies of freshwater.

Although rare (0–8 infections per year), *N. fowleri* infection is nearly always fatal (>97% fatality rate). Infection primarily affects healthy young males and can occur during swimming in warm, freshwater lakes, ponds, reservoirs, rivers, or streams. Cases have also been associated with inadequately chlorinated swimming pools, an artificial whitewater river, a manmade surf park, and splash pads. After the amoebae enter the nasal cavity, they migrate to the brain via the olfactory nerve. Signs and symptoms of *N. fowleri* infection are clinically similar to bacterial meningitis.

According to CDC's One Health Harmful Algal Bloom Surveillance System, during 2020, 13 states reported 227 harmful algal blooms that resulted in 95 human illnesses and 1170 animal illnesses.¹ Marine and freshwater organisms that cause blooms occur naturally; however, rapid growth can result in harmful blooms that sometimes release toxins. Warmer water temperatures and excess of nutrients are factors that can affect their growth. Blooms can appear as foam, scum, or mats on the surface of water, although not every bloom produces toxins. Some blooms might not be easily visible if they grow below the surface of the water. Cyanobacteria ("blue-green algae") are the most common cause of harmful freshwater blooms. Cyanobacteria produce toxins known as cyanotoxins (including microcystin and cylindrospermopsin) that cause a range of illnesses, from skin or eye irritation to respiratory, gastrointestinal, or neurologic symptoms depending on the type of toxin, the route of exposure, and the exposure dose.

Cyanotoxin exposures can also cause severe illness and deaths to pets and livestock from swimming or drinking in affected waterbodies. This can occur quickly and can be an early indicator that a water body contains a harmful cyanobacterial bloom.

In marine waters, harmful algal blooms are usually caused by microalgae called diatoms and dinoflagellates. The dinoflagellate *Karenia brevis* can produce brevetoxin and is responsible for the red tide blooms observed in the Gulf Coast of the southeast United States. Inhalation or dermal exposure to brevetoxin in marine waters can result in respiratory tract, skin, or eye irritation. Additional information about harmful blooms and associated illnesses and outreach materials including fact sheets, communication resources and other media, is available from the CDC's harmful algal bloom-associated illnesses website (www.cdc.gov/habs).

During swimming, the water is shared among a few to thousands of people each day, depending on venue size. Fecal contamination of recreational water venues is a common occurrence because of the high incidence of diarrhea and fecal incontinence (particularly in young children [ie, age <5 years]) and the presence of residual fecal material on bodies of swimmers (up to 10 g on young children). Reported recreational water-associated outbreaks can disproportionately affect young children, usually occur during the summer months, and most frequently manifest as acute

¹ Vigar M, Thuneibat M, Gerdes M, Jacobi A, Roberts VA. Summary Report—One Health Harmful Algal Bloom System (OHHABS), United States, 2020. Atlanta, GA: Centers for Disease Control and Prevention; 2022. Available at: www.cdc.gov/habs/data/2020-ohhabs-data-summary.html

gastrointestinal illness. In addition to fecal contamination by swimmers, untreated recreational waters can be impacted by sewage treatment plant discharges, septic systems, or agricultural waste, which might contain a wide range of potentially infectious pathogens (eg, norovirus, *E coli*, *Shigella* species, *Cryptosporidium* species). Other microorganisms in untreated recreational waters might also cause infection (eg, *Vibrio vulnificus* and *Vibrio parahaemolyticus*, see Other *Vibrio* Infections p 955).

To help protect swimmers from infectious pathogens, water in treated recreational water venues is chlorinated. Maintaining pH and disinfectant concentration as recommended by the CDC (www.cdc.gov/healthywater/swimming/) is sufficient to inactivate most infectious pathogens within minutes. However, some infectious pathogens are moderately to extremely chlorine tolerant and can survive for extended periods of time, even in properly chlorinated pools (eg, *Giardia duodenalis* has been shown to survive for up to 45 minutes). *Legionella* and *Pseudomonas* species are effectively controlled by chlorination, but because they persist in biofilms, they can proliferate when proper disinfectant concentrations are not maintained. *Cryptosporidium* oocysts can survive for more than 7 days even in properly chlorinated pools, thus contributing to the role of *Cryptosporidium* as the leading cause of recreational water-associated outbreaks. Additional water treatments (eg, ultraviolet light, ozone) can more efficiently inactivate *Cryptosporidium* oocysts.

Recreational water use is a major route for *Cryptosporidium* transmission because of the organism's extreme chlorine tolerance, low infectious dose, immediate infectiousness upon excretion, and high pathogen excretion volume, in addition to poor swimmer hygiene (eg, swimming when ill with diarrhea) and swimmer behavior (eg, ingesting recreational water). One or more swimmers who are ill with diarrhea can contaminate large volumes of water and expose large numbers of swimmers to *Cryptosporidium* and, if pool disinfection is inadequate, other pathogens. Outbreaks associated with treated recreational water venues generally can be prevented and controlled through a combination of proper pH, adequate disinfectant concentration, and improved swimmer hygiene and behavior. Pediatricians and parents of young children can learn more about healthy swimming at www.cdc.gov/healthywater/swimming/. Over-the-counter test strips can be purchased to check the level of free chlorine (the active form of chlorine that inactivates pathogens) and pH of swimming pool or splash pad water. The CDC also publishes the Model Aquatic Health Code (www.cdc.gov/mahc/editions/current.html), which provides detailed and regularly updated guidance to reduce risk of RWI and injury through the design, construction, operation, and management of treated recreational water venues open to the public.

Control Measures

Swimming is generally a healthy and safe means of physical activity. Transmission of infectious pathogens that cause most RWIs can be prevented by reducing contamination of recreational water venues and limiting exposure to contaminated water. Pediatricians should counsel families as follows:

- Regularly test pools and splash pads to ensure that the water's free chlorine or bromine (another commonly used disinfectant) concentration and the pH are correct and safe:
 - ♦ Free chlorine concentration should be at least 1 part per million (ppm).
 - ♦ Bromine concentration should be at least 3 ppm.
 - ♦ pH should be 7.0 to 7.8.

- Do not go into recreational water when ill with diarrhea.
 - ♦ After complete cessation of symptoms, people who had diarrhea attributable to *Cryptosporidium* species also should avoid recreational water activities for an additional 2 weeks. This is because of prolonged excretion of infectious *Cryptosporidium* oocysts after complete cessation of symptoms, the potential for intermittent exacerbations of diarrhea, and the increased transmission potential in treated recreational water venues (eg, swimming pools) because of the organism's extreme chlorine tolerance.
 - ♦ After cessation of symptoms, children who had diarrhea attributable to other potential waterborne pathogens (eg, *Shigella* species) and who are incontinent should avoid recreational water activities for 1 additional week (or as advised by local public health authorities).
- Avoid ingestion of recreational water.
- Do not go into recreational water with open wounds (eg, from surgery or a piercing), because wounds can serve as portals of entry for pathogens.
- Stay out of the water in lakes, rivers, or oceans if:
 - ♦ Beaches are closed or an advisory is posted for high bacterial levels or other conditions, such as sewage spills or harmful algal blooms.
 - ♦ Recent heavy rainfall has occurred in the previous 48 to 72 hours (rain can wash contaminants from the land, like septic tank overflows or animal feces, into the water).
 - ♦ If discharge pipes are draining into or around the water.
 - ♦ Fish or other animals in or near the water are dead.
 - ♦ Water is discolored, malodorous, foamy, scummy, or cloudy (cloudier than usual).
- The only certain way to prevent *N. fowleri* infection caused by swimming is to refrain from water-related activities in warm freshwater. To reduce exposure risk to *N. fowleri*:
 - ♦ Use nose clips, hold nose shut, or keep head above water when taking part in water-related activities in bodies of warm freshwater.
 - ♦ Avoid putting your head under water in hot springs or other untreated thermal waters.
 - ♦ Avoid water-related activities in warm freshwater during periods of high temperature.
- To reduce exposure risk to harmful blooms caused by cyanobacteria or microalgae:
 - ♦ Check for local or state advisories (may be found on websites of local environmental or health departments; also see www.epa.gov/cyanohabs/state-habs-monitoring-programs-and-resources).
 - ♦ Avoid water that contains algal blooms (when in doubt, stay out).
 - ♦ Keep children and pets from drinking or playing in discolored, malodorous, foamy, or scummy water.
 - ♦ Get out and rinse off with clean tap water as soon as possible after swimming in water that might contain a harmful bloom.
 - ♦ Rinse off pets, especially dogs, immediately if they swim in discolored, malodorous, foamy, or scummy water. Do not let pets lick the algae off their fur.
- Practice good swimmer hygiene:
 - ♦ Shower with soap and water for at least 1 minute before entering recreational water.
 - ♦ Instruct children not to urinate or defecate in the water.

- ♦ Take children to the bathroom every hour. Check diapered children every hour and change diapers in a bathroom or diaper changing area—not waterside—to help keep infectious agents, urine, and feces out of the water. Swim diapers and swim pants, although able to hold in some solid feces, do not prevent leakage of pathogens such as *Cryptosporidium* species into the water.
- ♦ Wash hands with soap and water after using the bathroom and changing diapers and before consumption of food and drink.

Healthy swimming promotion materials are available at www.cdc.gov/healthywater/swimming/materials/index.html.

“Swimmer’s Ear”/Acute Otitis Externa

Participation in recreational water activities can predispose children to infections of the external auditory canal. Acute otitis externa (AOE) or “swimmer’s ear,” one of the most common infections encountered by clinicians and responsible for an estimated 4.7 million illnesses annually in the United States,¹ is a diffuse inflammation of the external auditory canal and is usually attributable to bacterial infection. Recreational water activities, showering, and bathing can introduce water into the ear canal, wash away protective ear wax, increase the pH, and cause maceration of the thin skin of the ear canal, thus predisposing the ear canal to infection. AOE is most common among children 5 to 14 years of age but can occur in all age groups, including adults. A marked seasonality is observed, with cases peaking during the summer months. Warm, humid environments and frequent submersion of the head while swimming are risk factors for AOE.

Bacterial infections cause 90% of AOE cases. The 2 most common bacterial causes of AOE are *Pseudomonas aeruginosa* and *Staphylococcus aureus*. Many cases are polymicrobial. Fungal pathogens (eg, *Aspergillus* species and *Candida* species) are responsible for a minority (10%) of AOE cases. Cultures of swab specimens taken from the external ear canal in AOE may not be entirely diagnostic because these can reflect normal ear canal flora or pathogenic organisms.

AOE readily responds to treatment with topical antimicrobial agents with or without a topical steroid. Unless the infection has spread to surrounding tissues or the patient has complicating factors (eg, has diabetes or is immunocompromised), topical treatment alone should be sufficient, and systemic antimicrobials usually are not required. Polymyxin B sulfate/neomycin sulfate, gentamicin sulfate, and ciprofloxacin for 7 to 10 days are topical antibiotic agents used commonly. If clinical improvement is not noted by 48 to 72 hours, the patient should be reevaluated for possible foreign body obstruction of the canal, noncompliance with therapy, or alternate diagnoses, such as contact dermatitis or traumatic cellulitis. If delivery of topical antibiotics is being impeded by drainage obstructing the external auditory canal, placement of a cellulose wick or referral to an otolaryngologist for aural toilet should be considered. Topical agents that have the potential for ototoxicity (eg, gentamicin, neomycin, agents with a low pH, hydrocortisone-neomycin-polymyxin) should not be used in children with tympanostomy tubes or a perforated tympanic membrane. Patients with AOE should avoid submerging their head in water for 7 to 10 days, but competitive

¹ Collier SA, Deng L, Adam EA, et al. Estimate of burden and direct healthcare cost of infectious waterborne disease in the United States. *Emerg Infect Dis*. 2021;27(1):140-149

swimmers might be able to return to the pool if pain has resolved and they use well-fitting ear plugs.

All swimmers should be instructed to keep their ear canals as dry as possible. This can be accomplished by covering the opening of the external auditory canal with a bathing cap or by using ear plugs or molds. Following swimming or showering, the ears should be dried thoroughly using a towel or a hairdryer on the lowest heat and fan setting.

If a person experiences recurring episodes of AOE, consideration can be given to use of antimicrobial otic drops after recreational water exposure as an additional preventive measure. Commercial ear-drying agents are available for use as directed, or a 1:1 mixture of acetic acid (white vinegar) and isopropanol (rubbing alcohol) may be placed in the external ear canal after swimming or showering to restore the proper acidic pH to the ear canal and to dry residual water. Otic drying agents should not be used in the presence of tympanostomy tubes, tympanic membrane perforation, AOE infection, or ear drainage.

Additional information on prevention of otitis externa is available at **www.cdc.gov/healthywater/swimming/swimmers/rwi/ear-infections.html**.

Summaries of Infectious Diseases

Actinomycosis

CLINICAL MANIFESTATIONS: Actinomycosis results from pathogen introduction following a breakdown in mucocutaneous protective barriers. Spread within the host is by direct invasion of adjacent tissues, typically forming sinus tracts that cross tissue planes. The most common species causing human disease is *Actinomyces israelii*.

There are 3 common anatomic sites of infection. **Cervicofacial** is most common, often occurring after tooth extraction, oral surgery, or other oral/facial trauma or even from carious teeth. Localized pain and induration may progress to cervical abscess and “woody hard” nodular lesions (“lumpy jaw”), which can develop draining sinus tracts, usually at the angle of the jaw or in the submandibular region. Infection may contribute to recurrent or persistent tonsillitis. **Thoracic** disease most commonly is secondary to aspiration of oropharyngeal secretions but can be an extension of cervicofacial infection. It occurs rarely after esophageal disruption secondary to surgery or nonpenetrating trauma. Thoracic presentation includes pneumonia, which can be complicated by abscesses, empyema, and rarely, pleurodermal sinuses. Focal or multifocal mediastinal and pulmonary masses may be mistaken for tumors. **Abdominal** actinomycosis usually is attributable to penetrating trauma or intestinal perforation. The appendix and cecum are the most common sites; signs and symptoms can mimic appendicitis. Slowly developing masses may simulate abdominal or retroperitoneal neoplasms. Intra-abdominal abscesses and peritoneal-dermal draining sinuses occur eventually. Chronic localized disease often forms draining sinus tracts with purulent discharge. **Other sites** of infection include the liver, pelvis (in some cases, linked to use of intrauterine devices), heart, testicles, and brain (usually associated with a primary pulmonary focus). Noninvasive primary cutaneous actinomycosis has occurred. *Actinomyces* infections have been associated with adverse pregnancy outcomes and cases of neonatal bacteremia have been described.

ETIOLOGY: *A. israelii* and at least 5 other *Actinomyces* species cause human disease. All are slow-growing, microaerophilic or facultative anaerobic, gram-positive, filamentous branching bacilli. They can be part of normal oral, gastrointestinal tract, or vaginal flora. *Actinomyces* species frequently are copathogens in tissues harboring multiple anaerobic and/or aerobic species. Isolation of *Aggregatibacter (Actinobacillus) actinomycetemcomitans*, frequently detected with *Actinomyces* species, may predict the presence of actinomycosis.

EPIDEMIOLOGY: *Actinomyces* species occur worldwide, being components of endogenous oral and gastrointestinal tract flora. *Actinomyces* species are opportunistic pathogens in the setting of disrupted mucosal barriers. Infection is uncommon in infants and children, with 80% of cases occurring in adults. The male-to-female ratio in children is 1.5:1. Although microbiologically confirmed infections caused by *Actinomyces* species now are less common, there are reports in patients who have undergone transplantation or are receiving biologics.

The **incubation period** varies from several days to several years.

DIAGNOSTIC TESTS: Microscopic demonstration of beaded, branched, gram-positive bacilli in purulent material or tissue specimens suggests the diagnosis. Only specimens from normally sterile sites should be submitted for culture. Specimens must be obtained, transported, and cultured anaerobically on semiselective (kanamycin/vancomycin) media such as the modified Thayer-Martin agar or buffered charcoal yeast extract (BCYE) agar. Acid-fast testing can distinguish *Actinomyces* species, which are acid-fast negative, from *Nocardia* species, which are variably acid-fast positive staining. Yellow “sulfur granules” visualized microscopically or macroscopically in drainage or loculations of purulent material suggest the diagnosis. A Gram stain of “sulfur granules” discloses a dense aggregate of bacterial filaments mixed with inflammatory debris. *A israelii* forms “spiderlike” microcolonies on culture medium after 48 hours. *Actinomyces* species can be identified in tissue specimens using a nucleic acid amplification test (NAAT), matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry, or sequencing of the 16s rRNA.

TREATMENT: Management of actinomycosis is informed exclusively by case reports, case series, and in vitro susceptibility testing. Initial therapy should include intravenous penicillin G or ampicillin for 4 to 6 weeks followed by high doses of oral penicillin (up to 2 g/day for adults), usually for a total of 6 to 12 months depending on the extent of disease and success of surgical management (when indicated). Surgical drainage often is a necessary adjunct to medical management and may shorten duration of antimicrobial therapy. Treatment for mild disease can be initiated with oral therapy and may not require as long a treatment duration. Amoxicillin and doxycycline are alternative choices. Amoxicillin/clavulanate, piperacillin/tazobactam, ceftriaxone, clarithromycin, linezolid, and imipenem/meropenem also show high activity in vitro but may be unnecessarily broad-spectrum. All *Actinomyces* species appear to be resistant to ciprofloxacin and metronidazole.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended. Person-to-person spread does not occur.

CONTROL MEASURES: Appropriate oral hygiene, regular dental care, and careful cleansing of wounds, including human bite wounds, can prevent infection.

Adenovirus Infections

CLINICAL MANIFESTATIONS: Adenovirus infections of the upper respiratory tract are common and often subclinical; when symptomatic, adenoviruses may cause common cold symptoms, pharyngitis, tonsillitis, otitis media, or pharyngoconjunctival fever. Adenoviruses occasionally cause a pertussis-like syndrome, croup, bronchiolitis, influenza-like illness, exudative tonsillitis, severe hepatitis, and hemorrhagic cystitis. Ocular adenovirus infections may present as follicular conjunctivitis or as epidemic keratoconjunctivitis. Enteric adenoviruses are an important cause of childhood gastroenteritis. Life-threatening disseminated infection, lower respiratory infection (eg, severe pneumonia, bronchiolitis obliterans), hepatitis, meningitis, and encephalitis occur occasionally, especially among young infants and immunocompromised people.

ETIOLOGY: Adenoviruses are double-stranded, nonenveloped DNA viruses of the *Adenoviridae* family and *Mastadenovirus* genus, with more than 100 recognized types and

multiple genetic variants divided into 7 species (A–G) that infect humans. Some adenovirus types are associated primarily with respiratory tract disease (types 1–5, 7, 14, 21, and 55), epidemic keratoconjunctivitis (types 8, 37, 53, 54, and 64 [previously 19a]), or gastroenteritis (types 40 and 41). Severe respiratory infections are often attributable to adenovirus types 3, 7, and 14.

EPIDEMIOLOGY: Infection in children can occur at any age. Adenoviruses causing respiratory tract infections usually are transmitted by respiratory tract secretions through person-to-person contact, airborne droplets, and fomites. Adenoviruses are hardy viruses, can survive on environmental surfaces for long periods, and are not easily inactivated by many disinfectants. Outbreaks of febrile respiratory tract illness attributable to adenoviruses can be a significant problem in military trainees, college students, children attending overnight camps, patients hospitalized in hematopoietic cell transplant units, and residents of long-term care facilities. Community outbreaks of adenovirus-associated pharyngoconjunctival fever have been attributed to water exposure from contaminated swimming pools and fomites, such as shared towels. Health care-associated transmission of adenoviral infections can occur in hospitals, residential institutions, and nursing homes from exposures to infected health care personnel, patients, or contaminated equipment. Adenovirus infections in solid organ transplant recipients can occur from donor tissues as well as endogenous reactivation. Epidemic keratoconjunctivitis commonly occurs by direct contact and has been associated with equipment used during eye examinations. Enteric strains of adenoviruses are transmitted by the fecal-oral route.

Adenoviruses do not demonstrate the marked seasonality of other respiratory tract viruses and instead circulate throughout the year. Enteric disease also occurs year-round and primarily affects children younger than 4 years. Adenovirus infections are most communicable during the first few days of an acute illness, but persistent and intermittent shedding for longer periods, even months, can occur, especially among people with weakened immune systems. In healthy people, infection with one adenovirus type should confer type-specific immunity or at least lessen symptoms associated with reinfection, which forms the basis of adenovirus vaccines used in military populations (see Control Measures).

The **incubation period** for respiratory tract infection varies from 2 to 14 days; for gastroenteritis, the **incubation period** is 3 to 10 days.

DIAGNOSTIC TESTS: Methods for diagnosis of adenovirus infection include molecular detection, isolation in cell culture, and antigen detection. Molecular assays (eg, nucleic acid amplification tests [NAATs]) are the preferred diagnostic method for detection of adenoviruses, and these assays are widely available. However, the persistent and intermittent shedding that commonly follows an acute adenoviral infection can complicate the clinical interpretation of a positive molecular test result. Quantitative adenovirus assays can be useful for management of immunocompromised patients, such as hematopoietic cell and solid organ transplant recipients. Adenoviruses associated with respiratory tract and ocular disease can be isolated by culture from respiratory specimens (eg, nasopharyngeal swab, oropharyngeal swab, nasal wash, sputum) and eye secretions in standard susceptible cell lines. Rapid antigen-detection techniques, including immunofluorescence and enzyme immunoassay, have been used to detect virus in respiratory tract secretions, conjunctival swab specimens, and stool, but these methods lack

sensitivity. Adenovirus typing by molecular methods is available from some reference laboratories. Although its clinical utility is limited, typing can help establish an etiologic association with disease and to investigate clusters of adenovirus-associated illness. Serodiagnosis is used primarily for epidemiologic studies and has no clinical utility.

TREATMENT: Treatment of adenovirus infection is primarily supportive, with most adenoviral infections in otherwise healthy persons being self-limited. Symptomatic infection in immunocompromised patients, however, should be managed with reduced immunosuppression, when feasible, and consideration of use of antiviral agents, with options presented below. For immunocompromised patients with asymptomatic detection of adenovirus DNA in the blood, there is no consensus regarding optimal management. This scenario is often encountered in the transplant setting in which patients are monitored post-transplant with serial quantitative NAATs. The detection of defined thresholds of blood DNA in this setting might allow for risk-based preemptive treatment strategies including reduced immunosuppression, when appropriate, and antiviral agents.

There are no antivirals approved by the US Food and Drug Administration for the treatment of adenovirus infections. Intravenous cidofovir has emerged as the preferred antiviral agent for treatment of severe, progressive, or disseminated adenovirus diseases in immunocompromised hosts, but its utilization is limited by its associated nephrotoxicity and myelotoxicity and there is no consensus on the optimal dose. Brincidofovir, an oral prodrug of cidofovir, was evaluated in a randomized controlled trial of pediatric and adult hematopoietic cell transplant recipients, and although brincidofovir-treated subjects had a tendency to lower odds of treatment failure and all-cause mortality compared with the placebo recipients, the differences were not statistically significant. Ribavirin has shown inconsistent therapeutic benefit in case reports and a small cohort study.

There is some evidence that ganciclovir has inhibitory effects at concentrations achievable when applied topically against some adenovirus types causing keratoconjunctivitis, raising its potential role as a topical agent in this setting. For conjunctival disease, topical cidofovir has been shown to be effective in the eradication of actively replicating viruses and limiting the duration of symptoms. However, further study is needed to determine the long-term adverse effects of both topical ganciclovir and topical cidofovir.

Transplant patients with severe hypogammaglobulinemia at the time of active adenovirus infection might benefit from immune globulin administration. Adoptive transfer of adenovirus-specific T-lymphocytes is under investigation for the treatment of severe adenovirus diseases in hematopoietic cell transplant recipients, but there are limited data in solid organ transplant recipients and other populations.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions for young children with respiratory tract infections, contact and droplet precautions are indicated for the duration of hospitalization. In immunocompromised patients, contact and droplet precautions should be extended because of the likelihood of prolonged shedding of the virus. For patients with conjunctivitis and for diapered and incontinent children with adenoviral gastroenteritis, contact precautions are indicated for the duration of illness.

CONTROL MEASURES: Appropriate hand hygiene, respiratory hygiene, and cough etiquette should be followed. However, adenoviruses are difficult to inactivate with

alcohol-based gels, and they may remain viable on skin, fomites, and environmental surfaces for extended periods. Thus, assiduous adherence to hand hygiene and use of disposable gloves when caring for infected patients are recommended.

Children who are in group child care, particularly children from 6 months through 2 years of age, are at increased risk of adenoviral respiratory tract infections and gastroenteritis. Effective measures for preventing spread of adenovirus infection in group child care settings have not been determined, but frequent hand hygiene is recommended. If 2 or more children in a group child care setting develop conjunctivitis in the same period of time, advice should be sought from the health consultant of the program or the state health department.

Adequate chlorination of swimming pools is recommended to prevent pharyngoconjunctival fever. Epidemic keratoconjunctivitis associated with ophthalmologic practice can be difficult to control and requires use of single-dose medication dispensing and strict attention to hand hygiene and instrument sterilization procedures. Health care professionals with known or suspected adenoviral conjunctivitis should avoid direct patient contact until symptoms have resolved.

A live, nonattenuated, oral adenovirus vaccine for types 4 and 7 (2 oral tablets, 1 for each of the 2 strains) is licensed by the US Food and Drug Administration for prevention of febrile acute respiratory tract disease among persons 17 through 50 years of age. The vaccine is currently only approved for use in the US military.

Amebiasis

CLINICAL MANIFESTATIONS: Most individuals infected with *Entamoeba histolytica* have asymptomatic noninvasive intestinal tract carriage. When present, symptoms associated with *E histolytica* infection generally include cramps, watery or bloody diarrhea, and weight loss. Occasionally, the parasite may spread to other organs, most commonly the liver (liver abscess), in which case fever and right upper quadrant pain are common. Disease is more severe in the very young, the elderly, malnourished people, pregnant individuals, and people who receive corticosteroids. People with symptomatic intestinal amebiasis generally have gradual onset of symptoms over 1 to 3 weeks. The mildest form of intestinal tract disease is nondysenteric colitis. Amebic dysentery is the most common clinical manifestation of amebiasis and generally includes diarrhea with either gross or microscopic blood or mucous in the stool, lower abdominal pain, and tenesmus. Weight loss is common because of the gradual onset, but fever occurs only in a minority of patients (8%–38%). Symptoms may be chronic, with periods of diarrhea and intestinal spasms alternating with periods of constipation. The presentation may mimic that of inflammatory bowel disease. Progressive involvement of the colon may produce toxic megacolon, fulminant colitis, ulceration of the colon and perianal area, and rarely, perforation. Colonic perforation may occur at multiple sites and has a high fatality rate. Progression may occur in patients treated inappropriately with corticosteroids or ant motility drugs. An amebic granuloma (ameboma) may form as an annular lesion of the colon and may present as a palpable mass on physical examination. Amebomas can occur in any area of the colon but are most common in the cecum and may be mistaken for colonic carcinoma. Amebomas usually resolve with antiamebic therapy and do not require surgery.

Extraintestinal disease occurs in a small proportion of patients. The liver is the most common extraintestinal site, and infection may spread from there to the pleural space, lungs, and pericardium. Liver abscess may be acute, with fever, abdominal pain, tachypnea, liver tenderness, and hepatomegaly, or may be chronic, with weight loss and vague abdominal symptoms. Liver abscess can also be asymptomatic and only discovered on abdominal imaging performed for other reasons. Rupture of abscesses into the abdomen or chest may lead to death. Infection also may spread directly from the colon to the genitourinary tract and the skin. The organism may spread hematogenously to the brain and other areas of the body. Evidence of recent or concurrent intestinal tract infection usually is absent in extraintestinal disease.

ETIOLOGY: The genus *Entamoeba* includes 6 species that live in the human intestine. Four of these species are identical morphologically: *E histolytica*, *Entamoeba dispar*, *Entamoeba moshkovskii*, and *Entamoeba bangladeshi*. *Dientamoeba fragilis* also can lead to asymptomatic infection and intraluminal intestinal disease. Not all *Entamoeba* species are virulent. *E dispar* and *Entamoeba coli* generally are recognized as commensals. Although *E moshkovskii* generally was believed to be nonpathogenic, it may be associated with diarrhea in infants. The pathogenic potential of *E bangladeshi* is not clear. *Entamoeba* and *Dientamoeba* organisms are excreted as cysts or trophozoites in stool of infected people.

EPIDEMIOLOGY: *E histolytica* can be found worldwide but is more prevalent in people of lower socioeconomic status who live in resource-limited countries, where prevalence of amebic infection may be as high as 50% in some communities. Groups at increased risk of infection in industrialized countries include immigrants from or long-term visitors to areas with endemic infection, institutionalized people, and men who have sex with men. Intestinal and asymptomatic infection are distributed equally across the sexes, but incidence of invasive disease, especially liver abscess, is significantly higher in male adults, possibly because of a male susceptibility to invasive disease.

E histolytica is transmitted via ingestion of infective amebic cysts, through fecally contaminated food or water, or oral-anal sexual practices. Transmission also can occur via direct rectal inoculation through colonic irrigation devices. Ingested cysts, which are unaffected by gastric acid, undergo excystation in the alkaline small intestine and produce trophozoites that can cause invasive disease in the colon. Cysts that develop subsequently are the source of transmission, especially from asymptomatic cyst excretors. Infected patients excrete cysts intermittently, sometimes for years if untreated. Cysts can remain viable in the environment for weeks to months and are relatively resistant to chlorine. Ingestion of a single cyst is sufficient to cause disease.

The **incubation period** is variable, ranging from a few days to months or years, but commonly is 2 to 4 weeks for colitis and longer for amebic liver abscess.

DIAGNOSTIC TESTS: Intestinal amebiasis can be diagnosed by molecular tests, direct microscopy, and antigen detection tests. Stool nucleic acid amplification tests (NAATs) have the highest sensitivity and specificity, are available in US Food and Drug Administration (FDA)-approved multiplex assays, and can differentiate *E histolytica* from other *Entamoeba* species. Traditionally, diagnosis of intestinal tract infection was made by identifying trophozoites or cysts in stool specimens, either on wet mount or after fixing and staining. This technique is still used in some laboratories, but it is labor intensive, its sensitivity is lower than for NAATs, and it requires review of multiple

stool samples. Microscopy also does not differentiate between *E histolytica* and less pathogenic species, although trophozoites containing ingested red blood cells are more likely to be *E histolytica*. Antigen test kits are available in some clinical laboratories for testing of *E histolytica* directly from stool specimens. Examination of biopsy specimens, endoscopy scrapings (not swabs), and abscess aspirates using microscopy or antigen detection typically is not fruitful; a NAAT is preferred, when available but is only FDA approved for stool specimens. Some monoclonal antibody-based antigen detection assays also can differentiate *E histolytica* from other *Entamoeba* species. *D fragilis* is diagnosed by microscopy.

The indirect hemagglutination (IHA) test has been replaced by commercially available enzyme immunoassay (EIA) kits for routine serodiagnosis of amebiasis, especially in countries without endemic disease. The EIA detects antibody specific for *E histolytica* in $\geq 95\%$ of patients with extraintestinal amebiasis, 70% of patients with active intestinal tract infection, and 10% of asymptomatic people who are passing cysts of *E histolytica*. Patients may continue to have positive serologic test results even after adequate therapy. In countries without endemic disease, diagnosis of an *E histolytica* liver abscess or other extraintestinal infections typically is made by a combination of serologic testing and radiologic evaluation, because stool testing by microscopy or NAAT is often negative.

Ultrasonography, computed tomography, and magnetic resonance imaging can identify liver abscesses presumptively; those caused by *E histolytica* typically are solitary, homogenous, and hypoechoic on ultrasonography. Imaging also can identify other extraintestinal sites of infection.

TREATMENT: Treatment should be provided to all patients with *E histolytica*, including those who are asymptomatic, given the propensity of this organism to spread among family members and other contacts and to cause invasive infection. In settings where tests to distinguish species are not available, treatment should be administered to symptomatic people based on positive results of microscopic examination. Corticosteroids and antimotility drugs should not be used, because they can worsen symptoms and aggravate the disease process. The following treatment regimens and follow-up are recommended:

- **Asymptomatic cyst excretors (intraluminal infections):** treat with an intraluminal amebicide alone (paromomycin, iodoquinol [also known as diiodohydroxyquinoline], or diloxanide furoate). (See Table 4.11, Drugs for Parasitic Infections, p 1068). Metronidazole and tinidazole are not effective against cysts and these agents are not necessary for asymptomatic excretors.
- **Patients with invasive colitis manifesting as mild, moderate, or severe intestinal tract symptoms or extraintestinal disease (including liver abscess):** treat with a tissue agent, metronidazole or tinidazole (See Table 4.11, Drugs for Parasitic Infections, p 1068), followed by an intraluminal amebicide at the same doses as for asymptomatic infection. Nitazoxanide or secnidazole also may be effective as tissue agents for mild to moderate intestinal amebiasis, although they are not approved by the FDA for this indication.
- **Additional considerations in patients with hepatic abscess, pleural or pericardial abscess, or other severe complications:** In most cases of liver abscess, drainage is not required and does not speed recovery. Percutaneous or surgical aspiration of large liver abscesses occasionally may be required when response of

the abscess to medical therapy is unsatisfactory or there is risk of rupture. Although patients typically improve symptomatically within days, it may take months for a liver abscess to resolve on ultrasonography. Rupture into the peritoneal or pleural space usually requires drainage. For patients who have peritonitis attributable to intestinal perforation, broad-spectrum antibacterial therapy should be used in addition to an amebicide. In cases with toxic megacolon, colectomy may be necessary.

Follow-up stool examination is recommended after completion of therapy for intestinal disease, because no pharmacologic regimen is completely effective in eradicating intestinal tract infection. Household members and other suspected contacts should have stool examinations performed and should be treated if results are positive for *E histolytica*.

E dispar and *Entamoeba coli* generally are considered nonpathogenic and do not necessarily require treatment. The pathogenic significance of *E moshkovskii* and *E bangladeshi* is unclear; treatment of symptomatic infection is reasonable. *D fragilis* is treated with iodoquinol, paromomycin, or metronidazole.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are considered adequate for hospitalized patients; health care-associated transmission is rare.

CONTROL MEASURES: Careful hand hygiene after defecation, sanitary disposal of fecal material, and treatment of drinking water will control spread of infection. Sexual transmission may be controlled by use of condoms and avoidance of sexual activity with those who have diarrhea or recently recovered from diarrhea. Because of the risk of shedding infectious cysts, people diagnosed with amebiasis should refrain from using recreational water venues (eg, swimming pools, water parks) until after their course of luminal chemotherapy is completed and diarrhea has resolved. Some states prohibit return to work or school for food handlers or children until symptoms have resolved.

Amebic Meningoencephalitis and Keratitis

(*Naegleria fowleri*, *Acanthamoeba* species, and *Balamuthia mandrillaris*)

CLINICAL MANIFESTATIONS: *Naegleria fowleri* can cause a rapidly progressive, almost always fatal, primary amebic meningoencephalitis (PAM). Early symptoms include fever, headache, nausea, and vomiting. The illness progresses rapidly to signs of meningoencephalitis, including nuchal rigidity, lethargy, confusion, personality changes, altered level of consciousness, and rarely, disturbances of smell and taste. Seizures are common, and death generally occurs within a week of onset of symptoms. No distinct clinical features differentiate this disease from fulminant bacterial meningitis other than history of freshwater exposure.

Granulomatous amebic encephalitis (GAE) caused by *Acanthamoeba* species and *Balamuthia mandrillaris* has a more insidious onset than PAM and develops as a subacute or chronic disease. In general, patients with GAE die several weeks to months after onset of symptoms. Signs and symptoms may include altered mental status, personality changes, seizures, headaches, ataxia, cranial nerve palsies, hemiparesis, and other focal neurologic deficits. Fever often is low grade and intermittent. The course may resemble that of a bacterial brain abscess or a brain tumor. Chronic granulomatous skin lesions (pustules, nodules, ulcers) may be present with or without central nervous system (CNS) involvement, particularly in patients who are immunocompromised. Lesions

may be present for months before brain involvement in some cases. *Acanthamoeba* also can cause rhinosinusitis, which can present alone or with skin or CNS involvement.

The most common symptoms of amebic keratitis, a vision-threatening infection usually caused by *Acanthamoeba* species, are eye pain (often out of proportion to clinical signs), photophobia, tearing, and foreign body sensation. Characteristic clinical findings include radial keratoneuritis and stromal ring infiltrate. *Acanthamoeba* keratitis generally follows an indolent course and initially may resemble herpes simplex or bacterial keratitis; delay in diagnosis is associated with worse outcome.

ETIOLOGY: *N. fowleri*, *Acanthamoeba* species, and *B. mandrillaris* are free-living amebae that exist as motile, infectious trophozoites and environmentally hardy cysts.

EPIDEMIOLOGY: *N. fowleri* is found in warm fresh water and moist soil. Most infections with *N. fowleri* have been associated with swimming in natural bodies of warm fresh water, such as ponds, lakes, and hot springs, but other sources have included tap water from household plumbing systems and geothermal sources as well as poorly chlorinated swimming pools, splash pads, and municipal water. Disease has been reported worldwide but is uncommon. In the United States, infection occurs primarily in the summer and usually affects children and young adults. The recent northward extension of reported cases may be the result of climatic changes. Disease has followed use of tap water for ritual or therapeutic nasal irrigation or exposures related to recreational activities (eg, tap water used for a backyard waterslide). Trophozoites of the amebae invade the brain directly from the nose along the olfactory nerves via the cribriform plate.

Acanthamoeba species are distributed worldwide and have been found in soil; dust; cooling towers of electric and nuclear power plants; heating, ventilating, and air conditioning units; fresh and brackish water; whirlpool baths; and physiotherapy pools. The environmental niche of *B. mandrillaris* is not delineated clearly, although it has been isolated from soil. CNS infection attributable to *Acanthamoeba* species occurs primarily in debilitated and immunocompromised people. Some patients, and nearly all reported children infected with *B. mandrillaris*, have had no demonstrable underlying disease or defect. CNS infection by both amebae probably occurs most commonly by inhalation or direct contact with contaminated soil or water. The primary foci of these infections most likely are respiratory tract or skin, followed by hematogenous spread to the brain. *Acanthamoeba* rhinosinusitis and GAE have been associated with nasal rinsing with tap water. Fatal encephalitis caused by *Balamuthia* species transmitted by a donated organ has been reported.

Acanthamoeba keratitis occurs primarily in people who wear contact lenses,¹ although it also has been associated with corneal trauma. Poor contact lens hygiene and/or disinfection practices as well as swimming with contact lenses are risk factors.

The **incubation period** for *N. fowleri* infection ranges from 1 to 9 days.

The **incubation periods** for *Acanthamoeba* and *Balamuthia* GAE are unknown. It is believed to take several weeks or months to develop the first symptoms of CNS disease following exposure to the amebae. Patients exposed to *Balamuthia* through solid organ transplantation can develop symptoms of *Balamuthia* GAE more quickly—within a few weeks.

The **incubation period** for *Acanthamoeba* keratitis is unknown but believed to range from several days to several weeks.

¹ Centers for Disease Control and Prevention. Contact lens–related corneal infections—United States, 2005–2015. *MMWR Morb Mortal Wkly Rep*. 2016;65(32):817–820

DIAGNOSTIC TESTS: In *N. fowleri* infection, computed tomography scans of the head without contrast are unremarkable or show only cerebral edema but with contrast might show meningeal enhancement of the basilar cisterns and sulci. These changes, however, are not specific for amebic infection. Cerebrospinal fluid (CSF) pressure usually is elevated (300 to >600 mm water), and CSF indices may show a polymorphonuclear pleocytosis, red blood cells, an increased protein concentration, and a normal to very low glucose concentration. Motile trophozoites may be visualized by microscopic examination of CSF on a wet mount. If structures resembling trophozoites are seen but no motility is observed, smears of CSF should be stained with Giemsa, trichrome, or Wright stains to verify the trophozoites. Gram staining is unhelpful in *N. fowleri* CNS infection, because heat fixation may destroy amebae. Trophozoites, but not cysts, can be visualized in sections of brain during autopsy. Microscopic images containing suspicious amebic structures can be evaluated by the morphology experts at the Centers for Disease Control and Prevention (CDC)'s DPDx (Laboratory Identification of Parasites of Public Health Concern; www.cdc.gov/dpdx/index.html). Nucleic acid amplification tests (NAATs) and immunofluorescence assays performed on CSF and biopsy material to identify the organism are available through the CDC, as are consultation services for diagnosis and management (email: parasites@cdc.gov; telephone: 404-718-4745; after hours: 770-488-7100).

In infection with *Acanthamoeba* species and *B. mandrillaris*, computed tomography and magnetic resonance imaging of the head may show single or multiple space-occupying, ring-enhancing lesions that can mimic brain abscesses, neurocysticercosis, tumors, cerebrovascular accidents, or other diseases. In GAE infections, CSF indices often are nonspecific but may include a lymphocytic pleocytosis and an increased protein concentration with normal or low glucose. Trophozoites are seen rarely in CSF and can be identified with Giemsa stain. Trophozoites and cysts can be visualized in sections of brain, skin, and other organs; in cases of *Acanthamoeba* keratitis, they also can be visualized in corneal scrapings and by confocal microscopy in vivo in the cornea on examination by an expert ophthalmologist. NAATs and immunofluorescence assays can be performed on clinical specimens to identify *Acanthamoeba* species and *Balamuthia* species; these tests are available through the CDC, as are consultation services for diagnosis and management (email: parasites@cdc.gov; telephone: 404-718-4745; after hours: 770-488-7100).

TREATMENT: The most current guidance for treatment of PAM can be found on the CDC website (www.cdc.gov/parasites/naegleria/treatment-hcp.html) or by contacting the CDC (email: parasites@cdc.gov; telephone: 404-718-4745; after hours: 770-488-7100). Early diagnosis and institution of combination high-dose drug therapy is believed to be important for optimizing outcome. If meningoencephalitis possibly caused by *N. fowleri* is suspected, treatment should not be withheld pending confirmation. Presence of amebic organisms in CSF is valuable for probable diagnosis, but confirmatory diagnostic tests should be performed. Although an effective treatment regimen for PAM has not been identified, amphotericin B deoxycholate is the drug of choice in combination with other agents. In vitro testing indicates that *N. fowleri* is highly susceptible to amphotericin B. Miltefosine, which is approved for treatment of leishmaniasis, has been used successfully to treat PAM caused by *N. fowleri*. The CDC no longer provides miltefosine for treatment of free-living ameba infections; miltefosine is available commercially in the United States (impavido.com). There

have been 4 US survivors of PAM, and on the basis of most recent cases, treatment with the combination of amphotericin B, azithromycin, fluconazole, miltefosine, and rifampin is recommended. These patients also received dexamethasone to control cerebral edema.

Effective treatment for infections caused by *Acanthamoeba* species and *B. mandrillaris* has not been established. Several patients with *Acanthamoeba* GAE and *Acanthamoeba* cutaneous infections without CNS involvement have been treated successfully with a multidrug regimen consisting of fluconazole or ketoconazole, trimethoprim-sulfamethoxazole, and rifampin. Metronidazole may be added to this combination. Miltefosine has in vitro activity against *Acanthamoeba* infections and also may be considered as part of combination drug therapy for *Acanthamoeba* GAE. Other drugs that have been used include various combinations of pentamidine, sulfadiazine, and flucytosine, often with one or more of the above drugs. Caspofungin has in vitro activity against *Acanthamoeba* species, but clinical data are limited for its use in this infection. Isolated *Acanthamoeba* skin lesions can be treated with topical application of ketoconazole and/or chlorhexidine gluconate, but skin lesions often represent disseminated disease, particularly in immunocompromised patients, which requires systemic therapy. For patients with *B. mandrillaris* encephalitis, successful treatment typically has required multiple drugs in combination—for example, pentamidine, sulfadiazine, fluconazole, either azithromycin or clarithromycin, and flucytosine. Surgical resection of the CNS lesions, accompanied by antimicrobial therapy, also has been reported to be successful. Miltefosine has amebicidal activity against *B. mandrillaris* in vitro.

Patients with *Acanthamoeba* keratitis should be evaluated and treated by an ophthalmologist. Early diagnosis and therapy are important for a good outcome.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: People should assume that there is always a slight risk of developing PAM caused by *N. fowleri* when entering warm fresh water. Only avoidance of such water-related activities can prevent *Naegleria* infection, although the risk might be reduced by taking measures to limit water exposure through known routes of entry, such as getting water up the nose (eg, diving, swimming underwater, doing handstands in water). Using tap water for sinus rinses generally is discouraged, but when used should be either previously boiled or properly filtered or labeled as sterile or distilled (additional information available at www.cdc.gov/naegleria).

Presently, no clearly defined recommendations are available to prevent GAE attributable to *Acanthamoeba* species or *B. mandrillaris*; avoiding nasal rinsing with tap water is recommended.

To prevent *Acanthamoeba* keratitis, steps should be taken to avoid corneal trauma, such as the use of protective eyewear during high-risk activities, and contact lens users should maintain good contact lens hygiene and disinfection practices, use only sterile solutions as applicable, change lens cases frequently, and avoid swimming and showering while wearing contact lenses. Advice for people who wear contact lenses can be found on the CDC website (www.cdc.gov/contactlenses).¹

¹ Centers for Disease Control and Prevention. Estimated burden of keratitis—United States, 2010. *MMWR Morb Mortal Wkly Rep*. 2014;63(45):1027-1030

Anthrax¹

CLINICAL MANIFESTATIONS: Anthrax resulting from wild-type infection or secondary to a bioterror event can occur in multiple forms, depending on the route of infection: cutaneous, inhalation, ingestion, or injection.

Manifestations of anthrax are mainly from the 2 primary toxins, lethal toxin and edema toxin. **Cutaneous** anthrax accounts for 95% of all human infections and begins as a pruritic papule or vesicle that progresses over 2 to 6 days to an ulcerated lesion with subsequent formation of a central black eschar. The lesion characteristically is painless and has surrounding edema and hyperemia; there can be associated regional lymphadenopathy and lymphangitis. Some patients may have fever, malaise, and headache. Up to 30% of adults with cutaneous anthrax will progress to invasive, systemic disease.

Inhalation anthrax is a frequently lethal form of the disease and is a medical emergency. The initial presentation is nonspecific and usually includes fever, malaise, and nonproductive cough. Many patients also complain of chest pain, headache, nausea, vomiting, and abdominal pain; sweating may be profuse. Illness usually progresses to the fulminant phase within 2 to 5 days. Illness has been noted to sometimes be biphasic, with a period of improvement between prodromal symptoms and overwhelming illness. Significant vital sign abnormalities are often present early, and fulminant manifestations include hypotension, dyspnea, hypoxia, cyanosis, and shock. Most patients with inhalation anthrax fulfill sepsis criteria, and up to half develop meningitis. Imaging abnormalities noted at presentation include pleural effusions in most, widened mediastinum in up to half, and pulmonary infiltrates in many.

Ingestion anthrax usually presents as one of 2 clinical syndromes: gastrointestinal or oropharyngeal. Patients with the gastrointestinal form often have nausea, anorexia, vomiting, and fever that progresses to severe abdominal pain, often accompanied by marked ascites. Vomiting and diarrhea, which are not always present, may be bloody. Although gastrointestinal tract involvement at multiple sites may occur following hematogenous spread, the cecum and terminal ileum often are involved when the disease is primary. Patients with oropharyngeal anthrax may have dysphagia accompanied by posterior oropharyngeal necrotic ulcers. There may be marked, often unilateral neck swelling, regional lymphadenopathy, fever, and sepsis. Evidence of coagulopathy is common.

Injection anthrax occurs primarily among adult injection drug users, associated with anthrax-contaminated heroin, and has not been reported in children. Smoking and snorting contaminated heroin also have been identified as exposure routes.

Any route of infection can lead to bacteremia and sepsis. Patients with inhalation, ingestion, or injection anthrax should be considered to have systemic illness. Patients with cutaneous anthrax should be considered to have systemic illness if they develop tachycardia, tachypnea, hypotension, hyperthermia, hypothermia, or leukocytosis or have lesions that involve the head, neck, or upper torso or that are large, bullous, multiple, or surrounded by edema. Anthrax meningitis or hemorrhagic meningoencephalitis can occur in any patient with systemic illness and in patients without another apparent route of infection. With appropriate treatment and supportive care, case fatality rates range from <2% for cutaneous anthrax to 45% for inhalation anthrax and 92% for anthrax meningitis.

¹ www.cdc.gov/anthrax/index.html

ETIOLOGY: *Bacillus anthracis* is an aerobic, gram-positive, encapsulated, spore-forming, nonhemolytic, nonmotile rod. *B anthracis* has 3 major virulence factors: an antiphagocytic capsule and 2 exotoxins, called lethal toxin and edema toxin. The toxins are responsible for most of the morbidity associated with anthrax and clinical manifestations of hemorrhage, edema, and necrosis.

EPIDEMIOLOGY: Anthrax is a zoonotic disease that most commonly affects domestic and wild herbivores and occurs in many rural regions of the world. *B anthracis* spores can remain viable in the soil for decades, representing a potential source of infection for livestock or wildlife through ingestion of spore-contaminated vegetation or water. In exposed susceptible hosts, spores germinate to become vegetative bacteria. Wild-type infection of humans occurs through contact with infected animals or contaminated animal products, including carcasses, hides, hair, wool, meat, and bone meal. Outbreaks of ingestion anthrax have occurred after consumption of meat from infected animals. Historically, more than 95% of anthrax cases in the United States were cutaneous infections among animal handlers or mill workers. The incidence of wild-type human anthrax decreased in the United States from an estimated 130 cases annually in the early 1900s to 0 to 2 cases per year from 1979 through 2011. Only 2 anthrax cases (both cutaneous) were confirmed in the United States from 2012–2021. Cases of inhalation, cutaneous, and ingestion (gastrointestinal) anthrax have occurred in drum makers working with animal hides contaminated with *B anthracis* spores and in people participating in events where spore-contaminated drums were played. Severe soft tissue infections among injection heroin users, including cases with disseminated systemic infection, have been reported in Europe.

B anthracis is one of the agents most likely to be used as a biological weapon, because (1) its spores are highly stable; (2) spores can infect via the respiratory route; and (3) the resulting disease, inhalation anthrax, has a high fatality rate, even with appropriate treatment. In 1979, an accidental release of *B anthracis* spores from a military microbiology facility in the former Soviet Union resulted in at least 68 deaths. In 2001, 22 cases of anthrax (11 inhalation, 11 cutaneous) were identified in the United States after intentional contamination of the mail; 5 (45%) of the inhalation anthrax cases were fatal. In addition to aerosolization, *B anthracis* spores introduced into food products or water supplies could theoretically pose a risk to the public's health. Use of *B anthracis* in a biological attack would require immediate response and mobilization of public health resources ([www.cdc.gov/anthrax/bioterrorism/index.html](http://www.cdc.gov anthrax/bioterrorism/index.html)).¹

Although the **incubation periods** for both cutaneous and ingestion anthrax are typically less than 1 week, rare cases for both have been reported more than 2 weeks after exposure. Because of spore dormancy (persistence of viable spores that have not yet germinated) and slow clearance of spores from the lungs, the **incubation period** for inhalation anthrax may be prolonged and has been reported to range from 2 days to 6 weeks in humans and up to 2 months in experimental nonhuman primates. Discharge from cutaneous lesions is potentially infectious, but person-to-person transmission has only rarely been reported, and other forms of anthrax have not been associated with person-to-person transmission. Both inhalation and cutaneous anthrax have occurred in laboratory workers.

¹ Centers for Disease Control and Prevention. Clinical framework and medical countermeasure use during an anthrax mass-casualty incident: CDC recommendations. *MMWR Recomm Rep*. 2015;64(RR-4):1-22

DIAGNOSTIC TESTS: *B anthracis* is readily isolated on routine agar media (eg, sheep's blood agar) used in clinical laboratories and can be presumptively identified through traditional microbiological methods. Depending on the clinical presentation, Gram stain and culture should be performed on blood, pleural fluid, cerebrospinal fluid (CSF), swabs from lesions, and other clinical specimens. Whenever possible, specimens for these tests should be obtained before initiating antimicrobial therapy, because previous treatment with antimicrobial agents lessens the sensitivity of isolation by culture and visualization of the organism by Gram stain.

B anthracis isolates can be definitively identified using tests such as a nucleic acid amplification test (NAAT) via the Laboratory Response Network (LRN) in each state, accessed through state and local health departments. Additional diagnostic tests for anthrax are available through state health departments and the Centers for Disease Control and Prevention (CDC), including bacterial DNA detection in specimens by NAAT, tissue immunohistochemistry, an enzyme immunoassay that measures immunoglobulin G antibodies against *B anthracis* protective antigen in paired sera, and a matrix-assisted laser desorption/ionization–time-of-flight (MALDI-TOF) mass spectrometry assay measuring lethal factor activity in acute sera (www.cdc.gov/anthrax/lab-testing/index.html).

Clinical evaluation of patients with suspected inhalation anthrax should include a chest radiograph and/or computed tomography scan to evaluate for pleural effusion, widened mediastinum, and/or pulmonary infiltrates. Because hemorrhagic meningitis is a common complication of systemic anthrax, cranial imaging followed by lumbar punctures should be performed whenever feasible to guide therapy on systemically ill patients with any type of anthrax.

For mass-exposure bioterrorism events, the CDC will provide current information on diagnosis, susceptibility, and suggestions for management at www.cdc.gov/anthrax/bioterrorism/index.html.

TREATMENT^{1,2}: No controlled trials in humans have been performed to validate current treatment recommendations for anthrax. A high index of suspicion and rapid administration of appropriate antibiotic therapy to people suspected of being infected, along with access to critical care support, are essential for effective treatment of anthrax. Consultation with an expert in infectious diseases is recommended.

For localized cutaneous anthrax (ie, lacking systemic systems), monotherapy may be used with oral first-line agents including ciprofloxacin, levofloxacin, doxycycline, or minocycline. If the isolate is known to be penicillin susceptible, amoxicillin and penicillin VK are alternatives. If the strain is beta-lactamase positive, amoxicillin/clavulanate may be used. Details on dosing, alternative antibiotics, and use of antitoxins are available.¹ If the localized cutaneous disease was naturally acquired, the regimen should continue for 7 to 10 days or until the patient is clinically stable; following this, if an aerosol exposure might have occurred (eg, bioterrorism-related or drum-incident) then patients should transition to a postexposure prophylaxis (PEP)

¹ Bower WA, Yu Y, Person MK, et al. CDC guidelines for the prevention and treatment of anthrax, 2023. *MMWR Recomm Rep*. 2023;72(RR-6):1-47

² Bower WA, Schiffer J, Atmar RL, et al. Use of anthrax vaccine in the United States: recommendations of the Advisory Committee on Immunization Practices, 2019. *MMWR Recomm Rep*. 2019;68(4):1-14

regimen. The total duration of treatment plus PEP should be 42 to 60 days from illness onset, depending on the patient's age and anthrax vaccine status (see Control Measures).

First-line treatment for systemic anthrax with or without meningitis includes combination intravenous therapy with 2 first-line agents from different antibiotic classes plus a protein synthesis (preferred if available) or RNA synthesis inhibitor. Empiric regimens can include ciprofloxacin (or levofloxacin) plus meropenem plus either linezolid or minocycline; or ciprofloxacin (or levofloxacin) plus meropenem plus rifampin. If the isolate is known to be susceptible to penicillin, ampicillin or penicillin G may be used plus a protein synthesis inhibitor (eg, linezolid, minocycline, or doxycycline). These patients are at high risk for meningitis. However, if it has been determined that meningitis is not present, the regimen can be simplified to be a first-line agent (eg, meropenem or ciprofloxacin) plus a protein synthesis inhibitor (eg, linezolid or doxycycline). Additional details on regimens, including first-line antibiotics, alternative antibiotics, and recommendations in cases of antibiotic shortages, are available.¹ Because of intrinsic resistance, cephalosporins and trimethoprim-sulfamethoxazole should not be used.

An anthrax antitoxin should be added when available. There are 3 antitoxins approved by the US Food and Drug Administration (FDA): the monoclonal antibodies raxibacumab and obiltoxaximab, and polyclonal anthrax immune globulin intravenous (AIGIV).¹ When available, raxibacumab or obiltoxaximab is preferred over AIGIV. Consult with state or local public health authorities and the CDC to discuss antitoxin use and release from the strategic national stockpile.

Adjunctive corticosteroids should be considered for edema involving the head and neck, evidence of anthrax meningitis (started at the time of initial antibiotic therapy), and vasopressor-resistant shock.²

For patients with systemic disease, antibiotic therapy should continue for 14 days or longer. However, intravenous treatment may be transitioned to oral therapy on the basis of patient improvement and clinical judgment. Whether patients should receive PEP following treatment for systemic anthrax depends on whether there was an aerosol exposure and whether the patient is immunocompetent. PEP is not needed in patients with naturally acquired (not in a bioterror event) noninhalation anthrax. Following an aerosol exposure to *B anthracis* spores, immunocompetent patients will develop immunity, making PEP unnecessary. However, immunocompromised patients with aerosol exposures should transition to an oral PEP regimen and be vaccinated. The total duration of treatment plus PEP is 60 days from illness onset.

Anthrax can progress rapidly, making access to critical care essential for many patients. If pleural fluid or ascites is present, aggressive drainage may improve survival. The edema that may complicate cutaneous anthrax of the face or neck can obstruct the airway, and aggressive monitoring for airway compromise is indicated in these patients. Anthrax hemorrhagic meningoencephalitis management requires neurologic

¹ Bower WA, Yu Y, Person MK, et al. CDC guidelines for the prevention and treatment of anthrax, 2023. *MMWR Recomm Rep*. 2023;72(RR-6):1-47

² Hendricks KA, Wright ME, Shadomy SV, et al. Centers for Disease Control and Prevention expert panel meetings on prevention and treatment of anthrax in adults. *Emerg Infect Dis*. 2014;20(2).

critical care because of the profound brain injury, hemorrhage, and swelling documented in animal models and humans.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended. In addition, contact precautions should be implemented when draining cutaneous lesions are present. Cutaneous lesions become sterile within 24 hours of starting appropriate antimicrobial therapy. Patients with cutaneous illness pose minimal risk for transmission if the wound is kept covered during the first day of antimicrobial therapy. Contaminated dressings and bedclothes should be incinerated or steam sterilized (121°C for 30 minutes) to destroy spores. Terminal cleaning of the patient's room can be accomplished with an Environmental Protection Agency-registered hospital-grade disinfectant and should follow standard facility practices typically used for all patients. Autopsies performed on patients with systemic anthrax require special precautions.

CONTROL MEASURES¹: BioThrax (anthrax vaccine adsorbed [AVA]) and Cyfendus (AVA Adjuvanted) are the only anthrax vaccines currently licensed in the United States for use in humans. Both are non-live vaccines prepared from a cell-free culture filtrate. AVA's efficacy for prevention of anthrax is based on animal studies, a single placebo-controlled human trial of the alum-precipitated precursor of the current AVA, observational data from humans, and immunogenicity data from humans and other mammals. In a human trial in adult mill workers, the alum-precipitated precursor to AVA demonstrated 93% efficacy for preventing cutaneous and inhalation anthrax. AVA Adjuvanted was approved by the US Food and Drug Administration in July 2023 for postexposure prophylaxis. Multiple reviews and publications evaluating AVA safety have found adverse events usually are local injection site reactions, with rare systemic symptoms, including fever, chills, muscle aches, and hypersensitivity.

PEP for exposure to aerosolized *B anthracis* spores includes 2 components: antimicrobials and vaccine. Symptom monitoring and PEP are critical for preventing wild-type anthrax in people. Options for PEP antimicrobials include ciprofloxacin, levofloxacin, doxycycline, moxifloxacin, clindamycin, and for penicillin-susceptible strains, amoxicillin or penicillin. In the event of a bioterrorism event, information for health care professionals and the public relevant to that exposure will be posted on the CDC anthrax website (www.cdc.gov/anthrax/index.html).

PEP for previously unvaccinated people 18 years or older who have been exposed to aerosolized *B anthracis* spores consists of up to 60 days of appropriate antimicrobial prophylaxis combined with 3 subcutaneous doses of anthrax vaccine. The anthrax vaccines are not licensed for use in pregnant people; however, in a postevent setting that poses a high risk of exposure to aerosolized *B anthracis* spores, pregnancy is neither a precaution nor a contraindication to their use as PEP vaccination. Similarly, they are not licensed for use in pediatric populations and have not been studied prospectively in children. However, anthrax vaccine is likely to be made available for children at the time of an event as an investigational vaccine under an appropriate regulatory mechanism that will include informed consent. Information on the process required for use of anthrax vaccines in children will be available on the CDC website at the time of

¹ Bower WA, Schiffer J, Atmar RL, et al. Use of anthrax vaccine in the United States: recommendations of the Advisory Committee on Immunization Practices, 2019. *MMWR Recomm Rep*. 2019;68(4):1-14

an event (www.cdc.gov anthrax/index.html) as well as through the American Academy of Pediatrics (AAP) and the FDA. All exposed children 6 weeks and older should receive anthrax vaccine postexposure in addition to 60 days of antimicrobial chemoprophylaxis. Children younger than 6 weeks of age should immediately begin antimicrobial prophylaxis, but initiation of the vaccine series should be delayed until they reach 6 weeks of age.

Until information becomes available about antimicrobial susceptibility of the implicated strain of *B anthracis*, oral ciprofloxacin, doxycycline, and levofloxacin are equivalent first-line antimicrobial agents for initial PEP for all people ≥ 1 month of age.¹ If the antimicrobial susceptibility profile of isolated strains demonstrates appropriate sensitivity to amoxicillin, public health authorities may recommend changing PEP antimicrobial therapy for children either to oral amoxicillin at 75 mg/kg per day, divided into 3 daily doses administered every 8 hours (each dose not to exceed 500 mg), or to penicillin VK at 50–75 mg/kg/day divided into 4 doses (each dose not to exceed 500 mg). Additional agents and dosing are available.¹ Because of intrinsic resistance, cephalosporins and trimethoprim-sulfamethoxazole should not be used for prophylaxis.

Public Health Reporting. Anthrax is a nationally and immediately notifiable condition, as specified by the US Council of State and Territorial Epidemiologists; therefore, every suspected case should be reported **immediately** to the state or local health department.

Arboviruses (also see Chikungunya, p 295, Dengue, p 352, West Nile Virus, p 957, and Zika, p 963)

(Including Cache Valley, Colorado Tick Fever, Eastern Equine Encephalitis, Heartland, Jamestown Canyon, Japanese Encephalitis, La Crosse, Powassan, St. Louis Encephalitis, Tick-borne Encephalitis, and Yellow Fever Viruses)

CLINICAL MANIFESTATIONS: Most infections with arthropod-borne viruses (arboviruses) are subclinical. Symptomatic illness usually manifests as 1 of 3 primary clinical syndromes: generalized febrile illness, neuroinvasive disease, or hemorrhagic fever (Table 3.1).

- **Generalized febrile illness.** Most arboviruses are capable of causing a nonspecific febrile illness that often includes headache, arthralgia, myalgia, and rash. Some arboviruses can cause more characteristic clinical manifestations, such as neuroinvasive disease (see West Nile Virus, p 957), severe polyarthralgia (see Chikungunya, p 295), thrombocytopenia and leukopenia (eg, Heartland virus), or jaundice (eg, yellow fever virus). With some arboviruses, fatigue, malaise, and weakness can linger for weeks following the initial infection.
- **Neuroinvasive disease.** Many arboviruses cause neuroinvasive disease, including aseptic meningitis, encephalitis, or myelitis. Less common neurologic manifestations (eg, Guillain-Barré syndrome) also can occur. Neurologic symptoms may be preceded by a prodrome similar to the generalized febrile illness, or neurologic findings may be the initial indication of infection. Specific symptoms vary by virus but can

¹ Bower WA, Yu Y, Person MK, et al. CDC guidelines for the prevention and treatment of anthrax, 2023. *MMWR Recomm Rep.* 2023;72(RR-6):1-47

Table 3.1. Clinical Manifestations for Selected Domestic and International Arboviral Diseases

Virus	Generalized Febrile Illness	Neuroinvasive Disease ^a	Hemorrhagic Fever
Domestic			
Cache Valley	Yes	Yes	No
Colorado tick fever	Yes	Rare	No
Eastern equine encephalitis	Yes	Yes	No
Heartland ^b	Yes	No	No
Jamestown Canyon	Yes	Yes	No
La Crosse	Yes	Yes	No

^aMeningitis, encephalitis, or myelitis.

^bAs of 2021, no pediatric infections documented; however, testing of children has been limited.

^cEndemic with periodic outbreaks in US territories (Puerto Rico, US Virgin Islands, American Samoa); local mosquito-borne transmission of chikungunya, dengue, and Zika viruses previously identified in Florida and Texas; local transmission of dengue virus also previously identified in Hawaii.

include vomiting, stiff neck, mental status changes, seizures, or focal neurologic deficits. Some viruses (eg, West Nile and Japanese encephalitis viruses) can cause a syndrome of acute flaccid paralysis, either in conjunction with meningoencephalitis or as an isolated finding. Severity and long-term outcome of the illness vary by etiologic agent and the underlying characteristics of the host, such as age, immune status, and preexisting medical conditions.

- **Hemorrhagic fever.** Hemorrhagic fever can be caused by some arboviruses, such as dengue (see Dengue, p 352) and yellow fever viruses. After several days of nonspecific febrile illness, the patient may develop overt signs of hemorrhage (eg, petechiae, ecchymoses, bleeding from the nose and gums, hematemesis, melena) and shock (eg, decreased peripheral circulation, azotemia, tachycardia, hypotension). Hemorrhagic fever and shock caused by yellow fever virus has a high mortality rate and may be confused with other viral hemorrhagic fevers that can occur in

the same geographic areas (eg, Argentine hemorrhagic fever, Bolivian hemorrhagic fever, Ebola, Lassa fever, or Marburg). Although dengue may be associated with severe hemorrhage, the shock is attributable primarily to a capillary leak syndrome, which, if properly treated with fluids, has a good prognosis. For information on other potential infections causing hemorrhagic manifestations, see Dengue (p 352), Hemorrhagic Fevers Caused by Arenaviruses (p 417), Hemorrhagic Fevers Caused by Bunyaviruses (p 420), and Hemorrhagic Fevers Caused by Filoviruses: Ebola and Marburg (p 423).

ETIOLOGY: Arboviruses are RNA viruses that are transmitted to humans primarily through bites of infected arthropods (mosquitoes, ticks, sand flies, and biting midges). More than 100 arboviruses are known to cause human disease. The viral families responsible for most arboviral infections in humans are *Flaviviridae* (genus *Flavivirus*), *Togaviridae* (genus *Alphavirus*), *Peribunyaviridae* (genus *Orthobunyavirus*), and *Phenuiviridae* (genera *Phlebovirus* and *Bandavirus*). *Reoviridae* (genus *Coltivirus*) also are responsible for a smaller number of human arboviral infections (eg, Colorado tick fever) (Table 3.2).

EPIDEMIOLOGY: Most arboviruses maintain enzootic cycles of transmission between birds or small mammals and arthropod vectors. Humans and domestic animals usually are infected incidentally as “dead-end” hosts. Important exceptions are chikungunya, dengue, yellow fever, and Zika viruses, which can be spread from person-to-arthropod-to-person (anthroponotic transmission). For other arboviruses, humans usually do not develop a sustained or high enough level of viremia to infect biting arthropod vectors. Direct person-to-person spread of some arboviruses has been documented to occur through blood transfusion, organ transplantation, sexual transmission, intrauterine transmission, perinatal transmission, and human milk (see Breastfeeding and Human Milk, p 135). Transmission through percutaneous, mucosal, or aerosol exposure to some arboviruses has occurred rarely in laboratory and occupational settings.

Arboviral infections occur in the United States primarily from late spring through early fall, when mosquitoes and ticks are most active. The number of domestic or imported arboviral disease cases reported in the United States varies greatly by specific etiology and year. Underdiagnosis of milder disease makes accurate determination of the number of cases difficult.

In general, the risk of developing severe clinical disease for most arboviral infections in the United States is higher among adults than among children. One notable exception is La Crosse virus infection, for which children are at highest risk of severe neurologic disease and possible long-term sequelae. Eastern equine encephalitis virus causes a low incidence of disease but has a high case fatality rate (30%–40%) across all age groups.

The **incubation periods** for arboviral diseases typically range between 2 and 15 days. Longer incubation periods can occur in immunocompromised people and with tick-borne viruses, such as Colorado tick fever, Powassan, and tick-borne encephalitis viruses.

DIAGNOSTIC TESTS: Arboviral infections are confirmed most frequently by detection of virus-specific antibody in serum or cerebrospinal fluid (CSF). Acute-phase serum specimens should be tested for virus-specific immunoglobulin (Ig) M antibody. With clinical and epidemiologic correlation, a positive IgM test result has good diagnostic predictive value, but cross-reaction between related arboviruses from the same viral

Table 3.2. Genus, Geographic Location, and Vectors for Selected Domestic and International Arboviral Diseases

Predominant Geographic Locations				
Virus	Genus	United States	Non-United States	Vector
Domestic				
Cache Valley	<i>Orthobunyavirus</i>	Widespread	Canada, Central America, and the Caribbean	Mosquitoes
Colorado tick fever	<i>Coltivirus</i>	Rocky Mountain and western states	Western Canada	Ticks
Eastern equine encephalitis	<i>Alphavirus</i>	Eastern, Midwest, and Gulf coast states	Americas	Mosquitoes
Heartland	<i>Bandavirus</i>	Central and Southeast	None	Ticks
Jamestown Canyon	<i>Orthobunyavirus</i>	Widespread	Canada	Mosquitoes
La Crosse	<i>Orthobunyavirus</i>	Midwest and Appalachia	Canada	Mosquitoes
Powassan	<i>Flavivirus</i>	Northeast and Midwest	Canada, Russia	Ticks
St. Louis encephalitis	<i>Flavivirus</i>	Widespread	Americas	Mosquitoes
West Nile	<i>Flavivirus</i>	Widespread	Americas, Europe, Africa, Asia	Mosquitoes
International				
Chikungunya	<i>Alphavirus</i>	Imported and periodic local transmission ^a	Worldwide in tropical and subtropical areas	Mosquitoes
Dengue	<i>Flavivirus</i>	Imported and periodic local transmission ^a	Worldwide in tropical and subtropical areas	Mosquitoes
Japanese encephalitis	<i>Flavivirus</i>	Imported only	Australia, and other limited parts of Asia	Mosquitoes
Tick-borne encephalitis	<i>Flavivirus</i>	Imported only	Europe, northern Asia	Ticks
Yellow fever	<i>Flavivirus</i>	Imported only	South America, Africa	Mosquitoes
Zika	<i>Flavivirus</i>	Imported and periodic local transmission ^a	Worldwide in tropical and subtropical areas	Mosquitoes

^aEndemic with periodic outbreaks in US territories (Puerto Rico, US Virgin Islands, American Samoa); local mosquito-borne transmission of chikungunya, dengue, and Zika viruses previously identified in Florida and Texas; local transmission of dengue virus also previously identified in Hawaii.

family can occur (eg, West Nile and St. Louis encephalitis viruses, both flaviviruses). For most arboviral infections, IgM is detectable within a week after onset of illness and persists for 30 to 90 days, but longer persistence has been documented, especially with West Nile and Zika viruses. Therefore, a positive serum IgM test result occasionally can reflect a prior infection. Serum collected within 10 days of illness onset might not have detectable IgM, and the test should be repeated on a convalescent-phase serum sample. IgG antibody generally is detectable in serum shortly after IgM and persists for years. A plaque-reduction neutralization test can be performed to measure virus-specific neutralizing antibodies and to discriminate between cross-reacting antibodies in primary arboviral infections. Either seroconversion or a fourfold or greater increase in virus-specific neutralizing antibodies between acute- and convalescent-phase serum specimens collected 2 to 3 weeks apart is diagnostic of recent infection. In patients who have been immunized against or infected with another arbovirus from the same virus family in the past (ie, secondary infection), cross-reactive antibodies in both the IgM and neutralizing antibody assays might make it difficult to identify which arbovirus is causing the patient's current illness. For some arboviral infections (eg, Colorado tick fever or Heartland virus disease), the immune response may be delayed, with IgM antibodies not appearing until 2 to 3 weeks after onset of illness and neutralizing antibodies taking up to a month to develop. Patients with significant immunosuppression (eg, patients who have received a solid organ transplant, recent chemotherapy, or certain immunosuppressive therapies, such as rituximab) may have a delayed or blunted serologic response, and nucleic acid amplification tests (NAATs) may be indicated in these cases. Immunization and travel history, date of symptom onset, and information regarding other arboviruses known to circulate in the geographic area that may cross-react in serologic assays should be considered when interpreting results.

Viral culture and NAATs for RNA detection can be performed on acute-phase serum, CSF, or tissue specimens. Arboviruses that are more likely to be detected using culture or NAATs early in the illness include Colorado tick fever, dengue, Heartland, yellow fever, and Zika viruses. For other arboviruses, results of these tests often are negative even early in the clinical course because of the relatively short duration of viremia in immunocompetent persons. Immunohistochemical staining (IHC) can detect specific viral antigen in fixed tissue.

Antibody testing for common domestic arboviral diseases is performed in most state public health laboratories and many commercial laboratories. Confirmatory plaque reduction neutralization tests, viral culture, NAATs, immunohistochemical staining, and testing for less common domestic and international arboviruses are performed at the Centers for Disease Control and Prevention (CDC; telephone: 970-221-6400) and selected other reference laboratories. Confirmatory testing typically is arranged through local and state health departments.

TREATMENT: The primary treatment for all arboviral disease is supportive care. Although various antiviral and immunologic therapies have been evaluated for several arboviral diseases, none has shown clear benefit.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS: Standard precautions are recommended.

CONTROL MEASURES: Reduction of vectors in areas with endemic transmission is important to decrease risk of infection. Use of personal protective methods, such as

insect repellent, wearing long pants and long-sleeved shirts while outdoors, conducting a full-body check for ticks after outdoor activities, staying in screened or air-conditioned dwellings, and limiting outdoor activities during peak vector feeding times, can help decrease risk of human infection (see Prevention of Mosquito-borne and Tick-borne Infections, p 207). Some arboviral infections also can be prevented through screening of blood donations or through immunization. The blood supply in the United States is screened routinely for West Nile virus. Some arboviruses can be transmitted through human milk, although transmission appears rare. Mothers should be encouraged to breastfeed even in areas of active arboviral transmission because benefits of breastfeeding seem to outweigh the low risk of illness in breastfeeding infants (see Breastfeeding and Human Milk, p 135). The CDC has issued guidance for prevention of sexual transmission (see Zika, p 963).

Vaccines available in the United States to protect against arbovirus disease include the following products.

Yellow Fever Vaccine.¹ Live attenuated (17D strain) yellow fever vaccine is available from state-approved clinics or immunization providers. Unless contraindicated, yellow fever immunization is recommended for all people 9 months or older living in or traveling to areas with endemic disease in South America and Africa and is required by international regulations for travel to and from certain countries (wwwnc.cdc.gov/travel/). Infants younger than 6 months should not be immunized with yellow fever vaccine, because they have an increased risk of vaccine-associated encephalitis. The decision to immunize infants between 6 and 9 months of age must balance the infant's risk of exposure with risk of vaccine-associated encephalitis.

Booster doses of yellow fever vaccine are no longer recommended for most travelers, because a single dose of yellow fever vaccine provides long-lasting protection. Additional doses are recommended for certain populations (ie, people initially vaccinated when they were pregnant, patients who received a hematopoietic cell transplant after their initial vaccination, and people infected with human immunodeficiency virus [HIV]; www.cdc.gov/mmwr/preview/mmwrhtml/mm6423a5.htm#Box), as they might not have a robust or sustained immune response to yellow fever vaccine compared with other recipients. Additional doses may be administered to certain groups believed to be at increased risk for yellow fever disease because of their itinerary and duration of travel or because of more consistent exposure to the virus (eg, laboratory workers).

Yellow fever vaccine is a live-virus vaccine produced in chicken eggs and, thus, is contraindicated in people who have a history of acute hypersensitivity to eggs or egg products and in people who are immunocompromised. Procedures for immunizing people with severe egg allergy are described in the vaccine package insert. Generally, people who are able to eat eggs or egg products may receive the vaccine.

Pregnancy and breastfeeding are precautions to yellow fever vaccine administration, because rare cases of transmission of the vaccine virus in utero or through breastfeeding have been documented (see Immunization in Pregnancy, p 89, and Breastfeeding and Human Milk, p 135). Whenever possible, pregnant and breastfeeding individuals should defer travel to areas where yellow fever is endemic. If travel to an area with endemic disease is unavoidable and risks for yellow fever virus exposure are believed to outweigh the vaccination risks, a pregnant or breastfeeding person

¹ Centers for Disease Control and Prevention. Yellow Fever ACIP Vaccine Recommendations. Available at: www.cdc.gov/vaccines/hcp/acip-recs/vacc-specific/yf.html

should be vaccinated. If risks of vaccination are believed to outweigh risks for yellow fever virus exposure, a pregnant or breastfeeding person should be excused from immunization and issued a medical waiver letter to fulfill health regulations. For more detailed information on the yellow fever vaccine, including adverse events, precautions, and contraindications, visit wwwnc.cdc.gov/travel/ or www.cdc.gov/yellowfever/healthcareproviders/vaccine-info.html or see Travel-Related Immunizations (p 128).

Japanese Encephalitis Vaccine.¹ Risk of Japanese encephalitis for most travelers to Asia is very low but varies based on destination, duration of travel, season, activities, and accommodations. All travelers to countries with endemic Japanese encephalitis should be informed of the potential for infection and should use personal protective measures to reduce risk of mosquito bites. For some travelers who might be at increased risk for Japanese encephalitis, Japanese encephalitis vaccine can reduce the risk for infection further. Japanese encephalitis vaccine is recommended for those becoming residents of a country with endemic transmission, longer-term travelers (eg, a month or longer), and frequent travelers to areas with endemic disease (www.cdc.gov/vaccines/hcp/acip-recs/vacc-specific/je.html). Japanese encephalitis vaccine also should be considered for shorter-term travelers if they plan to travel outside of an urban area and have an itinerary or activities that will increase their risk of mosquito exposure in an area with endemic transmission. Information on the location of Japanese encephalitis virus transmission and detailed information on vaccine recommendations and adverse events can be obtained from the CDC (www.cdc.gov/japaneseencephalitis/).

The Japanese encephalitis vaccine licensed in the United States is non-live Vero cell culture-derived vaccine (Ixiaro [JE-VC]) available for use in adults and children 2 months and older. The primary vaccination series is 2 doses administered 28 days apart for those younger than 18 years or older than 65 years of age, and 7–28 days apart for those 18 to 65 years of age. The dose is 0.25 mL for children 2 months through 2 years of age and 0.5 mL for adults and children 3 years and older. For adults and children, a booster dose may be administered at 1 year or longer after the primary series if ongoing exposure or re-exposure is expected.

No safety concerns have been identified in passive postmarketing surveillance of more than 1 million doses of JE-VC distributed in the United States. Safety, immunogenicity, and efficacy of JE-VC have not been assessed in pregnant individuals.

Dengue Vaccine.² A recombinant live attenuated tetravalent dengue vaccine (Dengvaxia) is licensed in multiple countries in Asia, Latin America, and Europe. The US Food and Drug Administration has approved Dengvaxia in 2019 for use in people 6 through 16 years of age who have laboratory evidence of previous dengue virus infection and who live in areas with endemic infection (see Dengue, p 352). The vaccine is given as a 3-dose series with 6 months between doses. The Centers for Disease Control and Prevention (CDC) Advisory Committee on Immunization Practices (ACIP) currently recommends vaccination with the Dengvaxia vaccine for children 9 through 16 years of age who live in an area where dengue is endemic and have evidence of a previous dengue infection;

¹ Hills SL, Walter EB, Atmar RL, Fischer M. Japanese encephalitis vaccine: Recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR Recomm Rep* 2019;68(RR-2):1–33.

² Paz-Bailey G, Adams L, Wong JM, et al. Dengue vaccine: recommendations of the Advisory Committee on Immunization Practices, United States, 2021. *MMWR Recomm Rep*. 2021;70(6):1-16

as of December 2023, the ACIP had not yet voted on recommending its lower age range align with the FDA's approved range. Recommendations for use of dengue vaccine in the United States were published in 2021, and vaccination in Puerto Rico began in 2022.

Tick-borne Encephalitis Vaccine.¹ A tick-borne encephalitis vaccine became available for the first time in the United States in August 2021. Risk for tick-borne encephalitis is very low for most travelers to the parts of Europe and Asia where the disease is endemic. Some people are at increased risk for infection based on their season and location of travel and their activities. Tick-borne encephalitis vaccine is recommended for people who are moving or traveling to an area with endemic infection and will have extensive exposure to ticks based on their planned outdoor activities and itinerary. It may be considered for others who might engage in outdoor activities in areas with endemic infection, with the decision to vaccinate based on assessment of their planned activities and itinerary, risk factors for a poorer medical outcome, and personal perception and tolerance of risk. Detailed information on the location of tick-borne encephalitis, risk factors for infection, and vaccine considerations can be found on the CDC website (www.cdc.gov/tick-borne-encephalitis/index.html).

The non-live tick-borne encephalitis vaccine can be used in adults and children 1 year and older. The 3-dose primary vaccination series for children and adolescents 1 through 15 years of age consists of 0.25-mL doses on day 0 (dose 1), at 1–3 months after the first vaccination (dose 2), and 5–12 months after the second vaccination (dose 3). The schedule for persons 16 years and older is similar, but dose 2 can be given as early as 14 days after dose 1. The vaccine dose recommended for people 16 years and older is 0.5 mL. A booster dose may be administered at least 3 years after completion of the primary series if ongoing exposure or re-exposure is expected.

The vaccine is contraindicated in any person with a history of a severe allergic reaction (eg, anaphylaxis) to any vaccine component, including chicken protein, neomycin, gentamicin, and protamine sulfate. A complete list of components is provided in the package insert.

Public Health Reporting. Most arboviral diseases are nationally notifiable conditions and should be reported to the appropriate local and state health authorities. Underdiagnosis of these diseases because of challenges with laboratory confirmation and lack of active surveillance is common, suggesting that the actual numbers of cases are likely significantly higher. For select arboviruses (eg, chikungunya, dengue, Zika, and yellow fever viruses), patients may remain viremic during their acute illness. Such patients pose a risk for further person-to-mosquito-to-person transmission, increasing the importance of timely reporting.

***Arcanobacterium haemolyticum* Infections**

CLINICAL MANIFESTATIONS: Acute pharyngitis attributable to *Arcanobacterium haemolyticum* often is indistinguishable from group A streptococcal pharyngitis. *A. haemolyticum* has been associated with fever, pharyngeal erythema and exudates, cervical lymphadenopathy, and rash, but palatal petechiae and strawberry tongue are typically absent. A morbilliform or scarlatiniform exanthem is present in half of cases, usually

¹ Hills SL, Poehling KA, Chen WH, Staples JE. Tick-borne encephalitis vaccine: recommendations of the Advisory Committee on Immunization Practices, United States, 2023. *MMWR Recomm Rep*. 2023;72(RR-5):1-29

beginning on extensor surfaces of the distal extremities, spreading to the torso, back, and neck, sparing the face, palms, and soles. Rash typically develops 1 to 4 days after onset of sore throat, although the rash may precede pharyngitis. Desquamation can occur. Respiratory tract infections that mimic diphtheria, including membranous pharyngitis, and peritonsillar and pharyngeal abscesses occasionally occur. Skin and soft tissue infections, including chronic ulcers, cellulitis, paronychia, and wound infection, have been attributed to *A haemolyticum*. Rarely, invasive infections have been reported, including Lemierre syndrome, bacteremia, sepsis, endocarditis, brain abscess, orbital cellulitis, and pyogenic arthritis.

ETIOLOGY: *A haemolyticum* is a catalase-negative, weakly acid-fast, facultatively anaerobic, hemolytic, gram-positive to gram-variable, slender, sometimes club-shaped bacillus.

EPIDEMIOLOGY: Humans are the primary reservoir of *A haemolyticum*. Household studies suggest that spread occurs from person to person, presumably via droplet respiratory secretions. Severe disease occurs almost exclusively among immunocompromised people; invasive cases have been reported rarely in previously healthy people. *Arcanobacterium* pharyngitis occurs primarily in adolescents and young adults and only rarely in young children. *A haemolyticum* accounts for approximately 0.5% of pharyngeal infections overall and up to 2.5% of pharyngeal infections in 15- to 25-year-olds. Isolation of the bacterium from the nasopharynx of asymptomatic people is rare.

The **incubation period** is unknown.

DIAGNOSTIC TESTS: *A haemolyticum* grows on blood-enriched agar, but colonies are small, have narrow bands of beta hemolysis, and may not be visible for 48 to 72 hours. The organism is not detected by rapid antigen tests for group A streptococci. Detection is enhanced by culture on rabbit or human blood agar, which yields larger colony size and wider zones of hemolysis compared with sheep blood agar. Presence of 5% carbon dioxide enhances growth, and pits characteristically form under colonies on blood agar plates. *A haemolyticum* may be missed in routine throat cultures on sheep blood agar if laboratory personnel are not trained specifically to identify the organism. Two biotypes of *A haemolyticum* have been identified: a rough biotype predominates in respiratory tract infections and a smooth biotype typically is found in skin and soft tissue infections.

TREATMENT: Optimal management of patients with *A haemolyticum* pharyngitis has not been determined, and symptoms can resolve without antibiotic treatment. Erythromycin and azithromycin are drugs of choice for *A haemolyticum* tonsillopharyngitis, but no controlled trials have been performed. *A haemolyticum* generally is susceptible in vitro to macrolides, clindamycin, cephalosporins, ciprofloxacin, vancomycin, and gentamicin. Treatment failures with penicillin despite predicted susceptibility from in vitro testing occur and may be attributable to tolerance. Resistance to trimethoprim-sulfamethoxazole is common. In rare cases of invasive infection, susceptibility tests should be performed, and treatment should be individualized. While awaiting results, initial empiric combination therapy can be initiated using a parenteral beta lactam agent, with or without gentamicin or a macrolide, and with consideration of metronidazole if *Fusobacterium* infection is suspected, such as in cases of Lemierre syndrome.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: None.

***Ascaris lumbricoides* Infections**

CLINICAL MANIFESTATIONS: Most infections with *Ascaris lumbricoides* are asymptomatic, although moderate to heavy infections may lead to nonspecific gastrointestinal tract symptoms, malnutrition, and growth delay. During the larval migratory phase, an acute transient pneumonitis (Löfller syndrome) associated with cough, wheezing, substernal discomfort, shortness of breath, fever, and marked eosinophilia may occur. Acute intestinal obstruction has been associated with heavy infections. Children are prone to this complication because of the small diameter of the intestinal lumen and their propensity to acquire large worm burdens. Heavy worm burdens also can affect nutritional status, intellectual development, cognitive performance, and growth. Worm migration can cause peritonitis secondary to intestinal wall perforation as well as appendicitis or common bile duct obstruction resulting in biliary colic, cholangitis, or pancreatitis. Adult worms can be stimulated to migrate by stressful conditions (eg, fever, illness, or anesthesia) and by some anthelmintic drugs.

ETIOLOGY: After embryonated eggs are ingested, larvae hatch in the small intestine, penetrate the mucosa, and are transported passively by portal blood to the liver and lungs. After migrating from alveolar capillaries into the small airways, larvae ascend through the tracheobronchial tree to the pharynx, are swallowed, and mature into adults in the small intestine. Female worms produce approximately 200 000 eggs per day, which are excreted in stool and must incubate in soil to become infectious. Adult worms can live in the lumen of the small intestine for up to 18 months. Female worms are longer than male worms and can measure 40 cm in length and 6 mm in diameter.

EPIDEMIOLOGY: *A lumbricoides* is the most prevalent of all human intestinal nematodes (roundworms), with more than 800 million people infected worldwide. Infection is acquired by ingestion of *Ascaris* eggs in feces-contaminated food or dirt. Direct person-to-person transmission does not occur. Infection is most common in resource-limited countries, including rural and urban communities characterized by poor sanitation. *Ascaris suum*, a pig roundworm similar to *A lumbricoides*, also causes human disease. Sporadic clusters of ascariasis attributable to *A suum* associated with pig farming or use of pig stool for fertilizer have been reported in the United States.

The **incubation period** (interval between ingestion of eggs and development of egg-laying adults) is approximately 9 to 11 weeks.

DIAGNOSTIC TESTS: Ascariasis is diagnosed by examining a fresh or preserved stool specimen for eggs using light microscopy. Concentration techniques and examination of multiple specimens may be needed. Patients who harbor only male *Ascaris* worms will have negative test results on stool microscopy. Adult worms also may be passed from the rectum, through the nares, or from the mouth, usually in vomitus. Imaging of the gastrointestinal tract or biliary tree using computed tomography or ultrasonography may detect adult *Ascaris* worms, which can cause filling defects following administration of oral contrast.

TREATMENT: Albendazole and mebendazole are first-line agents for treatment of ascariasis, with cure rates from 90% to 100% with albendazole (see Drugs for Parasitic Infections, p 1068). Ivermectin, nitazoxanide, and pyrantel pamoate are alternative therapies. Albendazole, pyrantel pamoate, ivermectin, and nitazoxanide

are not approved by the US Food and Drug Administration for treatment of ascariasis, although albendazole has become the drug of choice for most soil-transmitted nematode infections, including ascariasis. Reexamination of stool specimens may be performed at approximately 2 weeks after deworming to document cure and again at 2 to 3 months to account for migrating larvae present at the time of treatment that may now be mature adults, because these anthelmintic agents are not effective against larvae. Patients who remain infected should be retreated, preferably with albendazole or the multidose regimen of mebendazole, and the reasons for the repeated infections should be explored and addressed.

Conservative management of small bowel obstruction, including nasogastric suction, intravenous fluids, and repletion of electrolytes, may alleviate symptoms before administration of anthelmintic therapy. Diatrizoate meglumine and diatrizoate sodium solution or careful use of mineral oil (cases of lipoid pneumonia have been reported after this use), administered orally or by nasogastric tube, may cause relaxation of a bolus of worms. Endoscopic retrograde cholangiopancreatography has been used successfully for extraction of worms from the biliary tree. Surgical intervention (eg, laparotomy) is indicated for intestinal or biliary tract obstruction that does not resolve with conservative therapy or for patients with volvulus or peritonitis secondary to perforation.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: Sanitary disposal of human feces prevents transmission. Vegetables cultivated in areas where human feces are used as fertilizer must be washed thoroughly and cooked before eating.

Preventive chemotherapy (once or twice annually with albendazole or mebendazole) targeting high-risk groups, most notably preschool and school-aged children and pregnant people (after the first trimester), is recommended by the World Health Organization for control of *A lumbricoides* and other soil-transmitted nematodes in high prevalence communities. Reinfection is common in these areas, and additional public health measures, including improved sanitation, safe drinking water, and health education, likely will be required to eliminate these infections.

Aspergillosis

CLINICAL MANIFESTATIONS: Aspergillosis manifests as 5 principal clinical entities: invasive aspergillosis, aspergilloma, allergic bronchopulmonary aspergillosis, allergic sinusitis, and chronic pulmonary aspergillosis. Colonization of the respiratory tract is common. The clinical manifestations and severity depend on host immune status (either immunocompromised or atopic).

- Invasive aspergillosis occurs mostly in immunocompromised patients with prolonged neutropenia, graft-versus-host disease, or impaired phagocyte function (eg, chronic granulomatous disease) or those who have received T-lymphocyte immunosuppressive therapy (eg, corticosteroids, calcineurin inhibitors) or biologic agents (eg, tumor necrosis factor [TNF]-alpha inhibitors, small-molecule kinase inhibitors). Children at highest risk include those with new-onset acute myelogenous leukemia, relapse of hematologic malignancy, aplastic anemia, chronic granulomatous disease, and recipients of allogeneic hematopoietic cell and solid organ (eg, particularly lung)

transplants. Invasive infection usually involves pulmonary, sinus, cerebral, or cutaneous sites. Rarely, endocarditis, osteomyelitis, meningitis, peritonitis, infection of the eye or orbit, and gastrointestinal tract involvement occur. The hallmark of invasive aspergillosis is angioinvasion with resulting thrombosis, dissemination to other organs, and occasionally erosion of the blood vessel wall with catastrophic hemorrhage. Invasive aspergillosis in patients with chronic granulomatous disease is unique in that it is more indolent and displays a general lack of angioinvasion. Invasive aspergillosis also has been described among patients in the intensive care unit with severe influenza and COVID-19 with or without underlying immunocompromise.

- Aspergillomas and otomycosis are 2 syndromes of nonallergic colonization by *Aspergillus* species in immunocompetent children. Aspergillomas (“fungal balls”) grow in preexisting pulmonary cavities or bronchogenic cysts without invading pulmonary tissue; almost all patients have underlying lung disease, such as cystic fibrosis or tuberculosis. Patients with otomycosis have chronic otitis media with colonization of the external auditory canal by a fungal mat that produces a dark discharge.
- Allergic bronchopulmonary aspergillosis is a hypersensitivity lung disease that manifests as episodic wheezing, expectoration of brown mucus plugs, low-grade fever, eosinophilia, and transient pulmonary infiltrates. This form of aspergillosis occurs most commonly in immunocompetent children with asthma or cystic fibrosis and can be a trigger for asthmatic flares and acute pulmonary exacerbation in patients with cystic fibrosis.
- Allergic sinusitis is a far less common allergic response to colonization by *Aspergillus* species than is allergic bronchopulmonary aspergillosis. Allergic sinusitis occurs in children with nasal polyps or previous episodes of sinusitis or in children who have undergone sinus surgery. Allergic sinusitis is characterized by symptoms of chronic sinusitis with dark plugs of nasal discharge and is different from invasive *Aspergillus* sinusitis.
- Chronic aspergillosis typically affects patients who are not immunocompromised or are less immunocompromised, although exposure to corticosteroids is common, and patients often have underlying pulmonary conditions. Diagnosis of chronic aspergillosis requires at least 3 months of chronic pulmonary symptoms or chronic illness or progressive radiologic abnormalities, along with an elevated *Aspergillus* immunoglobulin (Ig) G concentration or other microbiological evidence. Because of the ubiquitous nature of *Aspergillus* species, a positive sputum culture alone is not diagnostic.

ETIOLOGY: *Aspergillus* species are molds that grow on decaying vegetation and in soil and are very common in the environment. *Aspergillus fumigatus* is the most common (>75%) cause of invasive aspergillosis, with *Aspergillus flavus* being the next most common. Several other major species, including *Aspergillus terreus*, *Aspergillus nidulans*, and *Aspergillus niger*, also cause invasive human infections. *A. nidulans* is the second most encountered mold in patients with chronic granulomatous disease, causing almost exclusively invasive infections characterized by aggressive behavior including lung infection that invades the chest wall with contiguous osteomyelitis and chest wall abscesses. Of increasing concern are emerging *Aspergillus* species that are resistant to antifungals, such as *Aspergillus fumigatus*, which can harbor environmentally acquired resistance mutations to azole antifungals; *A. terreus*, which is intrinsically resistant to amphotericin B; and *Aspergillus calidoustus*, which is often resistant to most antifungals including azole antifungals (see Table 4.7, p 1021).

EPIDEMIOLOGY: The principal route of transmission is inhalation of conidia (spores) originating from multiple environmental sources (eg, plants, vegetables, dust from construction or demolition), soil, and water supplies (eg, shower heads). Incidence of disease in hematopoietic cell transplant recipients is highest during periods of neutropenia or during treatment for graft-versus-host disease. In solid organ transplant recipients, the risk is highest approximately 6 months after transplantation or during periods of increased immunosuppression. Disease has followed use of contaminated marijuana in the immunocompromised host. Health care-associated outbreaks of invasive pulmonary aspergillosis in susceptible hosts have occurred in which the probable source of the fungus was a nearby construction site or faulty ventilation system, but the source of health care-associated aspergillosis frequently is not known. Cutaneous aspergillosis occurs less frequently and usually involves sites of skin injury, such as intravenous catheter sites (including in neonates), sites of traumatic inoculation, and sites associated with occlusive dressings, burns, or surgery. Transmission by direct inoculation of skin abrasions or wounds is less likely. Person-to-person spread does not occur.

The **incubation period** is unknown and may be variable.

DIAGNOSTIC TESTS: Dichotomously branched and septate hyphae, identified by microscopic examination of 10% potassium hydroxide wet preparations or of Gomori methenamine-silver nitrate stain of tissue or bronchoalveolar lavage specimens, are suggestive of the diagnosis. Isolation of *Aspergillus* species in culture from a sterile site or molecular testing with specific reagents is required for definitive diagnosis. The organism usually is not recoverable from blood (except some species like *A terreus*) but is isolated readily from lung, sinus, and skin biopsy specimens when cultured on Sabouraud dextrose agar or brain-heart infusion media (without cycloheximide). *Aspergillus* species can be associated with colonization or may be a laboratory contaminant, but when evaluating results from immunocompromised patients, recovery of this organism frequently indicates infection. Biopsy with histopathology can be used to establish the diagnosis, but *Aspergillus* hyphae are similar to other hyaline molds (eg, *Fusarium*). Care should be taken to distinguish aspergillosis from mucormycosis, which can appear similar by diagnostic imaging studies, but mucormycosis is pauci-septate (few septa) and requires a different treatment regimen.

An enzyme immunosorbent assay for detection of galactomannan, a molecule found in the cell wall of *Aspergillus* species, from serum or bronchoalveolar lavage (BAL) fluid is available commercially and may be useful in children and adults with hematologic malignancies or hematopoietic cell transplant recipients. A test result of ≥ 0.5 from the serum or ≥ 1.0 from BAL fluid supports a diagnosis of invasive aspergillosis. Measuring galactomannan during periods of highest risk (eg, neutropenia and active graft-versus-host disease) if the patient is not receiving mold-active antifungal prophylaxis may be useful for early detection of invasive aspergillosis in these patients. False-positive test results have been reported and can be related to consumption of food products containing galactomannan (eg, rice and pasta), other invasive fungal infections (eg, *Fusarium*, *Penicillium*, *Histoplasma capsulatum*), and colonization of the gut of neonates with *Bifidobacterium* species. Previous cross-reactivity with antimicrobial agents derived from fungi, especially piperacillin-tazobactam, no longer occurs because of manufacturing changes.

A negative galactomannan test result does not exclude diagnosis of invasive aspergillosis, and its greatest utility may be in monitoring response to disease rather than in

its use as a diagnostic marker. False-negative galactomannan test results consistently occur in patients with chronic granulomatous disease, so the test should not be used in these patients. Galactomannan is not recommended for routine screening in patients receiving mold-active antifungal therapy or prophylaxis (see Table 4.7, p 1021). Galactomannan is not recommended for screening in solid organ transplant recipients because of very poor sensitivity.

Detection of *Aspergillus* DNA using a nucleic acid amplification test (NAAT) performed on 2 consecutive blood samples or 2 duplicate bronchoalveolar lavage fluid samples, or in 1 blood and one bronchoalveolar lavage sample, supports a diagnosis of invasive aspergillosis in high-risk adults with underlying hematologic malignancies and hematopoietic cell transplantation recipients; however, the clinical utility of the NAAT in children remains unknown. Some NAATs may also allow detection to the species level and identify mutations associated with triazole resistance.

Limited data suggest that testing for other nonspecific fungal biomarkers, such as 1,3- β -D glucan, may be useful in the diagnosis of aspergillosis. This test is not specific for aspergillosis, however, and specificity may be further limited in a variety of clinical settings, including exposure to certain antibiotics, hemodialysis, and coinfection with certain bacteria.

Unlike adults, children frequently do not manifest cavitation or the air crescent or halo signs on chest radiography, and lack of these characteristic signs does not exclude the diagnosis of invasive aspergillosis.

In allergic aspergillosis, diagnosis is suggested by a typical clinical syndrome with elevated total concentrations of IgE (≥ 1000 ng/mL) and *Aspergillus*-specific serum IgE, eosinophilia, and a positive result from a skin test for *Aspergillus* antigens. In people with cystic fibrosis, the diagnosis is more difficult because wheezing, eosinophilia, and a positive skin test result not associated with allergic bronchopulmonary aspergillosis often are present.

TREATMENT¹: Voriconazole is the drug of choice for all clinical forms of invasive aspergillosis (see Antifungal Drugs for Systemic Fungal Infections, p 1017), except in neonates, for whom amphotericin B deoxycholate in high doses is recommended because of voriconazole's potential visual adverse effects. Voriconazole has been shown to be superior to amphotericin B in a large, randomized trial in adults. Immune reconstitution is paramount; decreasing immunosuppression, if possible (specifically corticosteroid dose), is critical to disease control. The diagnostic workup needs to be aggressive to confirm disease, but it should never delay antifungal therapy in the setting of true concern for invasive aspergillosis. Therapy is continued for a minimum of 6 to 12 weeks, but treatment duration should be individualized on the basis of degree and duration of immunosuppression. Response to therapy may be assessed by monitoring of serum galactomannan concentrations in those with significant elevation at onset, along with clinical and radiologic evaluation.

Close monitoring of voriconazole serum trough concentrations is critical for both efficacy and safety. Most experts agree that voriconazole trough concentrations should be measured on day 3 or later after initiating treatment and for children, therapeutic trough concentrations are 2 to 6 μ g/mL. It is important to individualize dosing in

¹ Patterson TF, Thompson GR III, Denning DW. Practice guidelines for the diagnosis and management of aspergillosis: 2016 update by the Infectious Diseases Society of America. *Clin Infect Dis*. 2016;63(4):e1-e60

patients following initiation of voriconazole therapy, because there is high interpatient variability in metabolism.

Certain *Aspergillus* species (*A. calidoustus*) are inherently resistant to azoles, and isolation of azole-resistant *A. fumigatus* is increasing and may be related to environmental acquisition through use of agricultural fungicides in previously azole-naïve patients. Resistance can also develop in patients receiving long-term azole therapy.

Alternative therapies include liposomal amphotericin B, isavuconazole, posaconazole, or other lipid formulations of amphotericin B. Primary therapy with an echinocandin alone (caspofungin, micafungin) is not recommended, but an echinocandin can be used in settings in which an azole or amphotericin B are contraindicated. Posaconazole absorption is improved significantly with use of the extended-release tablet rather than the oral suspension; a new powder formulation for delayed-release oral suspension is available for children ≥ 2 years of age weighing ≤ 40 kg. Isavuconazole is noninferior to voriconazole for primary treatment of invasive aspergillosis, with fewer drug-related adverse events in adults, but has not been fully studied in children. Combination antifungal therapy with voriconazole and an echinocandin may be considered in select patients with documented invasive aspergillosis. In areas with high azole resistance, empiric therapy until antifungal susceptibilities are obtained should include voriconazole plus an echinocandin, or liposomal amphotericin B monotherapy.

If primary antifungal therapy fails, general strategies for salvage therapy include: (a) changing the class of antifungal; (b) tapering or reversal of underlying immunosuppression when feasible; (c) susceptibility testing of any *Aspergillus* isolates recovered; and (d) surgical resection of necrotic lesions in selected cases. In pulmonary disease, surgery is indicated when a mass is impinging on a great vessel.

Allergic bronchopulmonary aspergillosis is treated with antifungal therapy, usually with itraconazole or another mold-active azole; in addition, corticosteroids are a cornerstone of therapy for exacerbations. Itraconazole has a demonstrable corticosteroid-sparing effect. Guidelines specific to treatment of allergic bronchopulmonary aspergillosis in patients with cystic fibrosis are available (www.cff.org/Care/Clinical-Care-Guidelines/Infection-Prevention-and-Control-Clinical-Care-Guidelines/Allergic-Bronchopulmonary-Aspergillosis-Clinical-Care-Guidelines/).

Allergic sinus aspergillosis also is treated with corticosteroids, and surgery has been reported to be beneficial in many cases. Antifungal therapy has not been found to be useful but could be considered for refractory infection and/or relapsing disease. There may be an emerging role for immunotherapy.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: Outbreaks of invasive aspergillosis and *Aspergillus* colonization have occurred among hospitalized patients during construction in hospitals and at nearby sites. Environmental measures reported to be effective include erecting suitable barriers between patient care areas and construction sites, routine cleaning of air-handling systems, repair of faulty air flow, and replacement of contaminated air filters. High-efficiency particulate air filters and laminar flow rooms markedly decrease the risk of exposure to conidia in patient care areas. Plants and flowers may be reservoirs for *Aspergillus* and should be avoided in intensive care units and immunocompromised patient care settings. Use of high-efficiency respirators during transport away from

protective environment rooms has been associated with reduced incidence of invasive pulmonary aspergillosis during hospital construction.

Posaconazole has been shown to be effective in 2 randomized controlled trials as prophylaxis against invasive aspergillosis for patients 13 years and older who have undergone hematopoietic cell transplantation and have graft-versus-host disease as well as in patients with hematologic malignancies with prolonged neutropenia, although breakthrough disease has been reported in those with gastrointestinal tract issues (eg, graft-versus-host disease) affecting drug bioavailability. Low-dose amphotericin B, itraconazole, voriconazole, or posaconazole prophylaxis have been reported for other high-risk patients, but controlled trials have not been completed in pediatric patients.

Patients at risk of invasive infection should avoid high environmental exposure (eg, gardening) following discharge from the hospital. People with allergic aspergillosis should take measures to reduce exposure to *Aspergillus* species in the home.

Astrovirus Infections

CLINICAL MANIFESTATIONS: Astrovirus illness most commonly manifests as 2 to 5 days of acute watery diarrhea accompanied by low-grade fever, malaise, and nausea, and less commonly, vomiting and mild dehydration. Illness in an immunocompetent host is self-limited, lasting a median of 5 to 6 days. Asymptomatic infections are common. Astrovirus infections also have been associated with respiratory illness, encephalitis, and meningitis, particularly in immunocompromised individuals.

ETIOLOGY: Members of the family *Astroviridae*, astroviruses are nonenveloped, single-stranded RNA viruses with viral particles having a characteristic star-like appearance when visualized by electron microscopy. Astroviruses are classified into 2 genera: *Mamastrovirus* (MAstV) and *Avastrovirus*, which infect mammals and birds, respectively. Four MAstV species have been identified in humans: MAstV 1, MAstV 6, MAstV 8, and MAstV 9. MAstV 1 includes the 8 antigenic types of classic human astroviruses (HAsTV types 1–8), whereas MAstV 6, MAstV 8, and MAstV 9 are novel astroviruses that have been identified in recent years and include Melbourne (MLB) and Virginia/human-mink-ovine-like (VA/HMO) strains.

EPIDEMIOLOGY: Human astroviruses (HAsTVs) have a worldwide distribution. Multiple antigenic types cocirculate in the same geographic region. HAsTVs have been detected in as many as 5% to 17% of sporadic cases of nonbacterial gastroenteritis among young children in the community but appear to cause a lower proportion of cases of more severe childhood gastroenteritis requiring hospitalization (2.5%–9%). HAsTV infections occur predominantly in children younger than 4 years and have a seasonal peak during the late winter and spring in the United States. Transmission is via the fecal-oral route through contaminated food or water, person-to-person contact, or contaminated surfaces. Outbreaks tend to occur in closed populations of the young and the elderly, particularly among hospitalized children (health care-associated infections) and children in child care centers (Table 2.1). In general, virus is shed 1 to 2 days before illness and lasts a median of 5 days after onset of symptoms, but asymptomatic excretion after illness can last for several weeks in healthy children. Persistent excretion may occur in immunocompromised hosts. MAstV 6, MAstV 8, and MAstV 9 have been detected sporadically in stool samples, blood, respiratory samples, cerebrospinal fluid, and brain tissue of immunocompromised patients with acute encephalitis.

The **incubation period** is 3 to 4 days.

DIAGNOSTIC TESTS: There are several US Food and Drug Administration (FDA) approved multiplex nucleic acid-based assays for the detection of gastrointestinal tract pathogens, at least 2 of which include astrovirus (MAstV 1). Similar to tests for other gastroenteritis viruses, interpretation of assay results may be complicated by the detection of multiple gastrointestinal tract pathogens in a single sample, particularly in young children.

A few research and reference laboratories test stool samples using nucleic acid amplification tests (NAATs). To link cases from different disease clusters, positive samples can be typed by amplification and sequencing of small regions of the astrovirus capsid gene.

TREATMENT: No specific antiviral therapy is available. Oral or parenteral fluids and electrolytes are given to prevent and correct dehydration.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, contact precautions are recommended for diapered children or incontinent people for the duration of illness or to control institutional outbreaks.

CONTROL MEASURES: No specific control measures are available. The spread of infection in child care settings can be decreased by using general measures for control of diarrhea, such as training care providers in infection-control procedures, maintaining cleanliness of surfaces, keeping food preparation duties and areas separate from child care activities, exercising adequate hand hygiene, cohorting ill children, and excluding ill child care providers, food handlers, and children (see *Children in Group Child Care and Schools*, p 145).

Babesiosis

CLINICAL MANIFESTATIONS: *Babesia* infection in children and adolescents often is asymptomatic or associated with mild, nonspecific symptoms. The infection also can be severe and life-threatening, particularly in people who are immunocompromised, including those at the extremes of age (neonates and the elderly), those who lack a spleen, and those who have human immunodeficiency virus (HIV) infection/acquired immunodeficiency syndrome (AIDS) or cancer or are on immunosuppressive drugs. Babesiosis, like malaria, is characterized by the presence of fever and hemolytic anemia. Clinical manifestations can include malaise and fatigue, often followed by fever, chills, sweats, anorexia, myalgia, headache, arthralgia, and/or nausea. Severe babesiosis may require hospitalization for management of marked anemia, adult respiratory distress syndrome, disseminated intravascular coagulation, congestive heart failure, renal impairment, shock, or splenic rupture. Congenital infection with nonspecific manifestations suggestive of sepsis has been reported, as has persistent relapsing disease in highly immunocompromised hosts.

Babesiosis should be considered in a patient who resides in or traveled to an area with endemic infection and develops compatible symptoms and characteristic laboratory abnormalities, including anemia, thrombocytopenia, or evidence of intravascular hemolysis (abnormal aspartate aminotransferase [AST], alanine aminotransferase [ALT], alkaline phosphatase, lactate dehydrogenase [LDH], total and direct bilirubin concentrations, or reduced haptoglobin).

ETIOLOGY: *Babesia* species are intraerythrocytic protozoa that usually are transmitted by the bite of a hard-bodied tick. The etiologic agents of human babesiosis in the United States include *Babesia microti*, the most common cause of infection, *Babesia duncani*, and rarely, *Babesia divergens*.

EPIDEMIOLOGY: Babesiosis predominantly is a tick-borne zoonosis. *Babesia* parasites also can be transmitted via blood transfusion, via organ transplantation, and perinatally. The primary reservoir host for *B microti* in the United States is the white-footed mouse (*Peromyscus leucopus*), and the primary tick vector is *Ixodes scapularis*, which can transmit other pathogens, such as *Borrelia burgdorferi*, the causative agent of Lyme disease, and *Anaplasma phagocytophilum*, the causative agent of human granulocytic anaplasmosis. A tick bite often is not noticed, in part because the nymphal stage of the tick is approximately the size of a poppy seed. White-tailed deer (*Odocoileus virginianus*) serve as hosts for tick procreation and a blood meal, but deer are not reservoir hosts of *B microti*. An increase in deer populations in the Northeast and northern Midwest during the past few decades is thought to be a major factor in the increase and spread of *I scapularis* ticks. Most cases of babesiosis in the United States have been reported from states on the East Coast (Connecticut, Massachusetts, New Jersey, New York, Rhode Island) and the northern Midwest (Minnesota, Wisconsin), where deer populations have increased (www.cdc.gov/parasites/babesiosis/data-statistics/maps/maps.html). Over the last few years, increasing numbers of cases have been reported from neighboring states such as Maine, New Hampshire, and Vermont. Occasional human cases of babesiosis caused by *B duncani* have been described in California, Oregon, and Washington State, and single cases caused by *B divergens* have been reported in Arkansas, Kentucky, Michigan, Missouri, and Washington State. Most US vector-borne cases of babesiosis occur during late spring, summer, or fall; transfusion-associated cases can occur year-round. More than 2000 cases of babesiosis are reported annually to the Centers for Disease Control and Prevention, but the number of cases likely is higher.

The **incubation period** ranges from approximately 1 to 6 weeks after a tick bite. A study of transfusion-associated cases found a median incubation period following a contaminated blood transfusion of 37 days (range, 11 to 176 days), but it may be longer (eg, latent infection can become symptomatic after splenectomy).

DIAGNOSTIC TESTS¹: Acute, symptomatic cases of babesiosis typically are diagnosed by microscopic identification of *Babesia* parasites on Giemsa- or Wright-stained blood smears. *Babesia* parasites may be confused with *Plasmodium falciparum*, but they can be distinguished by an experienced microscopist. The tetrad (Maltese-cross) form is pathognomonic for *Babesia* but often is not present.

In cases in which blood smear examination is negative but the index of suspicion for babesiosis remains high, molecular testing using a nucleic acid amplification test (NAAT) offers increased sensitivity in settings of low-level *B microti* parasitemia. NAAT results may remain positive for several months to more than a year after successful treatment. Some physicians may order a NAAT rather than a blood smear to confirm the diagnosis, especially if a skilled microscopist is not available. NAATs are

¹ Krause PJ, Auwaerter PG, Bannuru RR, et al. Clinical practice guidelines by the Infectious Diseases Society of America (IDSA): 2020 Guideline on diagnosis and management of babesiosis. *Clin Infect Dis*. 2021;72(2):e49-e64

species-specific, and most laboratories only offer *B microti* NAAT (www.cdc.gov/dpdx/babesiosis/index.html).

A single serologic test for *Babesia* antibody detection should not be used to diagnose acute disease because of difficulty distinguishing acute disease from previous infection. In geographic areas where both *B microti* and *B burgdorferi* are endemic, between 2% and 20% of patients with early Lyme disease have been reported to experience concurrent babesiosis coinfection, and 10% to 50% of patients with babesiosis have been found to be coinfecting with *B burgdorferi*. Other tick-borne coinfections, such as anaplasmosis, should be considered as well in patients with babesiosis and/or Lyme disease. When coinfection is documented, patients should receive therapies appropriate for each infection.

TREATMENT¹: Atovaquone (administered orally) plus azithromycin (administered orally in ambulatory patients with mild to moderate disease and intravenously in hospitalized patients with severe disease) for 7 to 10 days is the regimen of choice (see Drugs for Parasitic Infections, p 1068). Oral or intravenous clindamycin plus oral quinine sulfate may be used for patients who do not respond to atovaquone and azithromycin, although quinine commonly causes serious adverse effects. Severe babesiosis can be life-threatening despite antimicrobial therapy. Limited data suggest exchange transfusion has potential benefits that may outweigh potential adverse effects, particularly in patients with high levels of parasitemia (>10%) or evidence of severe organ dysfunction. Treatment for at least 6 weeks or longer is recommended for severely immunocompromised patients experiencing persistent relapsing disease despite recommended antibiotic therapy, with negative blood smears for 2 weeks or longer before discontinuing therapy. Higher doses of azithromycin (500 to 1000 mg per day, orally, in adolescents/adults) should be considered when treating a highly immunocompromised patient (see Table 4.11, Drugs for Parasitic Infections, p 1068). Limited data are available for treatment of disease caused by *B duncani* or *B divergens*, but most reported patients have been treated with intravenous clindamycin plus oral quinine. Efficacy of atovaquone plus azithromycin in treating *B duncani* infection has not been evaluated.

Peripheral blood smears should be performed during acute illness to monitor *Babesia* parasitemia for all patients. Testing of immunocompromised patients should continue daily until parasitemia is less than 4% and then weekly until blood smear results are negative; a NAAT should be considered for those whose symptoms persist after the blood smear results have become negative. Immunocompetent persons do not require testing once symptoms have resolved; NAAT results may remain positive for months or years after appropriate treatment, and this does not indicate treatment failure.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: Recommendations for prevention of tick bites are similar to those for prevention of Lyme disease and other tick-borne infections (see Prevention of Mosquito-borne and Tick-borne Infections, p 207). People with a known history of *Babesia* infection are deferred indefinitely from donating blood. In 2019, the US Food and Drug Administration (FDA) issued guidance to industry for

¹ Krause PJ, Auwaerter PG, Bannuru RR, et al. Clinical practice guidelines by the Infectious Diseases Society of America (IDSA): 2020 Guideline on diagnosis and management of babesiosis. *Clin Infect Dis*. 2021;72(2):e49-e64

regional, year-round testing using a licensed NAAT for *Babesia* infection or use of an FDA-approved pathogen-reduction device in the 14 highest-risk states (www.fda.gov/regulatory-information/search-fda-guidance-documents/recommendations-reducing-risk-transfusion-transmitted-babesiosis).

Public Health Reporting. Babesiosis is a nationally notifiable disease. Please refer to the state or local health department for details on reporting cases.

Bacillus cereus Infections and Intoxications

CLINICAL MANIFESTATIONS: *Bacillus cereus* primarily causes 2 toxin-mediated food-borne illnesses, emetic and diarrheal, but it also can cause invasive extraintestinal infection. The **emetic syndrome** develops after a short incubation period, similar to staphylococcal foodborne illness. It is characterized by nausea, vomiting, and abdominal cramps, and diarrhea may follow in up to one third of patients. The **diarrheal syndrome** has a longer incubation period, is more severe, and resembles *Clostridium perfringens* foodborne illness. It is characterized by moderate to severe abdominal cramps and watery diarrhea, vomiting in approximately 25% of patients, and occasionally low-grade fever. Both illnesses usually are short-lived, about 24 hours, but the emetic toxin is occasionally associated with fulminant liver failure.

Invasive extraintestinal infection can be severe and includes wound and soft tissue infections; sepsis and bacteremia, including central line-associated bloodstream infection; endocarditis; osteomyelitis; purulent meningitis and ventricular shunt infection; pneumonia; and ocular infections (ie, endophthalmitis and keratitis). Infection can be acquired through use of contaminated blood products, especially platelets. *B. cereus* is a leading cause of bacterial endophthalmitis following penetrating ocular trauma. Endogenous endophthalmitis can result from bacteremic seeding. Other ocular manifestations include an indolent keratitis related to corneal abrasions and may be seen in contact lens users or those who have undergone cataract surgery.

Rare infections attributable to *B. cereus* strains that express anthrax toxin genes, which clinically resemble anthrax, have been reported.

ETIOLOGY: *B. cereus* is an aerobic and facultative anaerobic, spore-forming, gram-positive or gram-variable bacillus.

EPIDEMIOLOGY: *B. cereus* is ubiquitous in the environment because of the high resistance of its endospores to extreme conditions, including heat, cold, desiccation, salinity, and radiation, and commonly is present in small numbers in raw, dried, and processed foods and in the feces of healthy people. The organism is a common cause of foodborne illness in the United States but may be underrecognized because few people seek care for mild illness and health care providers and clinical laboratories do not routinely test for *B. cereus*. Several confirmed outbreaks were reported to the Centers for Disease Control and Prevention (CDC) in recent years. A wide variety of food vehicles has been implicated.

Spores of *B. cereus* are heat resistant and can survive pasteurization, brief cooking, boiling, and high saline concentrations. Spores germinate to vegetative forms that produce enterotoxins over a wide range of temperatures, both in foods and in the gastrointestinal tract.

The diarrheal syndrome is caused by several distinct toxins that are produced after spores germinate in the gastrointestinal tract. The diarrheal toxins are heat labile and can be destroyed by heating.

The emetic syndrome occurs after eating contaminated food containing a pre-formed toxin called cereulide. The best known association of the emetic syndrome is with ingestion of fried rice made from boiled rice stored at room temperature overnight, because *B cereus* can be present in uncooked rice. However, a wide variety of foods, especially starchy foods (including cereals), cheese products, meats, and vegetables, has been implicated. The toxin is elaborated by vegetative forms that germinate from spores when the food is reheated; it is heat stable and gastric acid resistant.

Risk factors for invasive disease attributable to *B cereus* include history of injection drug use, presence of indwelling intravascular catheters or implanted devices, neutropenia or immunosuppression, and preterm birth. *B cereus* endophthalmitis has occurred after penetrating ocular trauma and injection drug use. Hospital outbreaks have been associated with contaminated medical equipment, but pseudo-outbreaks are more common and refer to sharp increases in contamination rates of clinical specimens associated with common source contamination (eg, ethanol pads or solutions, linens, blood culture media).

Foodborne illness caused by *B cereus* is not transmissible from person to person. The **incubation period** for foodborne illness is 30 minutes to 6 hours for the emetic syndrome and 6 to 15 hours for the diarrheal syndrome (see Appendix VI, Clinical Syndromes Associated With Foodborne Diseases, p 1150).

DIAGNOSTIC TESTS: Diagnostic testing is not recommended for sporadic cases. For foodborne outbreaks, isolation of *B cereus* from the stool or vomitus of 2 or more ill people and not from control patients, or isolation of 10^5 colony-forming units/g or greater from epidemiologically implicated food, suggests that *B cereus* is the cause of the outbreak. Because the organism can be recovered from stool specimens from some well people, the presence of *B cereus* in feces or vomitus of ill people alone is not definitive evidence of infection. Food samples must be tested for both the emetic toxin and diarrheal enterotoxins, because either alone can cause illness. Although there currently is no commercial kit that detects the cereulide emetic toxin, *B cereus* colonies isolated from food or specimens of ill individuals may be identified using nucleic acid amplification tests (NAATs) for the emetic toxin gene in diagnostic laboratories.

In patients with risk factors for invasive disease (eg, preterm infants, people with immunosuppressing conditions), isolation of *B cereus* from wounds or from blood or other sterile body fluids is significant. The common perception of *Bacillus* species as “contaminants” may delay recognition and treatment of serious *B cereus* infections.

TREATMENT: *B cereus* foodborne illness usually requires only supportive care, including rehydration. Antimicrobial therapy is indicated for patients with invasive disease. Prompt removal of any potentially contaminated foreign bodies, such as central lines or implants, is essential. For intraocular infections, an ophthalmologist should be consulted regarding surgical management and use of intravitreal antimicrobial therapy in addition to systemic therapy. *B cereus* is usually resistant to beta-lactam antibiotics and often to clindamycin but is susceptible to vancomycin, which is the drug of choice. Alternative drugs, including linezolid, clindamycin, aminoglycosides, erythromycin, tetracyclines, and fluoroquinolones, may be considered depending on susceptibility results.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS: Standard precautions are recommended.

CONTROL MEASURES: Proper cooking and appropriate storage of foods will help prevent foodborne illness attributable to *B. cereus*. For example, rice cooked for later use should be refrigerated and not stored at room temperature. Information on recommended safe food handling practices, including time and temperature requirements during cooking, storage, and reheating, can be found at **www.foodsafety.gov**. In health care settings, careful hand hygiene and strict aseptic technique are important in caring for immunocompromised patients or patients with indwelling intravascular catheters to minimize the risk of invasive disease. The organism can survive in high concentrations of ethanol, but careful hand washing and use of 2% chlorhexidine are effective preventive measures.

Bacterial Vaginosis

CLINICAL MANIFESTATIONS: Bacterial vaginosis (BV) is a vaginal dysbiosis characterized by changes in vaginal flora, with a replacement of normal hydrogen peroxide- and lactic-acid-producing *Lactobacillus* species with a diverse community of BV-associated bacteria. BV is diagnosed primarily in sexually active postpubertal female individuals.¹ Symptoms may include vaginal discharge and/or vaginal odor. However, studies have shown that up to 50% to 75% of people who meet microbiologic criteria for a diagnosis of BV are asymptomatic. Classic signs, when present, include a thin off-white, homogenous, adherent vaginal discharge with an unpleasant fishy odor. Symptoms of pruritus, dysuria, or abdominal pain are not typically associated with BV but can be suggestive of mixed vaginitis (symptoms attributable to more than 1 infectious cause). In pregnant people, BV has been associated with adverse outcomes, including intra-amniotic infection, premature rupture of membranes, preterm delivery, and postpartum endometritis.

Vaginitis and vulvitis in prepubertal female children rarely, if ever, are manifestations of BV. Vaginitis in prepubertal children frequently is nonspecific. Causes of vaginitis in this population include things that alter the vaginal flora, such as certain soaps, detergents, foreign bodies, and infections attributable to group A streptococci, *Escherichia coli*, herpes simplex virus, *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *Trichomonas vaginalis*, or enteric bacteria, including *Shigella* species. In any prepubertal female child who has symptoms of BV, a full history and workup should be considered to rule out sexual abuse and/or a sexually transmitted infection (STI [see Sexual Assault and Abuse in Children and Adolescents/Young Adults, p 182]). If sexual abuse is suspected, those who are mandated to report need to follow their state's regulations for immediate reporting.

ETIOLOGY: BV is a result of a change in the vaginal microbiota. Hydrogen peroxide-producing lactobacilli, which normally predominate and play a protective role by maintaining a low vaginal pH, are replaced by mostly anaerobic organisms. High concentrations of *Gardnerella vaginalis*, *Prevotella* species, *Atopobium vaginae*, *Porphyromonas* species, *Bacteroides* species, *Peptostreptococcus* species, *Mycoplasma hominis*, *Ureaplasma urealyticum*, and *Mobiluncus*, *Megasphaera*, *Sneathia*, *Clostridiales*, and *Fusobacterium* species have been identified in individuals with BV. These anaerobes produce large amounts of proteolytic enzymes, which break down vaginal peptides into a variety of malodorous amines, leading to the typical BV vaginal odor.

¹ The terms female and male refer to sex assigned at birth.

EPIDEMIOLOGY: BV is the most common cause of vaginal discharge in sexually active adolescents and adults. BV occurs more frequently in female individuals with multiple sexual partners (male or female), those with a new sexual partner, those who do not use condoms, and those who douche. BV rarely develops in a female person who has never been sexually active. BV can increase the risk of acquisition of other STIs, including human immunodeficiency virus (HIV), herpes simplex virus, *Mycoplasma genitalium*, *N. gonorrhoeae*, *C. trachomatis*, *T. vaginalis*, and human papillomavirus (HPV), and increase the risk of infectious complications following gynecologic surgeries and complications of pregnancy. BV can also increase the risk of HIV transmission to male sexual partners.

DIAGNOSTIC TESTS: The Amsel criteria and the Nugent score are commonly used to clinically diagnose BV when microscopy is available. At least 3 of the Amsel criteria are required for a BV diagnosis:

- Homogenous, thin grey or white vaginal discharge that smoothly coats the vaginal walls;
- Vaginal fluid pH greater than 4.5;
- A fishy (amine) odor of vaginal discharge before or after addition of 10% potassium hydroxide (ie, the “whiff test”); or
- Presence of clue cells (squamous vaginal epithelial cells covered with bacteria, which cause a stippled or granular appearance and ragged “moth-eaten” borders) representing at least 20% of the total vaginal epithelial cells seen on microscopic evaluation of vaginal fluid.

The Nugent score is used as the gold standard for diagnosing BV in the research setting and is commonly a standard against which newer diagnostic tests for BV are measured. A Gram stain of the vaginal fluid is evaluated, and a numerical score is generated on the basis of the apparent quantity of lactobacilli relative to BV-associated bacteria (*G. vaginalis* and *Mobiluncus* species). The score is interpreted as normal (0–3), intermediate (4–6), or BV (7–10).

With microscopy use declining, a wide variety of available commercial laboratory tests are increasingly used to diagnose BV, ranging from point-of-care tests to nucleic acid amplification tests (NAATs) performed in clinical labs. The NAATs are based on detection of specific BV-associated bacterial nucleic acids and have high sensitivity and specificity for specific BV-associated bacteria and certain lactobacilli. They can be performed on either clinician- or self-collected vaginal specimens, and results are usually available in less than 24 hours. BV NAATs should only be used to test symptomatic patients.

Despite the availability of BV NAATs, because of their lower cost and ability to provide a rapid diagnosis, traditional BV diagnostics methods, such as Amsel criteria, Nugent score, and DNA probe tests, remain useful for diagnosing BV in symptomatic patients.

No recommendations exist to screen asymptomatic female individuals for BV. Culture for *G. vaginalis* is not recommended as a diagnostic tool, because it is not specific, and Papanicolaou (Pap) testing is not recommended because of its extremely low sensitivity.

Sexually active individuals with BV should be evaluated for STI coinfection, including chlamydia, gonorrhea, trichomoniasis, syphilis, and HIV infection. If the hepatitis B and HPV vaccine series have not been completed, these immunizations should be offered.

TREATMENT¹: Symptomatic patients with BV should be treated. The goals of treatment are to relieve the symptoms and signs of infection and potentially to decrease the risk of acquiring other STIs. Treatment considerations should include patient preference for oral versus intravaginal treatment, possible adverse effects, and the presence of coinfections.

Nonpregnant people with BV may be treated orally with metronidazole or topically with metronidazole gel 0.75% or clindamycin cream 2% (see Table 4.4, p 1007, and Table 4.5, p 1014). Alternative regimens include oral tinidazole, oral clindamycin, oral secnidazole, or clindamycin intravaginal ovules. Patients should refrain from sexual intercourse or use condoms during treatment, keeping in mind that clindamycin cream is oil based and can weaken latex condoms and diaphragms for up to 5 days after completion of therapy. Douching may increase the risk for relapse, and no data support douching for treatment or symptom relief. There is no evidence that treatment of sexual partners affects treatment response or recurrence risk. Follow-up is not necessary if symptoms resolve.

Pregnant people with symptoms of BV should be treated, because they are at high risk of adverse pregnancy outcomes. Metronidazole crosses the placenta, but there are no studies showing any teratogenicity. Because oral therapy has not been shown to be superior to topical therapy for treating symptomatic BV, symptomatic pregnant people can be treated with either the oral or vaginal metronidazole or clindamycin regimens recommended for nonpregnant people. Tinidazole should be avoided during pregnancy, as animal studies have shown teratogenic effects. Data are insufficient regarding efficacy and adverse effects of secnidazole, clindamycin 2% vaginal cream, metronidazole 1.3% vaginal gel, and 750-mg vaginal metronidazole tablets during pregnancy, so their use should be avoided in pregnant people.

Breastfeeding people with symptoms of BV should be treated. Metronidazole is secreted in human milk. Multiple reported case series identified no evidence of metronidazole-associated adverse effects for breastfed infants. Clindamycin has the potential to cause adverse effects on the breastfed infant's gastrointestinal flora. Infant side effects are less likely with vaginal clindamycin than oral use, because only approximately 30% of a vaginal dose is systemically absorbed. Because safety information on tinidazole or secnidazole in breastfeeding people is limited, they should only be used in difficult to treat cases. Interruption of breastfeeding is recommended during treatment and for 3 days after the last dose of secnidazole and tinidazole.

Approximately 30% of appropriately treated people have a BV recurrence within 3 months. Retreatment with the same regimen or an alternative regimen are both reasonable options for treating persistent or recurrent BV after the first occurrence. For people with multiple recurrences (more than 3 in the previous 12 months), either 0.75% metronidazole gel or 750-mg metronidazole vaginal suppository twice weekly for at least 3 months has been shown to reduce recurrences, although this benefit does not persist when suppressive therapy is discontinued. Limited data suggest an oral nitroimidazole (metronidazole or tinidazole, 500 mg, twice daily for 7 days) followed by intravaginal boric acid (600 mg daily for 21 days) and suppressive 0.75% metronidazole gel (twice weekly for 4 to 6 months) might be an option for patients with

¹ Centers for Disease Control and Prevention. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(RR-4):1-187. Available at: www.cdc.gov/std/treatment-guidelines/bv.htm

multiple recurrences of BV. Boric acid can cause death if ingested orally; it should be stored in a secure place inaccessible to children. Boric acid should not be used in pregnancy. Monthly oral metronidazole, 2 g, administered with fluconazole, 150 mg, has also been evaluated as suppressive therapy; this regimen reduced the incidence of BV and promoted colonization with normal vaginal microbiota. Studies thus far do not support currently available *Lactobacillus* formulations or probiotics as an adjunctive or replacement therapy for BV management.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: None.

***Bacteroides*, *Prevotella*, and Other Anaerobic Gram-Negative Bacilli Infections**

CLINICAL MANIFESTATIONS: *Bacteroides*, *Prevotella*, and other anaerobic gram-negative bacilli (AGNB) residing in the oral cavity have been associated with chronic sinusitis, chronic otitis media, parotitis, dental infection, peritonsillar abscess, cervical adenitis, retropharyngeal space infection, aspiration pneumonia, lung abscess, pleural empyema, or necrotizing pneumonia. Species residing in the gastrointestinal tract have been recovered in patients with peritonitis, intra-abdominal abscess, pelvic inflammatory disease, Bartholin cyst abscess, tubo-ovarian abscess, endometritis, acute and chronic prostatitis, prostatic and scrotal abscesses, scrotal gangrene, postoperative wound infection, and vulvovaginal and perianal infections. Invasion of the bloodstream from the oral cavity or gastrointestinal tract may result in brain abscess, meningitis, endocarditis, arthritis, or osteomyelitis. Skin and soft tissue infections include bacterial gangrene and necrotizing fasciitis; omphalitis in newborn infants; cellulitis at the site of fetal monitor probes, human bite wounds, or burns; infections adjacent to the oral cavity or rectum; and infected decubitus ulcers. Neonatal infections, including conjunctivitis, pneumonia, bacteremia, or meningitis, rarely occur. When *Bacteroides*, *Prevotella*, and other AGNB are implicated, infections are typically polymicrobial.

ETIOLOGY: Most *Bacteroides*, *Prevotella*, *Porphyromonas*, and *Fusobacterium* organisms associated with human disease are pleomorphic, non-spore-forming, facultatively anaerobic, gram-negative bacilli.

EPIDEMIOLOGY: *Bacteroides*, *Prevotella*, and other AGNB are part of the normal oral, gastrointestinal tract, and genital tract flora. The *Bacteroides fragilis* group predominates in gastrointestinal tract flora. Enterotoxigenic *B fragilis* may be associated with diarrhea. Members of the *Prevotella melaninogenica* (formerly *Bacteroides melaninogenicus*) and *Prevotella oralis* (formerly *Bacteroides oralis*) groups reside in the oral cavity. These species result in infections as opportunists, usually after an alteration in skin or mucosal membranes in conjunction with other endogenous species, and often are associated with chronic mucosal injury. Rates of upper respiratory tract, head, and neck infections associated with AGNB are higher in children than in adults. Endogenous infection results from aspiration, bowel perforation, or damage to mucosal surfaces from trauma, surgery, or chemotherapy. Mucosal injury or granulocytopenia predispose to infection. Except in infections resulting from human bites, no evidence of person-to-person transmission of AGNB exists. The prevalence of AGNB infections is likely

underestimated because of preanalytical collection, transportation, and specimen cultivation issues.

The **incubation period** is variable and depends on the inoculum and the site of involvement but usually is 1 to 5 days.

DIAGNOSTIC TESTS: Anaerobic culture media are necessary for recovery of *Bacteroides*, *Prevotella*, and other AGNB. Because infections usually are polymicrobial, aerobic and anaerobic cultures should be obtained when AGNB species are suspected. A putrid odor, with or without gas in the infected site, suggests anaerobic infection. Use of an anaerobic transport tube or a sealed syringe is recommended for collection of clinical specimens.

TREATMENT: Abscesses should be drained when feasible; abscesses involving the brain, liver, and lungs may resolve with effective antimicrobial therapy alone. Necrotizing soft tissue lesions require surgical débridement and antimicrobial therapy.

The choice of antimicrobial agent(s) is based on anticipated or known in vitro susceptibility testing and local antimicrobial resistance patterns. Anaerobic infections of the oral and respiratory tracts generally are susceptible to penicillin G, ampicillin, and clindamycin. However, because some species of *Bacteroides* and almost 50% of *Prevotella* species produce beta-lactamase, and penicillin treatment failure has emerged, penicillin is not recommended for empiric coverage or for treatment of severe oropharyngeal or pleuropulmonary infections or for any abdominopelvic infections. A beta-lactam combined with a beta-lactamase inhibitor (ampicillin-sulbactam, amoxicillin-clavulanate, or piperacillin-tazobactam) can be used to treat these infections.

Anaerobic infections of the gastrointestinal tract are often caused by *B fragilis*, which is typically resistant to penicillin G but susceptible to metronidazole, beta-lactam plus beta-lactamase inhibitors, carbapenems, cefoxitin, and chloramphenicol. The emergence of clindamycin resistance in *B fragilis* now limits its use. Tigecycline has in vitro activity against *Prevotella* and *Bacteroides* species but limited pediatric dosing and safety data are available, particularly for children younger than 8 years. Tigecycline has a black box warning for an increase in all-cause mortality and should be reserved for situations in which alternative agents are not suitable. Moxifloxacin may be an alternative to treat anaerobic infections in children with severe beta-lactam allergies, although emerging resistance is a concern. Cefuroxime, cefotaxime, and ceftriaxone are not reliably effective.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: None.

***Balantidium coli* Infections**

(Balantidiasis)

CLINICAL MANIFESTATIONS: Most human infections are asymptomatic. Symptomatic infection is characterized either by acute onset of bloody or watery mucoid diarrhea with abdominal pain or with chronic or intermittent episodes of diarrhea, anorexia, and weight loss. Inflammation of the gastrointestinal tract and local lymphatic vessels can result in bowel dilation, ulceration, perforation, and extraintestinal spread or secondary bacterial invasion. Colitis produced by *Balantidium coli* can mimic that of *Entamoeba histolytica* or noninfectious causes. Fulminant disease can occur in

malnourished or otherwise debilitated or immunocompromised patients. Rare cases of appendicitis, pneumonia, and urinary tract infections have been reported.

ETIOLOGY: *B. coli*, a ciliated protozoan, is the largest pathogenic protozoan known to infect humans.

EPIDEMIOLOGY: Pigs are the primary host reservoir of *B. coli*, but the parasite has also been found in other mammals, especially primates and livestock. Infections have been reported in most areas of the world but are more common in tropical and subtropical areas or areas with poor sanitation systems. Cysts excreted in feces can be transmitted directly from hand to mouth or indirectly through fecally contaminated water or food. Excysted trophozoites infect the colon. A person is infectious as long as cysts are excreted in stool. Cysts may remain viable in the environment for months.

The **incubation period** is not established but may be several days.

DIAGNOSTIC TESTS: Diagnosis usually is made by demonstrating trophozoites (or less frequently, cysts) in stool, intestinal biopsy specimens, or ova and parasite examination of fluid aspirates from extraintestinal sites. Excretion of parasites can be intermittent, and repeated stool examinations over several days may be necessary. Trophozoites are more often identified in diarrheal stools, and cysts (40–60 µm in diameter) are more common in formed stools. Trophozoites exhibit characteristic spiraling motility on wet mount. Because trophozoites degenerate rapidly, fresh diarrheal stools require either prompt microscopic examination or placement in stool fixation medium. Stool studies may be negative in the rare cases of extraintestinal manifestations of disease.

TREATMENT: The drugs of choice are tetracycline and metronidazole (see Table 4.11, Drugs for Parasitic Infections, p 1068). Alternative drugs include iodoquinol and nitazoxanide.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard and contact precautions are recommended, because human-to-human transmission can occur rarely.

CONTROL MEASURES: Avoiding food or water that may be contaminated with feces (especially pig feces) is key to avoiding infection. Control measures include sanitary disposal of human and porcine feces and good handwashing. Cysts are resistant to the levels of chlorination used for drinking water, and waterborne outbreaks of disease have occurred despite chlorination. Fresh produce should be avoided in high-risk settings as washing alone may be insufficient to eliminate transmission.

***Bartonella henselae* (Cat-Scratch Disease)**

CLINICAL MANIFESTATIONS: Cat scratch disease, the predominant clinical manifestation of *Bartonella henselae* infection, presents in 85% to 90% of children as a localized cutaneous and regional lymphadenopathy disorder. A skin papule or pustule develops within 12 days at the presumed site of inoculation in approximately two thirds of cases and usually precedes development of lymphadenopathy by 1 to 2 weeks (range, 7–60 days). Lymphadenopathy occurs in nodes that drain the site of inoculation, typically axillary, but cervical, submandibular, submental, epitrochlear, or inguinal nodes can be involved. Low-grade fever lasting several days develops in 30% of patients. The skin overlying affected lymph nodes can be normal or can be tender, warm, erythematous, and indurated, and approximately 10% to 20% of affected nodes suppurate. Typically, lymphadenopathy resolves spontaneously in 2 to 4 months.

Less common manifestations of *B henselae* infection likely reflect bloodborne disseminated disease and include culture-negative endocarditis, encephalopathy, osteolytic lesions, glomerulonephritis, pneumonia, thrombocytopenic purpura, erythema nodosum, and prolonged fever with granulomata in the liver and spleen. Chronic *Bartonella* infection in nonimmunocompromised children has not been substantiated scientifically.

Ocular manifestations occur in 5% to 10% of patients. The most classic and frequent presentation of ocular *B henselae* infection is Parinaud oculoglandular syndrome, which consists of follicular conjunctivitis and ipsilateral preauricular lymphadenopathy. Another occasional ocular manifestation is neuroretinitis, which is characterized by abrupt unilateral (and rarely bilateral) painless vision impairment, granulomatous optic disc swelling, and macular edema, with lipid exudates (macular star). Rare presentations include retinochoroiditis, anterior uveitis, vitritis, pars planitis, retinal vasculitis, retinitis, branch retinal arteriolar or venular occlusions, macular hole, or, very rarely, retinal detachments.

B henselae (as well as *Bartonella quintana*) can cause bacillary angiomatosis (vascular proliferative lesions of skin and subcutaneous tissue) and bacillary peliosis (reticuloendothelial lesions in visceral organs, primarily the liver). These are primarily reported in immunocompromised patients, including people with HIV, but can also occur in immunocompetent people.

ETIOLOGY: *B henselae* is a fastidious, slow-growing, gram-negative bacillus. Other *Bartonella* species, such as *Bartonella clarridgeiae*, also have been found to cause cat scratch disease (CSD). *B henselae* is related closely to *B quintana*, a louse-borne disease that causes a distinct febrile illness with relapsing fevers, shin pain, headache, and myalgia. This illness resulted in significant disease among troops during World War I, leading to its former name of “trench fever.” People experiencing homelessness are at increased risk of *B quintana* infection because of lack of access to adequate sanitation and hygiene. *B quintana* also can cause bacillary angiomatosis and endocarditis.

EPIDEMIOLOGY: *B henselae* is a common cause of regional lymphadenopathy in children. The highest incidence is found in children 5 to 9 years of age; infections occur more often during the fall and winter. Cats are the natural reservoir for *B henselae*, with a seroprevalence of 30% to 40% in domestic and adopted shelter cats in the United States. Other animals, including dogs, can be infected and are rarely associated with human illness. Cat-to-cat transmission occurs via the cat flea (*Ctenocephalides felis*), with feline infection resulting in bacteremia that usually is asymptomatic and lasts weeks to months. Fleas acquire the organism when feeding on a bacteremic cat and then shed infectious organisms in their feces. The bacteria are transmitted to humans by inoculation from cat saliva or flea feces through a scratch or wound from a cat. Most patients with CSD have a history of recent contact with apparently healthy cats, especially kittens. Kittens are nearly 5 times as likely to be bacteremic with *B henselae* than are older cats. Cats obtained from shelters or adopted as strays also have high rates of bacteremia. There is no convincing evidence that ticks can transmit *Bartonella* species to humans. No evidence of person-to-person transmission exists.

The **incubation period** from the time of the scratch to appearance of the primary cutaneous lesion is 3 to 12 days; the median period from the appearance of the primary lesion to the appearance of lymphadenopathy is 12 days (range, 7 to 60 days).

DIAGNOSTIC TESTS: Both enzyme immunoassay (EIA) and indirect immunofluorescent antibody (IFA) platforms for detection of IgM and IgG serum antibodies to antigens of *Bartonella* species are available for diagnosis of CSD. Both platforms have limitations in sensitivity and specificity. With both types of tests, cross-reactivity with other infectious agents (such as *Chlamydia pneumoniae*, *Coxiella burnetii*, and especially other *Bartonella* species) is common. Elevated immunoglobulin (Ig) M titers may suggest recent infection, but both false-positive and false-negative IgM test results occur. In adults, there is a high rate of anti-*B. henselae* IgG seroprevalence in the general population attributable to prior exposure. Usually, if an IFA or EIA IgG titer is <1:64, the patient does not have acute infection. Titers between 1:64 and 1:256 may represent past or acute infection, and follow-up titers in 2 to 4 weeks should be considered. An IgG titer of $\geq 1:256$ or a fourfold increase in IgG titer between acute and convalescent samples is consistent with acute infection.

Nucleic acid amplification tests (NAATs) are available in some commercial and research laboratories for testing of tissue or body fluids. *Bartonella* NAATs are highly specific and fairly sensitive for use on tissue, although some tests do not distinguish between the various *Bartonella* species. NAATs of valvular tissue can be important in cases of culture-negative endocarditis. The sensitivity of *Bartonella* NAATs is much lower for whole blood, and this specimen type is not generally recommended for NAATs but may be useful in select circumstances.

B. henselae is a fastidious organism; recovery by routine culture requires prolonged incubation (>10 days) and rarely is successful unless performed in specialized laboratories with experienced staff.

If tissue (eg, lymph node) specimens are available, bacilli occasionally may be visualized using a silver stain (eg, Warthin-Starry or Steiner stain); however, these stains are not specific for *B. henselae*. Early histologic changes in lymph node specimens consist of lymphocytic infiltration with epithelioid granuloma formation. Later changes consist of polymorphonuclear leukocyte infiltration with granulomas that become necrotic and resemble granulomas from patients with tularemia, brucellosis, or mycobacterial infections.

TREATMENT: Management of localized uncomplicated CSD primarily is aimed at relief of symptoms, because the disease is self-limited, resolving spontaneously in 2 to 4 months. No antibiotic regimen has been shown to be beneficial in improving the clinical cure rate, and in most cases, antibiotic therapy is not indicated. Painful suppurative nodes can be treated with needle aspiration for relief of symptoms. Incision and drainage should be avoided, because this may facilitate fistula formation; surgical excision generally is unnecessary.

Some experts recommend antimicrobial therapy in acutely or severely ill immunocompetent patients with systemic symptoms, particularly people with retinitis, hepatic or splenic involvement, osteomyelitis, or painful adenitis. Several antimicrobial agents (azithromycin, clarithromycin, ciprofloxacin, doxycycline, trimethoprim-sulfamethoxazole, ceftriaxone, gentamicin, and rifampin) have in vitro activity against *B. henselae*. However, outcomes for most forms of CSD are generally excellent with or without antibiotic therapy.

Doxycycline plus rifampin are often used for treatment of patients with neuroretinitis. A duration of therapy of 4 to 6 weeks generally has been used on the basis of a small case series in young adults. Doxycycline may be used regardless of patient age.

Reports in the literature note that a large majority of such patients experience significant visual recovery to 20/40 or better. Corticosteroids should be considered in conjunction with ophthalmology consultation.

Antimicrobial therapy is recommended for all immunocompromised people, because treatment of bacillary angiomatosis and bacillary peliosis has been shown to be beneficial. Azithromycin or doxycycline is effective for treatment of these conditions; therapy should be administered for 3 months for bacillary angiomatosis and for 4 months for bacillary peliosis to prevent relapse. Consultation with an infectious disease specialist is recommended for treatment in immunocompromised people.

For pediatric patients with unusual manifestations of *Bartonella* infection (eg, endocarditis or endovascular infection, neuroretinitis, disease in immunocompromised patients), consultation with a pediatric infectious diseases expert is recommended.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: CSD is a preventable infection. All cats >8 weeks of age should be treated topically for fleas and ticks regularly. Effort should be undertaken to avoid scratches and bites from cats or kittens. Sites of cat scratches or bites should be washed immediately, and cats should not be allowed to lick open cuts or wounds. Immunocompromised people should avoid contact with cats younger than 1 year, stray cats, and cats that scratch or bite. Testing or treatment of cats for *Bartonella* infection is not recommended, nor is declawing or removal of the cat from the household.

Baylisascaris Infections

CLINICAL MANIFESTATIONS: Clinical signs of infection with *Baylisascaris procyonis*, the common raccoon roundworm, are likely dependent on inoculum size. Clinically evident infections usually present as acute onset of central nervous system (CNS) disease (neural larva migrans [NLM], eosinophilic meningoencephalitis), with sudden lethargy or somnolence, weakness, irritability, behavioral regression, and decreased awareness and interaction. There may be nuchal rigidity, decreased head control, torticollis, loss of fine motor skills, seizures, impaired vision or speech, ataxia, and difficulty sitting or standing without assistance. Once CNS onset has occurred, usually 2 to 4 weeks after infection, signs may worsen rapidly. NLM is typically accompanied by marked peripheral and/or cerebrospinal fluid (CSF) eosinophilia. Outcomes are related to the amount of inflammatory and mechanical damage occurring from the presence of larvae in the CNS and range from severe neurologic sequelae and death to milder sequelae and, in some cases, improvement with early and aggressive treatment. Other clinical presentations include visceral and ocular larva migrans (VLM, OLM); all 3 types (NLM, VLM, and OLM) may occur concomitantly. The nonspecific signs of VLM, such as rash, fever, abdominal pain, pneumonitis, and hepatomegaly, may be overshadowed by the manifestations of NLM. OLM can result in diffuse unilateral subacute neuroretinitis (DUSN), and direct visualization of a larva in the retina is sometimes possible. Similar to larva migrans caused by *Toxocara* species, subclinical and covert infections seem to be the most common outcome and are likely the result of incidental, low-level *Baylisascaris* infection.

ETIOLOGY: *B. procyonis* is a 9- to 22-cm long roundworm (nematode) that infects raccoons, often subclinically, as its definitive host and a wide variety (>150 species) of mammals and birds as paratenic hosts, in which its larvae aggressively migrate throughout the body. Domestic dogs can also serve as definitive hosts, but less commonly. Some other carnivores (skunks, kinkajous, bears, etc) harbor related *Baylisascaris* species that are potential sources of infection, although no human cases with these animals as a source have been documented.

EPIDEMIOLOGY: *B. procyonis* is widely but variably distributed throughout the United States and Canada and also is found in Europe and Japan. In areas where it is endemic, 20% to >80% of raccoons can harbor the parasite in their intestines. When infective eggs or an infected paratenic host is eaten by a raccoon, the larvae grow to maturity in the small intestine, where adult female worms shed millions of eggs per day in the feces. Eggs become infective only after 2 to 4 weeks in the environment and may persist long-term in the soil. Embryonated eggs containing infective larvae are ingested from the soil by raccoons and other animals, including humans, particularly children. Risk of human infection is greatest in areas where significant raccoon populations live in peridomestic settings. More than 30 cases of *Baylisascaris* CNS disease (including 22 in children), 25 cases of OLM-DUSN (including 10 in children), and 100 seropositive asymptomatic cases have been reported in the United States and Canada, and it is likely that cases may be undiagnosed and/or underreported.

The main risk factor for *Baylisascaris* infection is contact with raccoon latrines, which are communal defecation sites often found at or on the base of trees; raised flat surfaces such as tree stumps, logs, rocks, decks, and rooftops; or unsealed attics or garages. Other risk factors include geophagia/pica, age younger than 4 years, and in older children, developmental delay. Most reported cases of CNS disease have been in male individuals.¹

Unlike *Toxocara* species, *Baylisascaris* larvae grow rapidly following infection, reaching considerable size (1400–1900 μm x 50–80 μm) by 10 to 15 days postinfection. They are aggressive migrators and may enter the brain of experimentally infected animals as early as 3 to 5 days postinfection. Only approximately 5% to 7% of larvae migrate into the CNS, but their size, numbers, aggressiveness, and metabolic products correlate with their high pathogenicity. In one fatal case in an 18-month-old, the brain alone contained an estimated >3200 larvae. Low-level infections, even those involving the CNS, can produce a spectrum of milder focal and/or nonspecific signs.

The **incubation period** in overt CNS cases is usually 2 to 4 weeks.

DIAGNOSTIC TESTS: *Baylisascaris* infection is confirmed by identification of larvae in biopsy specimens. A presumptive diagnosis of NLM can be made on the basis of clinical (meningoencephalitis, sometimes with concomitant VLM and/or OLM-DUSN), epidemiologic (raccoon exposure), and laboratory (blood and CSF eosinophilia) findings. Antibody detection in serum and CSF for patients with clinical symptoms is available at the Centers for Disease Control and Prevention as well as the National Reference Centre for Parasitology in Canada. Neuroimaging results can be normal initially, but as larvae migrate and cause damage to CNS tissues, diffuse or multifocal abnormalities typically develop symmetrically in deep periventricular white matter; the

¹ The term male refers to sex assigned at birth.

cerebellum, or elsewhere; these may progress to atrophic changes. In ocular disease, ophthalmologic examination can reveal chorioretinal lesions and rarely larvae. Stool examination is not helpful, because eggs are not shed in human feces.

TREATMENT: Early diagnostic consideration and treatment are critical. Albendazole, in conjunction with high-dose corticosteroids, has been advocated most widely on the basis of good CNS and CSF penetration and efficacy in experimental animals (see Drugs for Parasitic Infections, p 1068). If infection is suspected, treatment should be initiated promptly, even while the diagnostic evaluation is being completed. Empiric therapy with albendazole should be considered for children with a history of ingestion of soil known or potentially contaminated with raccoon feces; in controlled studies, experimentally infected animals given albendazole on days 1 to 10 postinfection did not develop CNS disease, whereas all untreated animals died. Treatment with albendazole and corticosteroids may not affect clinical outcome if severe CNS disease manifestations are evident. Limited data are available regarding safety and efficacy of alternate anthelmintic therapies in children, although mebendazole and ivermectin have been proposed as alternatives if albendazole is unavailable; both may show efficacy against somatic larvae especially early in infection, but because ivermectin does not cross the blood-brain barrier well, it has limited usefulness in clinical NLM. Larvae localized to the retina and away from sensitive areas can be killed by direct photocoagulation.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS: Standard precautions are recommended. The disease is not transmitted from person-to-person.

CONTROL MEASURES: *Baylisascaris* infections are prevented by avoiding ingestion of soil or other articles contaminated with the feces of infected animal reservoirs, primarily raccoons. People should be educated about the potential risks of this infection, and the keeping of raccoons and other wildlife as pets should be discouraged strongly. Children should be taught to recognize and avoid raccoon defecation sites (latrines) and other animal feces and to wash their hands after contact with soil, pets, or other animals. Raccoon visitation may be discouraged by limiting access to human or pet food sources; problematic animals can be trapped and removed by wildlife personnel. Raccoon latrines identified near homes, child care centers, and other facilities can be decontaminated by feces removal followed by treating the area with boiling water or a propane torch to kill residual eggs, in keeping with local fire safety regulations, or through proper removal if located within the home or other buildings (eg, attic, shed, garage).

Infections With *Blastocystis* Species

CLINICAL MANIFESTATIONS: The importance of *Blastocystis* species as a cause of gastrointestinal tract disease is controversial. The asymptomatic carrier state is well documented. Clinical symptoms reported include bloating, flatulence, acute or chronic watery diarrhea without fecal leukocytes or blood, constipation, abdominal pain, nausea, anorexia, weight loss, and poor growth; fever is generally absent. Some case series and reports have noted an association between infection with *Blastocystis* and chronic urticaria and irritable bowel syndrome. When *Blastocystis* organisms are identified in stool from symptomatic patients, other causes of this symptom complex, particularly

Giardia duodenalis and *Cryptosporidium parvum*, should be investigated before assuming that blastocystosis is the cause of the signs and symptoms. Nucleic acid amplification test (NAAT) fingerprinting suggests that some *Blastocystis* subtypes are disease associated and others are not. An emerging literature reflects increased interest in understanding the role of *Blastocystis* in the gastrointestinal tract microbiome.

ETIOLOGY: *Blastocystis* species (previously referred to as *Blastocystis hominis*) consists of multiple subtypes that reside in the gastrointestinal tracts of humans as well as other mammals, reptiles, amphibians, and fish. Some *Blastocystis* species believed to be specific to other animals are now recognized as being able to be transmitted to humans. Previously classified as a protozoan, more recent molecular studies have led the organism to be characterized as a stramenopile (a eukaryote). Multiple forms have been described: vacuolar, which is observed most commonly in clinical specimens; granular, which is seen rarely in fresh stools; ameboid; and cystic.

EPIDEMIOLOGY: *Blastocystis* infection (colonization) is observed commonly throughout the world, although prevalence among countries and communities varies. In general, prevalence is lower in high-income than lower-income countries, ranging from 1% in Japan to 100% in among school-aged children in countries without modern sanitation. Because transmission is believed to occur via the fecal-oral route, presence of the organism may be a marker for presence of other pathogens spread by fecal contamination. *Blastocystis* infection is more common among people with pets or living near farm animals, but exposure is not sufficient for infection as pathogenicity appears related to subtype, host immunocompetence, and other factors. Organisms may remain in the gastrointestinal tract for years.

The **incubation period** has not been established.

DIAGNOSTIC TESTS: Microscopy is used commonly for diagnosis. Trichome staining is more sensitive than wet mount staining with Lugol iodine. Because of irregular shedding of the parasite, multiple stool specimens should be obtained for evaluation. A variety of morphologies may be seen during microscopy; vacuolar and cystic forms are seen most commonly in stool specimens. The vacuolar form varies markedly in size from 2 to 200 μm and is characterized by a large central body (similar to large vacuole) surrounded by multiple nuclei. The cyst form is smaller, usually 3 to 5 μm , and can be difficult to identify. The parasite may be present in varying numbers, and infections may be reported as light to heavy. The presence of 5 or more organisms per high-power (x400 magnification for wet mount and x1000 for oil immersion) field can indicate heavy infection, which to some experts suggests causation when other enteropathogens are absent. Other experts consider the presence of 10 or more organisms per 10 oil immersion fields (x1000 magnification) to represent heavy infection. Laboratory cultures may improve sensitivity, although slower growing subtypes may be missed in mixed infections.

A serum antibody test is available, but its diagnostic utility is still unclear. Molecular testing with a nucleic acid amplification test (NAAT), including multiplex platforms, detects the presence of *Blastocystis* in far more people than does microscopy alone. The clinical significance and utility of such detections remain unclear. Codetection with other potential pathogens is common.

TREATMENT: Indications for treatment are not established. Some experts recommend that treatment should be reserved for patients who have persistent symptoms

and in whom no other pathogen or process is found to explain the gastrointestinal tract symptoms. Randomized controlled treatment trials with both metronidazole and nitazoxanide have demonstrated benefit in symptomatic patients, although microbiologic resolution does not always occur. Tinidazole is an alternative that may be tolerated better than metronidazole. Case series suggest high resolution of symptoms in symptomatic patients treated with trimethoprim-sulfamethoxazole but variable success in clearing the organism (see Table 4.11, Drugs for Parasitic Infections, p 1068). Case reports or small series indicate paromomycin, iodoquinol, and ketoconazole alone or in combination have varying success. Other experts believe that *Blastocystis* infection does not cause symptomatic disease and recommend only a careful search for other causes of symptoms. Apparent responses to therapy may reflect the natural courses of infection caused by other etiologies, or the therapeutic response of another, unrecognized causative organism by the drug selected to treat *Blastocystis*.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions should be followed; contact precautions also are recommended for diapered or incontinent people.

CONTROL MEASURES: Personal hygiene measures, including hand washing with soap and warm water after using the toilet, after changing diapers, and before preparing food, should be practiced.

Blastomycosis

CLINICAL MANIFESTATIONS: Infections can be acute, chronic, or fulminant but are asymptomatic in up to 50% of infected people. The most common clinical manifestation of blastomycosis in children is cough (often productive) accompanying pulmonary disease, with fever, chest pain, and nonspecific symptoms such as fatigue and myalgia. Rarely, patients may develop acute respiratory distress syndrome (ARDS). Typical radiographic patterns include consolidation, patchy pneumonitis, a mass-like infiltrate, or nodules. Blastomycosis can be misdiagnosed as bacterial pneumonia, tuberculosis, sarcoidosis, or malignant neoplasm. Disseminated blastomycosis, which can occur in up to 25% of symptomatic cases, most commonly involves the skin and osteoarticular structures. Cutaneous manifestations can be verrucous, nodular, ulcerative, or pustular. Abscesses usually are subcutaneous but can involve any organ. Erythema nodosum, which is common in patients with histoplasmosis and coccidioidomycosis, is rare in blastomycosis. Central nervous system infection is less common, and intrauterine or congenital infection is rare.

ETIOLOGY: Blastomycosis is caused by *Blastomyces* species (*Blastomyces dermatitidis*, *Blastomyces gilchristii*, *Blastomyces helices*, *Blastomyces percursus*, and *Blastomyces emzantsi*), which are thermally dimorphic fungi existing in the yeast form at 37°C (98°F) in infected tissues and in a mycelial form at room temperature and in soil. Conidia, produced from hyphae of the mycelial form, are infectious.

EPIDEMIOLOGY: Infection is acquired through inhalation of conidia from the environment. Increased mortality rates for patients with pulmonary blastomycosis have been associated with advanced age, chronic obstructive pulmonary disease, cancer, and Black race. Person-to-person transmission does not occur. In the United States,

blastomycosis is endemic in the central states, with most cases occurring in the Ohio and Mississippi river valleys, the southeastern states, and states that border the Great Lakes; however, sporadic cases have occurred outside these areas. *Blastomyces* species are found in moist soil and decomposing organic matter like wood and leaves. Similar to *Histoplasma capsulatum*, *Blastomyces* species can grow in bird and animal excreta. Occupational and recreational activities associated with infection often involve environmental disruption such as construction of homes or roads, boating and canoeing, tubing on a river, fishing, exploration of beaver dams and underground forts, and community compost piles.

The **incubation period** ranges from approximately 2 weeks to 3 months.

DIAGNOSTIC TESTS: Definitive diagnosis of blastomycosis is based on microscopic identification of characteristic thick-walled, broad-based, single budding yeast cells either by culture at 37°C or in histopathologic specimens. The organism may be seen in sputum, tracheal aspirates, cerebrospinal fluid, urine, or histopathologic specimens from lesions processed with 10% potassium hydroxide or a silver stain. Histopathology demonstrates granulomatous inflammation. Children with pneumonia who are unable to produce sputum may require bronchoalveolar lavage or open biopsy to establish the diagnosis. Bronchoalveolar lavage is high yield, including in patients with bone or skin manifestations. Organisms can be cultured on brain-heart infusion media and Sabouraud dextrose agar at 25°C to 30°C as a mold; identification can be confirmed by conversion to yeast phase at 37°C. Chemiluminescent DNA probes are available for identification of *B dermatitidis*; rare false-positive identification attributable to cross-reactivity with other endemic fungi has been reported. Nucleic acid amplification tests (NAATs) can be used directly on certain clinical specimens but are not widely performed.

Because serologic tests (immunodiffusion and complement fixation) lack adequate sensitivity, they are generally not useful for diagnosis. An enzyme immunoassay that detects *Blastomyces* antigen in urine and blood has replaced classic serologic studies and performs well for the diagnosis of disseminated and pulmonary disease as well as for monitoring response to antifungal therapy. Antigen testing in urine has higher sensitivity than antigen testing of serum, and antigen testing in bronchoalveolar lavage fluid or cerebrospinal fluid is also available. Cross-reactions may occur in patients with dimorphic fungal diseases (eg, coccidioidomycosis, histoplasmosis, paracoccidioidomycosis, sporotrichosis, *Emergomyces africanus* disease, and talaromycosis [formerly penicilliosis]); clinical and epidemiologic distinctions aid in differentiating these entities.

TREATMENT^{1,2}: Because of the high risk of dissemination, most experts recommend that all cases of blastomycosis in children should be treated. Amphotericin B deoxycholate or an amphotericin B lipid formulation is recommended for initial therapy of severe pulmonary disease for 1 to 2 weeks or until improvement, followed by 6 to 12 months of itraconazole therapy. Oral itraconazole is recommended for 6 to

¹ Chapman SW, Dismukes WE, Proia LA, et al. Clinical guidelines for the management of blastomycosis: 2008 update by the Infectious Diseases Society of America. *Clin Infect Dis*. 2008;46(12):1801–1812

² Thompson GR III, Le T, Chindamporn A, et al. Global guideline for the diagnosis and management of the endemic mycoses: an initiative of the European Confederation of Medical Mycology in cooperation with the International Society for Human and Animal Mycology [Erratum in: *Lancet Infect Dis*. 2021;21(11):e341]. *Lancet Infect Dis*. 2021;21(12):e364–e374

12 months for mild to moderate infection (see Table 4.7, p 1021). Some experts suggest 12 months of therapy for patients with osteoarticular disease. For central nervous system infection, a lipid formulation of amphotericin B is recommended for 4 to 6 weeks, followed by an azole for at least 12 months and until resolution of all cerebrospinal fluid and neuroimaging abnormalities. The optimal azole for prolonged central nervous system infection treatment is unknown, but voriconazole is suggested, given the limited central nervous system penetration of itraconazole. Itraconazole is indicated for treatment of non-life-threatening infection outside the central nervous system in adults and is recommended in children.

Serum trough concentrations of itraconazole should be 1 to 2 µg/mL. A trough level should be checked 10 days or later following initiation to ensure adequate drug exposure. When measured by high-pressure liquid chromatography, both itraconazole and its bioactive hydroxyitraconazole metabolite are reported, the sum of which should be considered in assessing the trough concentration. The itraconazole oral solution formulation is preferred over the capsule formulation because of improved absorption, and should be taken on an empty stomach. However, a super bioavailable (SUBA) itraconazole is now approved by the Food and Drug Administration for the treatment of pulmonary and extrapulmonary blastomycosis in individuals 18 years or older, with pharmacokinetic studies of this formulation demonstrating less variable absorption than conventional itraconazole capsules and a similar side effect profile; data in children are lacking.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: None. Immunocompromised individuals should avoid activities that disturb soil in areas where blastomycosis is common.

Bocavirus

CLINICAL MANIFESTATIONS: Human bocavirus (HBoV) was identified in 2005 from a cohort of children with acute respiratory tract symptoms. Pneumonia, bronchiolitis, exacerbations of asthma, upper respiratory tract infection, and acute otitis media have been attributed to HBoV. Rare cases of encephalitis, myocarditis, and disseminated infection have also been reported. Symptoms may include cough, rhinorrhea, wheezing, and fever. HBoV has been identified in up to 33% of children with acute respiratory tract infections in various settings (such as inpatients, outpatients, and group child care attendees). High rates of HBoV subclinical infections have been documented, complicating the etiologic association between HBoV detection and identification of disease. Confirming whether HBoV is a pathogen in human infection is further challenging because of frequent simultaneous detection of other viral pathogens. However, a number of lines of evidence support the role of HBoV as a pathogen, at least during primary infection. These include longitudinal cohort studies showing an association of primary infection with symptomatic illness and case-control studies showing associations of illness with monoinfection, high viral load, viremia, serologic evidence of new infection, and detection of HBoV mRNA. HBoV has been detected in stool samples from children with acute gastroenteritis; however, further studies are needed to better understand the role of HBoV in gastroenteritis.

ETIOLOGY: HBoV is a nonenveloped, single-stranded DNA virus classified in the family *Parvoviridae*, subfamily *Parvovirinae*, genus *Bocaparvovirus*, on the basis of its genetic similarity to the closely related **b**ovine parvovirus 1 and **c**anine minute virus, from which the name “**bocavirus**” was derived. Four distinct genotypes have been described (HBoV types 1–4). HBoV1 replicates in the respiratory tract and has been associated with upper and lower respiratory tract illness. HBoV2, HBoV3, and HBoV4 have been found predominantly in stool and are overall more likely to be detected among children with gastroenteritis than those without gastroenteritis.

EPIDEMIOLOGY: Detection of HBoV has been described only in humans. Transmission is believed to be mainly from respiratory tract secretions, although fecal-oral transmission might also be possible.

The frequent codetection of other viral pathogens of the respiratory tract in association with HBoV has led to speculation about the pathologic role played by HBoV; however, evidence indicates that HBoV can act as either a harmless passenger or lead to illness. Codetection of HBoV with other respiratory viruses is more common when HBoV is present at lower viral loads ($\leq 10^4$ copies/mL). Extended and intermittent shedding of HBoV has been reported for up to a year after initial detection; approximately 15% of children remain positive for 3 or more weeks. HBoV circulates worldwide and throughout the year. In temperate climates, seasonal clustering in the spring associated with increased transmission of other respiratory tract viruses has been reported.

DIAGNOSTIC TESTS: Commercial molecular diagnostic assays for HBoV are available. HBoV quantitative nucleic acid amplification tests (NAATs) (respiratory and serum specimens), detection of HBoV mRNA in the respiratory tract, and detection of HBoV-specific immunoglobulin (Ig) M and IgG antibody also are used by research laboratories to detect the presence of virus and infection.

Because HBoV can be shed for long periods after primary infection, can possibly reactivate during subsequent viral infections, and has a high rate of detection in healthy people, clinical interpretation of HBoV detection is challenging. A positive test result is more likely to represent the cause of illness if no other pathogens are detected, there is viremia, or there is serologic evidence of new infection.

TREATMENT: No specific therapy is available.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Because of the presence of virus in respiratory tract secretions and stool, standard, contact, and droplet precautions should be initiated to limit the spread of infection for the duration of the symptomatic illness in infants and young children. Prolonged shedding of virus in respiratory tract secretions and in stool can occur after resolution of symptoms, particularly among immunocompromised children; longer duration of precautions might be considered in these situations.

CONTROL MEASURES: Respiratory precautions should be followed. Although possible health care-associated transmission of HBoV has been described, transmission of HBoV in health care settings seems to be rare. Appropriate hand hygiene is recommended, particularly when handling respiratory tract secretions or diapers of ill children. The presence of HBoV DNA in serum also raises the possibility of transmission by transfusion, although this mode of transmission has not been documented.

***Borrelia* Infections Other Than Lyme Disease**

(Relapsing Fever)

CLINICAL MANIFESTATIONS: Several types of relapsing fever infections occur in humans: tick-borne relapsing fever spread by soft-bodied ticks, louse-borne relapsing fever, and *Borrelia miyamotoi* infection, or hard tick relapsing fever, spread by hard-bodied ticks. Tick-borne and louse-borne relapsing fevers have many clinical similarities; *B. miyamotoi* can cause an acute febrile illness but its clinical features are less well described. Both tick-borne relapsing fever and louse-borne relapsing fever are characterized by sudden onset of high fever, shaking chills, sweats, headache, muscle and joint pain, altered sensorium, and nausea. A fleeting macular rash of the trunk and petechiae of the skin and mucous membranes sometimes occur but are not common. Findings and complications can differ between types of relapsing fever and include hepatosplenomegaly, jaundice, thrombocytopenia, iridocyclitis, cough with pleuritic pain, pneumonitis, Bell's palsy, meningitis, and myocarditis. Neurologic complications are more common with tick-borne relapsing fever and occur in 10% to 40% of cases. Mortality rates are 10% to 70% in untreated louse-borne relapsing fever (possibly related to comorbidities and outbreaks associated with war, famine, and forced migration) and 4% to 10% in untreated tick-borne relapsing fever. Infection during pregnancy can result in spontaneous abortion, preterm birth, stillbirth, or neonatal infection with high perinatal mortality, as well as death of the pregnant individual. Fatal cases occur predominantly in infants, older adults, and people with underlying illnesses. Early treatment reduces mortality to less than 5%. Untreated, an initial febrile period (typically lasting 2 to 7 days for tick-borne and up to 10 for louse-borne) terminates spontaneously and is followed by an afebrile period of several days to weeks, then by 1 relapse or more. Relapses are more common with tick-borne disease, with generally ≥ 2 relapses (range: 0–13), than for louse-borne disease, with generally < 2 relapses (range: 1–5). Relapses typically become shorter and progressively milder as afebrile periods lengthen. Relapse is associated with expression of new borrelial antigens, and resolution of symptoms is associated with production of antibody specific to those new antigenic determinants.

B. miyamotoi, the cause of hard tick relapsing fever, is phylogenetically similar to the agents of (soft) tick-borne and louse-borne relapsing fevers but appears to cause a wider spectrum of illness, varying from subclinical to severe. Symptoms are similar to those seen with *Anaplasma phagocytophilum* infection and include fever, chills, fatigue, myalgias, arthralgias, lymphadenopathy, and occasionally rash. Relapses can occur but are less common than in tick-borne and louse-borne relapsing fevers. Severe manifestations such as meningoencephalitis can occur and likely are more common in immunocompromised people.

ETIOLOGY: Worldwide, at least 14 *Borrelia* species cause tick-borne relapsing fever, including *Borrelia hermsii*, *Borrelia turicatae*, and (rarely) *Borrelia parkeri* in North America. Louse-borne relapsing fever is caused by *Borrelia recurrentis*. *B. miyamotoi* is the only species known to cause hard tick relapsing fever.

EPIDEMIOLOGY: Because of differences in the distribution, life cycle, and feeding habits of their vector species, the epidemiology of tick-borne relapsing fever, louse-borne relapsing fever, and hard tick relapsing fever differ significantly. Tick-borne relapsing fever is transmitted through the bite of soft-bodied ticks (*Ornithodoros* species) and is

distributed widely throughout the world. Soft-bodied ticks typically live within rodent nests. They become infected by feeding on rodents or other small mammals, and then transmit infection via their saliva during subsequent blood meals. They inflict painless bites and feed briefly (seconds to 30 minutes), usually at night, so that people often are unaware of having been bitten. In the United States, vector soft-bodied ticks are found most often in mountainous areas of the West. Human infection typically follows sleeping in rustic, rodent-infested cabins, although cases have been associated with primary residences and luxurious rental properties. Cases occur sporadically or in small clusters among families or cohabiting groups. Multistate outbreaks have been associated with travel to national parks, where numerous groups may cycle through an infested cabin. *B. hermsii* is the most common cause of these infections. *B. turicatae* infections occur less frequently; most cases have been reported from Texas and are associated with tick exposures in rodent-infested caves. Clinically apparent human infections with *B. parkeri* in the United States are rare; the tick infected with this *Borrelia* species is associated with arid areas or grasslands in the western United States.

Louse-borne relapsing fever previously was widespread but currently is endemic in Ethiopia and occurs sporadically in surrounding countries; cases have been described in Western Europe in refugee and displaced populations originating from the horn of Africa. Epidemic transmission occurs when body lice (*Pediculus humanus*) become infected by feeding on humans with spirochetemia; infection is transmitted when infected lice are crushed and their body fluids contaminate a bite wound or skin abraded by scratching. No animal reservoir has been found for *B. recurrentis*; human-to-human transmission occurs through infected lice.

The hard-bodied ticks *Ixodes scapularis* and *Ixodes pacificus* transmit *B. miyamotoi* in North America. These ticks are better known as vectors of Lyme disease, anaplasmosis, and babesiosis; coinfections have been reported. Contact with *Ixodes* species that transmit *B. miyamotoi* occurs through outdoor activity, especially in woody, brushy, or grassy areas in regions where Lyme disease is endemic. Unlike Lyme disease, *B. miyamotoi* can be transmitted within the first 24 hours of tick attachment, and the probability of transmission increases with prolonged attachment. Most known cases of *B. miyamotoi* infection have occurred in July or August, which is later than most Lyme disease cases. This suggests that *B. miyamotoi* transmission occurs more often through the bite of larval, rather than nymphal, *Ixodes* ticks.

Unlike *B. burgdorferi*, which must be acquired by feeding on an infected host, relapsing fever spirochetes can be transmitted transovarially in ticks; thus, larvae may be infected. Ticks in all stages of life may transmit *B. miyamotoi* infection. The **incubation period** is about 7 days for tick-borne relapsing fever, 4 to 8 days (range, 2–15 days) for louse-borne relapsing fever, and 12 to 16 days for hard tick relapsing fever.

DIAGNOSTIC TESTS: Diagnostic testing differs for tick-borne relapsing fever, louse-borne relapsing fever, and hard tick relapsing fever. In tick-borne and louse-borne relapsing fevers, because of the high degree of spirochetemia during febrile episodes, spirochetes may be observed microscopically using dark-field technique and in Wright-, Giemsa-, or acridine orange-stained preparations of thick and thin smears. Organisms are visualized most easily in blood obtained during early febrile episodes before treatment. Direct detection using a nucleic acid amplification test (NAAT) is available at some commercial and reference laboratories and is more sensitive than microscopy, potentially allowing for detection during afebrile periods or in later

relapses, when spirochetemia is lower. Serum antibodies to *Borrelia* species also can be detected by enzyme immunoassay or Western immunoblot analysis at some reference and commercial specialty laboratories. Serum tested early in infection may be negative, so it is important to obtain a serum sample for serologic testing during the convalescent period (at least 21 days after symptom onset); development of an immunoglobulin (Ig) G response in the convalescent sample is supportive of a tick-borne relapsing fever diagnosis.

Hard tick relapsing fever attributable to *B. miyamotoi* can be diagnosed using a NAAT with blood or cerebrospinal fluid or serologic tests performed on acute and convalescent specimens. These are not available widely but may be ordered from a limited number of commercial and reference laboratories.

In interpreting serologic tests for *Borrelia* infections, it is important to note that early antibiotic treatment may limit antibody response. Antibody tests are not standardized and do not distinguish among relapsing fever species. Serologic cross-reactions can also occur with other spirochetes, including *B. burgdorferi*, *Treponema pallidum*, and *Leptospira* species. Many NAATs also do not distinguish among relapsing fever species.

For inquiries about laboratory testing at the Centers for Disease Control and Prevention, visit www.cdc.gov/laboratory/specimen-submission/list.html.

TREATMENT: Treatment of tick-borne relapsing fever with a 10-day course of doxycycline typically results in prompt clearance of spirochetes and remission of symptoms. Doxycycline can be used regardless of patient age. Effective treatment with macrolide antibiotics, including erythromycin and azithromycin, also has been described. Intravenous beta-lactam antibiotics, such as penicillin or ceftriaxone, are preferred for treatment for pregnant people, when central nervous system involvement is present, in severe illness, or when oral therapy is not well tolerated.

Single-dose treatment using doxycycline or penicillin is effective for louse-borne relapsing fever in the majority of cases, but a longer treatment course is usually applied to minimize the probability of recurrence. Erythromycin or azithromycin may be considered as second-line agents.

Reports of successful treatment of hard tick relapsing fever using a 2-week course of doxycycline suggest this is adequate therapy. Amoxicillin, cefuroxime, and ceftriaxone also have been used or have shown in vitro susceptibility. Azithromycin also may be effective.

A Jarisch-Herxheimer reaction (an acute febrile reaction accompanied by headache, myalgia, respiratory distress in some cases, and a worsening of symptoms lasting less than 24 hours) can occur during the first few hours after initiating antimicrobial therapy for relapsing fever. Because this reaction sometimes is associated with transient hypotension attributable to decreased effective circulating blood volume, patients should be hospitalized and monitored closely, particularly during the first 4 hours of treatment.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended. If louse infestation is present, contact precautions are indicated until delousing (see Pediculosis, p 644–650).

CONTROL MEASURES:

- Tick-borne relapsing fever: Soft-bodied ticks often can be found in rodent nests. Exposure is reduced most effectively by preventing rodent infestations of homes or

cabins by blocking rodent access to foundations and attics and using other forms of rodent control. Dwellings infested with soft ticks should be rodent-proofed and treated professionally with acaricides; rodent control without concurrent tick control may increase risk of infection transiently. In a single observational study from Israel, postexposure prophylaxis with single-dose doxycycline appeared to be effective in preventing tick-borne relapsing fever among 77 spelunkers, 10 of whom were children, following a high-risk exposure.

- Louse-borne relapsing fever: When in a louse-infested environment, body lice can be controlled by bathing, washing clothing at frequent intervals, and use of pediculicides (see Pediculosis, p 644–650).
- Hard tick relapsing fever: Hard-bodied tick exposure can be limited through awareness and avoidance of tick habitat, use of EPA-registered repellents, thorough and frequent tick checks of humans and pets, and bathing/showering soon after being outdoors. Attached ticks should be removed promptly (see Tick Inspection and Removal, p 213).

Reporting suspected cases of relapsing fever to health authorities is required in many states and is important for initiation of prompt investigation and institution of control measures.

Brucellosis

CLINICAL MANIFESTATIONS: Onset of brucellosis in children can be acute or insidious. Manifestations are nonspecific and include fever (often undulating or cyclical), night sweats, weakness, malaise, anorexia, weight loss, arthralgia, myalgia, back pain, abdominal pain, headache, or refusal to bear weight. Physical findings may include lymphadenopathy, hepatosplenomegaly, and arthritis. Abdominal pain and peripheral arthritis are reported more frequently in children than in adults. Meningitis, encephalitis, myelitis, radiculitis, neuropathies, and demyelinating syndromes have been reported. Diffuse hepatitis, hepatic granulomas, liver or spleen abscesses, epididymo-orchitis, pneumonia, lung nodules, pleural effusions, endocarditis, myocarditis, pericarditis, aortic aneurysms, uveitis, osteomyelitis, and cutaneous lesions have all been reported. Anemia, leukopenia, thrombocytopenia, or less frequently, pancytopenia and hemophagocytosis are hematologic findings that might suggest the diagnosis. The case fatality rate is less than 1%, and most deaths occur in children with endocarditis. A detailed history including travel, exposure to animals, food habits (including ingestion of unpasteurized milk or cheese), and occupational history should be obtained if brucellosis is considered. Chronic infection may last for years, and relapse following treatment of infection occurs in 5% to 15% of patients. Chronic disease is less common among children than among adults, although the rate of relapse has been found to be similar. Brucellosis in pregnancy is associated with risk of spontaneous abortion, stillbirth, or preterm delivery.

ETIOLOGY: *Brucella* bacteria are slow-growing, small, nonmotile, facultative intracellular gram-negative coccobacilli. The species that are commonly known to infect humans are *Brucella abortus*, *Brucella melitensis*, *Brucella suis*, and rarely, *Brucella canis*. However, human infections with *Brucella ceti*, *Brucella pinnipedialis*, *Brucella inopinata*, and *Brucella neotomae* also have been identified. *B abortus* strain RB51 is a live attenuated cattle vaccine strain that can be shed in milk and can cause infections in humans.

EPIDEMIOLOGY: Brucellosis is a zoonotic disease of wild and domestic animals. It is transmissible to humans by direct or indirect exposure to aborted fetuses, tissues, or fluids of infected animals. Transmission occurs by inoculation through mucous membranes or cuts and abrasions in the skin, inhalation of contaminated aerosols, ingestion of unpasteurized dairy products, or consumption of undercooked meats.¹ People in occupations such as farming, ranching, and veterinary medicine, as well as abattoir workers, meat inspectors, and laboratory personnel, are at increased risk. Clinicians should alert the laboratory if they anticipate *Brucella* organisms might grow from microbiologic specimens so that appropriate laboratory precautions can be taken. In the United States, approximately 80 to 120 cases of brucellosis are reported annually, and 3% to 10% of cases occur in people younger than 19 years. Human-to-human transmission is rare. Transplacental transmission and transmission via human milk are possible. Other less common modes of transmission include blood transfusion, hematopoietic cell transplant, and sexual transmission. The number of cases in the United States has decreased considerably with routine animal vaccination and pasteurization of milk products.

The **incubation period** varies from 3 days to 12 months, but most people become ill within 2 to 4 weeks of exposure.

DIAGNOSTIC TESTS: A definitive diagnosis is established by recovery of *Brucella* species from blood, bone marrow, or other tissue specimens. A variety of media will support growth of *Brucella* species, but the physician should contact laboratory personnel and ask that cultures be incubated for a minimum of 14 days. Newer blood culture systems can detect *Brucella* species within shorter periods. Caution should be taken with isolation of this organism because of the high risk of laboratory-acquired infection.

In patients with a clinically compatible illness, serologic testing using the serum agglutination test can confirm the diagnosis with a fourfold or greater increase in antibody titers between acute and convalescent phase serum specimens collected at least 2 weeks apart. The serum agglutination test, the gold standard test for serologic diagnosis, will detect antibodies against *B abortus*, *B suis*, and *B melitensis* but not against *B canis* or *B abortus* strain RB51. Although a single titer is not diagnostic, most patients with active infection in an area where brucellosis is not endemic will have a titer of 1:160 or greater within 2 to 4 weeks of clinical disease onset. Lower titers may be found early in the course of infection. Because of low sensitivity of some serologic assays, when results are negative but the clinical suspicion is high, testing should be repeated using a different assay. Enzyme immunoassay is a sensitive method for determining total or specific immunoglobulin (Ig) G, IgA, and IgM anti-*Brucella* antibody titers. The Centers for Disease Control and Prevention (CDC) recommends that positive enzyme immunoassay results be confirmed with an agglutination test.²

When interpreting serologic results, it is important to take into consideration exposure history, because a serologic response for *B canis* and *B abortus* strain RB51 will not be detected by commercially available tests. *Brucella* antibodies also cross-react with antibodies against other gram-negative bacteria, such as *Yersinia enterocolitica* serotype

¹ American Academy of Pediatrics, Committee on Infectious Diseases, Committee on Nutrition. Consumption of raw or unpasteurized milk and milk products by pregnant women and children. *Pediatrics*. 2014;133(1):175-179 (Reaffirmed November 2019)

² www.cdc.gov/brucellosis/pdf/brucellosi-reference-guide.pdf

09, *Francisella tularensis*, *Escherichia coli* O116 and O157, certain *Salmonella* species, *Vibrio cholerae*, *Xanthomonas maltophilia*, and *Afpia clevelandensis*. The timing of exposure and symptom development will assist in determining the classes of antibodies expected. IgM antibodies are produced within the first week, followed by a gradual increase in IgG antibodies. Low IgM titers may persist for months or years after initial infection. Increased concentrations of IgG agglutinins are found in acute infection, chronic infection, and relapse.

Nucleic acid amplification tests (NAATs) that can be performed on blood and body tissue samples have been developed and are available at the CDC. If a laboratory is not available to perform diagnostic testing for *Brucella* species, the physician should contact the local or state health department for assistance.

TREATMENT: Prolonged antimicrobial therapy is imperative for achieving a cure. Relapses generally are not associated with development of *Brucella* resistance but rather with premature discontinuation of therapy, localized infection, or monotherapy. Because monotherapy is associated with a high rate of relapse, combination therapy is recommended as standard treatment. Most combination regimens include oral doxycycline or trimethoprim-sulfamethoxazole plus rifampin.

Oral doxycycline is the drug of choice in persons 8 years of age and older, and should be administered together with oral rifampin for a minimum of 6 weeks. In children younger than 8 years, most data and experience support the use of trimethoprim-sulfamethoxazole administered together with oral rifampin for at least 6 weeks, although oral doxycycline plus rifampin is an alternative. An aminoglycoside can be used in place of rifampin (gentamicin for 7 days or streptomycin for 14 days), in combination with doxycycline or trimethoprim-sulfamethoxazole. See Table 4.3 (p 993) for antibiotic dosages. Failure to complete the full 6-week course of therapy may result in relapse.

For treatment of serious infections or complications, including endocarditis, meningitis, spondylitis, and osteomyelitis, a 3-drug regimen should be used, with gentamicin included for the first 7 days of therapy in addition to doxycycline (or trimethoprim-sulfamethoxazole if doxycycline is not used) and rifampin, for a minimum of 6 weeks. For life-threatening complications of brucellosis, such as meningitis or endocarditis, the duration of therapy often is extended for 4 to 6 months. Surgical intervention should be considered in patients with complications, such as deep tissue abscesses, endocarditis, mycotic aneurysm, and foreign body infections. Joint effusions may need to be drained.

Because of antibiotic resistance with *B abortus* strain RB51, rifampin and penicillin should not be used for treatment of infection caused by this cattle vaccine strain (see Control Measures).

The benefit of corticosteroids for people with neurobrucellosis is unproven. Occasionally, a Jarisch-Herxheimer-like reaction (an acute febrile reaction accompanied by headache, myalgia, respiratory distress in some cases, and a worsening of symptoms lasting less than 24 hours) occurs shortly after initiation of antimicrobial therapy, but this reaction rarely is severe enough to require corticosteroids.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, contact precautions are indicated for patients with draining wounds. If aerosol-generating procedures are performed, respiratory protection (eg, use of N95 or higher respirators) also is indicated.

CONTROL MEASURES: The control of human brucellosis depends on control of transmission of *Brucella* species from cattle, goats, swine, elk, bison, and other animals. Vaccination of cattle, sheep, and goats can be effective but needs to be sustained over several years. Contact with infected animals should be avoided, especially female animals that have aborted or are giving birth.

Lactating parents with active brucellosis should not breastfeed their infants until their infection is cleared. Breastfeeding infants of a lactating parent who is diagnosed with brucellosis should be closely monitored for evidence of infection. Pasteurization of dairy products for human consumption as well as thorough cooking of meat are important for preventing infection. The certification of unpasteurized milk does not eliminate the risk of transmission of *Brucella* organisms.

B abortus strain RB51 is a live attenuated cattle vaccine strain that can be shed in milk and can cause infections in humans. People who have consumed raw milk or raw milk products that are potentially contaminated with the live attenuated cattle vaccine strain *B abortus* strain RB51 are at high risk for brucellosis. For these people, postexposure prophylaxis with doxycycline plus trimethoprim-sulfamethoxazole is recommended for 21 days, in addition to symptom monitoring for 6 months following the last exposure. Because of antibiotic resistance with *B abortus* strain RB51, rifampin and penicillin should not be used (see <https://emergency.cdc.gov/han/han00417.asp>). Cases of brucellosis should be reported to the local health department.

Burkholderia Infections

CLINICAL MANIFESTATIONS: Species within the *Burkholderia cepacia* complex have been primarily associated with infections in individuals with cystic fibrosis (CF) or chronic granulomatous disease (CGD). Airway infections of *B cepacia* complex in people with CF usually occur later in the course of disease, after respiratory epithelial damage and bronchiectasis have occurred. Patients with CF can become chronically infected with little change in the rate of pulmonary decompensation or can experience an accelerated decline in pulmonary function and/or a very rapid clinical deterioration that results in death. In patients with chronic granulomatous disease, pneumonia is the most common manifestation of *B cepacia* complex infection; lymphadenitis also occurs. Disease onset is insidious, with low-grade fever early in the course of illness and systemic effects occurring 3 to 4 weeks later. Pleural effusions are common, and lung abscesses can also occur. Infections have also been reported in people with hemoglobinopathies, malignant neoplasms, and in preterm infants. Health care-associated infections including wound infections, urinary tract infections, pneumonia, and bacteremia have been reported. Infections in immunocompetent and otherwise healthy people are rare.

Burkholderia pseudomallei is the cause of melioidosis. Melioidosis can be asymptomatic or can manifest as a localized infection or as fulminant septicemia with or without pneumonia. Approximately 50% of adults with melioidosis are bacteremic on admission to the hospital; bacteremia is less common in children. Pneumonia is the most commonly reported clinical manifestation of melioidosis in adults, whereas localized cutaneous disease is the most common presentation in immunocompetent children. Genitourinary tract infections including prostatic abscesses, septic arthritis and osteomyelitis, and central nervous system involvement, including brain abscesses, also occur. Acute suppurative parotitis is a manifestation that occurs frequently in children

in Thailand and Cambodia but is less commonly seen in other areas with endemic infection. Necrotizing fasciitis has been reported with severe cutaneous infection. In disseminated infection, hepatic and splenic abscesses can occur, as can disseminated cutaneous abscesses. Relapses are common without prolonged therapy. Chronic melioidosis (presence of symptoms >2 months), which occurs in fewer than 10% of cases, presents most frequently as a subacute pulmonary disease, mimicking tuberculosis. The case fatality rate for melioidosis is 6% to 50%.

ETIOLOGY: The *Burkholderia* genus comprises more than 125 diverse species that are oxidase- and catalase-producing, non-lactose-fermenting, gram-negative bacilli. *B. cepacia* complex comprises at least 22 species. Additional members of the complex continue to be identified but are rare human pathogens. Other clinically important species of *Burkholderia* include *B. pseudomallei*, *Burkholderia mallei* (the agent responsible for glanders), *Burkholderia gladioli*, *Burkholderia thailandensis*, and *Burkholderia oklahomensis*.

EPIDEMIOLOGY: *Burkholderia* species are environmentally derived waterborne and soilborne organisms that can survive for prolonged periods in a moist environment, with the exception of *B. mallei*, which is host-adapted and not known to persist in the environment. Depending on the species, transmission may occur from other people (person to person), from contact with contaminated fomites, and from exposure to environmental sources.

Epidemiologic studies of recreational camps and social events attended by people with CF from different geographic areas have documented person-to-person spread of *B. cepacia* complex. The source of acquisition of *B. cepacia* complex by patients with CGD has not been clearly identified, although environmental sources seem likely. *B. cepacia* complex can persist in the environment and spread through lapses in infection control, including indirect contact via environmental surfaces. Health care-associated spread of *B. cepacia* complex has been associated with contamination of disinfectant solutions used to clean reusable patient equipment, such as bronchoscopes and pressure transducers, or to disinfect skin. Its intrinsic resistance to preservatives enables the organism to contaminate many types of aqueous medical and personal care products, leading to large outbreaks. Contaminated mouthwash, liquid docusate sodium, nasal sprays, sublingual probes, prefilled saline flush syringes, ultrasonography gel, and inhaled medications have been identified as causes of multistate outbreaks of colonization and infection. *B. gladioli* also is isolated from sputum of people with CF and may be mistaken for *B. cepacia* complex. *B. gladioli* may be associated with transient or more prolonged, chronic infection in patients with CF; poor outcomes have been noted in lung transplant recipients who have *B. gladioli* infection.

The geographic range of *B. pseudomallei* is expanding, and disease is known to be endemic in tropical and subtropical regions such as Southeast Asia, northern Australia, areas of the Indian Subcontinent, southern China, Hong Kong, Taiwan, several Pacific and Indian Ocean Islands, and some areas of South and Central America. The US Virgin Islands, Puerto Rico, the Gulf Coast region of Mississippi, and possibly areas in Texas have the organism present in soil. Melioidosis can occur in patients in the United States, usually among travelers returning from areas with endemic disease. A few US cases have been associated with exposure to imported products including freshwater tropical fish and an aromatherapy spray containing essential oils.

In areas of high endemicity, children may be exposed to *B. pseudomallei* early in life, with the highest seroconversion rates occurring between 6 months and 4 years of age.

Melioidosis is seasonal in countries with endemic infection, with more than 75% of cases occurring during the rainy season. Disease can be acquired by direct inhalation of aerosolized organisms or dust particles containing organisms, by percutaneous or wound inoculation with contaminated soil or water, or by ingestion of contaminated soil, water, or food. People also can become infected through laboratory exposures when proper techniques and/or proper personal protective equipment guidelines are not followed. Symptomatic infection can occur in children 1 year or younger, with pneumonia and parotitis reported in infants as young as 8 months; in addition, human milk transmission from breastfeeding parents with mastitis has been reported.

Risk factors for melioidosis include frequent contact with soil and water as well as underlying chronic disease, such as diabetes mellitus, renal insufficiency, chronic pulmonary disease, thalassemia, and immunosuppression not related to human immunodeficiency virus (HIV) infection. *B pseudomallei* also has been reported to cause pulmonary infection in people with cystic fibrosis and septicemia in children with CGD.

The **incubation period** for melioidosis is 1 to 21 days, with a median of 9 days, but can be prolonged (years).

DIAGNOSTIC TESTS: Culture is the appropriate method to diagnose *B cepacia* complex infection. In CF airway infection, culture of sputum on selective agar is recommended to decrease the potential for overgrowth by mucoid *Pseudomonas aeruginosa*. Confirmation of identification of *B cepacia* complex species by matrix-assisted laser desorption/ionization-time of flight (MALDI-TOF) mass spectrometry or by nucleic acid amplification test (NAAT) is recommended.

Definitive diagnosis of melioidosis is made by isolation of *B pseudomallei* from blood or other specimens. The likelihood of successfully isolating the organism is increased by culture of sputum, throat, rectum, and ulcer or skin lesion specimens, in addition to blood. Serologic testing is not adequate for diagnosis in areas with endemic infection because of high background seropositivity. However, a positive result by the indirect hemagglutination assay for a traveler who has returned from an area with endemic infection may support the diagnosis of melioidosis; definitive diagnosis still requires isolation of *B pseudomallei* from blood or other specimens.

Suspected isolates of *B pseudomallei* and *B mallei* should be referred to local or state Public Health Laboratory Response Network Laboratories. Whenever there is clinical suspicion for melioidosis or glanders, the initial laboratory should be notified so that staff can take appropriate precautions, and if identified, the potential for occupational exposure should be evaluated.

TREATMENT: Drugs that may have activity against *B cepacia* complex include trimethoprim-sulfamethoxazole, ceftazidime, minocycline, fluoroquinolones, carbapenems, and newer beta-lactam/beta-lactamase inhibitor combinations. Some experts recommend combinations of antimicrobial agents that provide synergistic activity against *B cepacia* complex in vitro. The majority of *B cepacia* complex isolates are intrinsically resistant to aminoglycosides and polymyxins and are resistant to many beta lactam agents such as penicillin, ampicillin, carboxypenicillins, and first- and second-generation cephalosporins.

The drugs of choice for initial treatment of melioidosis depend on the type of clinical infection, susceptibility testing, and presence of comorbidities in the patient (eg, diabetes mellitus, liver or renal disease, cancer, hemoglobinopathies, cystic fibrosis).

Treatment of severe invasive infection should include meropenem or ceftazidime (rare resistance) for a minimum of 14 days, with prolonged therapy (at least 4–8 weeks) for deep-seated and complicated infections. After acute therapy is completed, oral eradication therapy with trimethoprim-sulfamethoxazole for 3 to 6 months is recommended to reduce recurrence. Amoxicillin clavulanate is considered a second-line oral agent and may be associated with a higher rate of relapse.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

The Cystic Fibrosis Foundation recommends implementation of contact precautions in addition to standard precautions for care of all patients with CF in inpatient or ambulatory care settings, regardless of respiratory tract cultures. Human-to-human transmission is extremely rare for *B pseudomallei*, and standard precautions are recommended.

CONTROL MEASURES: Because some strains of *B cepacia* complex cause a highly virulent course in some patients with new acquisition, the Cystic Fibrosis Foundation recommends that all CF care centers limit contact between patients. This includes inpatient, outpatient, and social settings. When in a health care setting, patients with CF should wear a mask while outside of a clinic examination room or a hospital room. Education of patients and families about hand hygiene and appropriate personal hygiene is recommended.

Prevention of infection with *B pseudomallei* in areas with endemic disease can be difficult because contact with contaminated water and soil is common. People with diabetes mellitus, renal insufficiency, or general immunocompromising conditions should avoid contact with soil and standing water in areas suspected to be contaminated. Wearing boots and gloves during agricultural work in areas with endemic disease and thorough cleaning and protecting of skin wounds is recommended. Patients with CF and diabetes should be educated regarding their risk of infection when traveling to regions where *B pseudomallei* is endemic. A human vaccine is not available, but research is ongoing. Potential laboratory exposures with *B pseudomallei* or *B mallei* should be reviewed with public health authorities to determine management including indications for postexposure prophylaxis (generally with trimethoprim-sulfamethoxazole for 21 days or amoxicillin clavulanate for 21 days). Public health authorities may recommend postexposure prophylaxis to *B pseudomallei* in certain instances.

Public Health Reporting. Melioidosis is a nationally notifiable disease, and cases should be reported to local or state health departments.

Campylobacter Infections

CLINICAL MANIFESTATIONS: Predominant symptoms of *Campylobacter* infection include diarrhea, abdominal pain, malaise, and fever. Stools can contain visible or occult blood. In neonates and young infants, bloody diarrhea without fever can be the only manifestation of infection. Febrile seizures may precede gastrointestinal tract symptoms in young children. Abdominal pain resulting from campylobacteriosis can mimic appendicitis or intussusception. Mild infection lasts 1 or 2 days and resembles viral gastroenteritis. Most patients recover in less than 1 week, but 10% to 20% have a relapse or a prolonged or severe illness. Severe or persistent infection can mimic acute inflammatory bowel disease. Bacteremia is uncommon but can occur in patients with

underlying conditions. Immunocompromised hosts can have prolonged, relapsing, or extraintestinal infections, especially with *Campylobacter fetus*. Immunoreactive complications, such as Guillain-Barré syndrome (occurring in 1:1000), Miller Fisher variant of Guillain-Barré syndrome (ophthalmoplegia, areflexia, ataxia), reactive arthritis (with the classic triad consisting of arthritis, urethritis, and bilateral conjunctivitis), myocarditis, pericarditis, and erythema nodosum, can occur during convalescence. Postinfectious irritable bowel syndrome can occur after campylobacteriosis.

ETIOLOGY: *Campylobacter* species are motile, comma-shaped, gram-negative bacilli that are associated with gastroenteritis. There are at least 25 species within the genus *Campylobacter*, but *Campylobacter jejuni* and *Campylobacter coli* are the species isolated most commonly from patients with diarrhea. *C fetus* is predominantly associated with systemic illness in neonates and debilitated hosts. Other *Campylobacter* species, including *Campylobacter lari*, *Campylobacter upsaliensis*, and *Campylobacter hyointestinalis*, can result in similar diarrheal or systemic illnesses in children.

EPIDEMIOLOGY: Although many cases go unidentified, *Campylobacter* species was associated with an estimated 19.5 laboratory-confirmed infections per 100 000 people in 2019, the highest incidence of bacterial foodborne infection in the United States. Although incidence decreased in the early 2000s, data from the Foodborne Diseases Active Surveillance Network (FoodNet) indicated that in recent years, the incidence of reported infections increased, likely resulting from the increased use and sensitivity of culture-independent diagnostic tests (CIDTs). The highest rates of infection occur in children younger than 5 years. Most *Campylobacter* infections are acquired domestically, but up to 1 in 5 cases result from international travel. As few as 500 *Campylobacter* organisms can result in infection.

The gastrointestinal tracts of domestic and wild birds and animals are reservoirs of the bacteria. *C jejuni* and *C coli* have been isolated from feces of 30% to 100% of healthy chickens, turkeys, and waterfowl. Poultry carcasses commonly are contaminated. Many farm animals, pets, and meat sources can harbor the organism and are potential sources of infection. Most cases of *Campylobacter* infection are associated with consumption of undercooked poultry, meat, and other food that has been contaminated. Outbreaks of *Campylobacter* infection have been associated with unpasteurized dairy products, contaminated water, improperly cooked poultry, and produce.¹ Transmission of *C jejuni* and *C coli* occurs by ingestion of contaminated food or water or by direct contact with fecal material from infected animals or people. *Campylobacter* infections usually are sporadic; outbreaks are rarely detected but have occurred among school age participants on field trips to dairy farms where they consumed unpasteurized milk, and among people who had contact with pet store puppies (www.cdc.gov/campylobacter/outbreaks/outbreaks.html). Person-to-person spread occurs occasionally, particularly among very young children, and risk is greatest during the acute phase of illness. Person-to-person transmission has occurred from infected birthing parents to neonates and has resulted in health care-associated outbreaks in nurseries. In perinatal infection, *C jejuni* and *C coli* usually cause neonatal gastroenteritis, whereas *C fetus* often causes neonatal septicemia or meningitis. Enteritis occurs

¹ American Academy of Pediatrics, Committee on Infectious Diseases, Committee on Nutrition. Consumption of raw or unpasteurized milk and milk products by pregnant women and children. *Pediatrics*. 2014;133(1):175-179 (Reaffirmed November 2019)

in people of all ages. Excretion of *Campylobacter* organisms typically lasts 2 to 3 weeks without antimicrobial treatment but can occur for 7 weeks.

The **incubation period** usually is 2 to 5 days but can be longer.

DIAGNOSTIC TESTS: *C. jejuni* and *C. coli* can be recovered from feces, and *Campylobacter* species, including *C. fetus*, can be recovered from blood. Isolation of *C. jejuni* and *C. coli* from stool specimens requires selective media, microaerobic conditions, and an incubation temperature of 42°C. Additional methods may be necessary to isolate other species of *Campylobacter*, such as hydrogen-rich microaerobic conditions and filter plating on media without antibiotic supplements. Notably, not all clinical laboratories identify *Campylobacter* to the species level; clinicians can consult state public health laboratories for further identification. Molecular and antigen CIDs can provide rapid diagnostic testing; however, these tests will not produce an isolate to provide antibiotic susceptibilities. False-positive results from antigen-based tests have been reported. Molecular tests that detect bacterial DNA may not reflect viable organisms; therefore, clinical correlation is needed. Additionally, some diagnostics may not distinguish between *C. jejuni* and *C. coli* and may not detect other *Campylobacter* species. Referral of isolates and CIDT-positive specimens to state public health laboratories is based on state requirements. Molecular analysis of isolates is important for national *Campylobacter* surveillance and outbreak monitoring.

TREATMENT: Rehydration is the mainstay of treatment for all children with diarrhea. Most patients with *Campylobacter* diarrhea do not require antimicrobial therapy. Antibiotics should be given in invasive cases of *Campylobacter* infection (eg, bacteremia) and can be considered in patients at risk for severe disease including the very young, elderly, or immunosuppressed. Macrolide antibiotics such as azithromycin and erythromycin shorten the duration of illness and excretion of the bacteria. Approximately 2% of *C. jejuni* and 5% to 9% of *C. coli* isolates are resistant to macrolides. Antimicrobials may prevent relapse when administered early in gastrointestinal tract infection. Treatment with azithromycin usually eradicates the organism from stool within 2 or 3 days. Fluoroquinolones, such as ciprofloxacin, may be effective, but throughout the world, resistance to ciprofloxacin is common (up to 35% of *C. jejuni* and *C. coli* isolates in 2019 from the United States; see also Fluoroquinolones, p 973). *C. fetus* generally is susceptible to aminoglycosides, extended-spectrum cephalosporins, meropenem, imipenem, ampicillin, and erythromycin. Regularly updated resistance information for *C. jejuni* and *C. coli* based on CDC surveillance can be found at www.cdc.gov/narmsnow/. Antimicrobial susceptibility testing of the isolate or epidemiologic data from the location of acquisition can help guide appropriate therapy. If antimicrobial therapy is administered for treatment of gastroenteritis, the recommended duration is 3 to 5 days. Antimotility agents are generally not recommended in children because of their limited benefit and reports of adverse outcomes in those who received these agents as monotherapy.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, contact precautions are recommended for diapered and incontinent children for the duration of illness.

CONTROL MEASURES:

- Hand hygiene should be performed after handling raw poultry and cutting boards, and utensils should be washed with soap and hot water after contact with raw poultry. Food preparation areas and cutting boards used for raw poultry should be separate from all other foods, especially fruits and vegetables.

- Poultry should be cooked thoroughly.
- Hand hygiene should be performed after contact with feces of dogs, cats, and farm animals.
- People should not drink raw milk.¹ The certification of raw milk does not eliminate the risk of transmission of *Campylobacter* organisms.
- Chlorination of water supplies is important.
- People with diarrhea should be excluded from food handling, care of patients in hospitals, and care of people in custodial care and child care centers.
- Infected food handlers and hospital employees who are asymptomatic need not be excluded from work if proper personal hygiene measures, including hand hygiene, are maintained.
- People with diarrhea should not go into recreational water (see Prevention of Illnesses Associated With Recreational Water, p 214) and should abstain from recreational water for 1 week after resolution of symptoms (or as advised by local public health authorities).
- Outbreaks of campylobacteriosis are uncommon in child care centers. General measures for interrupting enteric transmission in child care centers are recommended (see Children in Group Child Care and Schools, p 145). Infants and children should be excluded from child care centers until either stools are contained in the diaper or, if the child is continent, when no longer having fecal accidents and stool frequency is no more than 2 stools above that child's normal frequency, even if the stools remain loose. Although antibiotics are not generally recommended, azithromycin or erythromycin treatment may reduce the potential for person-person transmission.
- Diagnostic testing of asymptomatic exposed children is not recommended.

Public Health Reporting. *Campylobacter* infection is a nationally notifiable disease, and cases should be reported to local or state health departments.

Candidiasis

CLINICAL MANIFESTATIONS: Mucocutaneous infection results in oral-pharyngeal (thrush) or vaginal or cervical candidiasis; intertriginous lesions of the gluteal folds, buttocks, neck, groin, and axilla; paronychia; and onychia. Dysfunction of T lymphocytes, other immunologic disorders, and endocrinologic diseases are associated with chronic mucocutaneous candidiasis. Chronic or recurrent oral candidiasis can be the presenting sign of human immunodeficiency virus (HIV) infection or primary immunodeficiency. Esophageal and laryngeal candidiasis can occur in immunocompromised patients. Candidemia can result from indwelling central vascular catheters, especially in patients receiving prolonged intravenous infusions with parenteral alimentation or lipids, or from translocation from the gastrointestinal tract, especially in the setting of neutropenia. End-organ involvement (ie, disseminated candidiasis) can present with or without candidemia. Disseminated candidiasis is more common in certain patient groups, such as extremely preterm neonates and immunocompromised or debilitated hosts, can involve virtually any organ or anatomic site, and can be fatal. Peritonitis can occur in patients undergoing peritoneal dialysis, especially in patients receiving

¹ American Academy of Pediatrics, Committee on Infectious Diseases, Committee on Nutrition. Consumption of raw or unpasteurized milk and milk products by pregnant women and children. *Pediatrics*. 2014;133(1):175-179 (Reaffirmed November 2019)

prolonged broad-spectrum antimicrobial therapy. Candiduria can occur in patients with indwelling urinary catheters, focal renal infection, or disseminated disease. Congenital cutaneous candidiasis involves the presence of a diffuse skin rash of major skin areas of the body, extremities, face, or scalp and/or funisitis presenting in the first week of life with identification of *Candida* species or yeast from culture or staining of the skin, placenta, or umbilical cord. Dermatologic findings include desquamation (scaling, peeling, flaking, or exfoliation), maculopapular, papulopustular, or erythematous rashes alone or in combination.

ETIOLOGY: *Candida* species are yeasts that reproduce by budding. *Candida albicans* and several other species form long chains of elongated yeast forms called pseudohyphae. *C. albicans* is the most common species associated with candidiasis, but in some regions and patient populations, non-*albicans* *Candida* species now account for more than half of invasive infections. *Candida parapsilosis* is the most common non-*albicans* species in pediatric and neonatal populations. Numerous other non-*albicans* species, including but not limited to *Candida tropicalis*, *Candida glabrata*, *Candida krusei*, *Candida guilliermondii*, *Candida lusitanae*, and *Candida dubliniensis*, can cause serious infections, especially in immunocompromised and debilitated hosts. *Candida auris* is a *Candida* species that is often multidrug resistant and generally acquired in health care settings.

EPIDEMIOLOGY: Mucocutaneous or invasive *Candida* infections occur endogenously from anatomical sites (eg, skin, mouth, intestinal tract, and vagina) colonized by *Candida* species. Vulvovaginal candidiasis is associated with pregnancy, and newborn infants can acquire the organism in utero, during passage through the vagina, or postnatally. Mild mucocutaneous infection is common in healthy infants. People with poorly controlled diabetes mellitus may also develop localized mucocutaneous infections. Invasive candidiasis typically occurs in those with impaired immunity. Factors such as extreme prematurity, neutropenia, or treatment with corticosteroids or cytotoxic chemotherapy increase the risk of invasive infection. People with neutrophil defects, such as chronic granulomatous disease or myeloperoxidase deficiency, also are at increased risk. People undergoing intravenous alimentation or receiving broad-spectrum antimicrobial agents, especially extended-spectrum cephalosporins, carbapenems, and vancomycin, or requiring long-term indwelling central venous or peritoneal dialysis catheters, have increased susceptibility to infection. Postsurgical patients can be at risk, particularly after cardiothoracic or abdominal procedures. Person-to-person transmission occurs rarely for most *Candida* species but can occur with *C. auris*.

The **incubation period** is unknown.

DIAGNOSTIC TESTS: Presumptive diagnosis of mucocutaneous candidiasis in the oropharynx (thrush) and inguinal (diaper candidiasis) or vaginal (vulvovaginal candidiasis) sites usually can be made clinically, although other organisms can cause clinically similar lesions. Yeast cells and pseudohyphae can be found in infected tissue and are identifiable by microscopic examination of scrapings prepared with Gram, calcofluor white, or fluorescent antibody stains or in a 10% to 20% potassium hydroxide suspension. Endoscopy is useful for diagnosis of esophagitis. Although ophthalmologic examination can reveal typical retinal lesions attributable to hematogenous dissemination, the yield of routine ophthalmologic evaluation in patients with candidemia is low. Lesions in the brain, kidney, liver, heart, or spleen can be detected by ultrasonography, computed tomography (CT), or magnetic resonance imaging, but these lesions may not be detected by imaging early in the course of disease or during neutropenia.

A definitive diagnosis of invasive candidiasis requires isolation of the organism from a normally sterile body site (eg, blood, cerebrospinal fluid, bone marrow) or demonstration of organisms in a tissue biopsy specimen. Negative results of culture for *Candida* species do not exclude invasive infection; the sensitivity of blood culture is <50%. Special fungal culture media are not needed to grow *Candida* species. A presumptive species identification of *C. albicans* can be made by demonstrating germ tube formation, and molecular fluorescence in situ hybridization testing can rapidly distinguish *Candida* species. Recovery of the organism is expedited using automated blood culture systems or a lysis-centrifugation method. Peptide nucleic acid fluorescent in situ hybridization (PNA FISH) probes cleared by the US Food and Drug Administration (FDA) and multiplex nucleic acid amplification tests (NAATs) have been developed for rapid detection of *Candida* species directly from positive blood culture bottles.

Because of its high resistance and transmissibility, it is important to distinguish *C. auris* from other *Candida* species. *C. auris* may be misidentified as another *Candida* species when using certain laboratory methods. Options for *C. auris* diagnostic testing are expanding, but the current gold standards for identifying *C. auris* isolates are matrix-assisted laser desorption/ionization–time-of-flight (MALDI-TOF) and whole genome sequencing.

Patients with suspected infection can have their serum tested using the assay for (1,3)-beta-D-glucan from fungal cell walls, but this biomarker has a number of limitations. It does not distinguish *Candida* species from other fungi. There are limited data from pediatric cohorts, there are a significant number of false-positive results, and the diagnostic cut-point for this assay is not well established in children. A molecular assay (T2Candida) cleared by the FDA uses magnetic resonance technology to identify 5 different *Candida* species from a whole blood specimen but data on the performance of this assay in children are limited.

Testing for azole susceptibility is recommended for all bloodstream and other clinically relevant *Candida* isolates. Testing for echinocandin susceptibility should be considered in patients who have had prior treatment with an echinocandin and among those who have infection with *C. glabrata*, *C. parapsilosis*, or *C. auris*.

TREATMENT¹:

Mucous Membrane and Skin Infections. Oral candidiasis in immunocompetent hosts is treated with oral nystatin suspension, clotrimazole troches applied to lesions, or miconazole mucoadhesive buccal tablets. Troches should not be used in infants. Fluconazole may be more effective than oral nystatin or clotrimazole troches and may be considered if other treatments fail. Fluconazole can be beneficial for immunocompromised patients with oropharyngeal candidiasis. For fluconazole-refractory disease, itraconazole, voriconazole, posaconazole, amphotericin B preparations, or intravenous echinocandins (caspofungin, micafungin) are alternatives.

Esophagitis caused by *Candida* species generally is treated with oral fluconazole. Intravenous fluconazole should be used for patients who cannot tolerate oral therapy. For disease refractory to fluconazole, itraconazole solution (because of improved absorption compared with capsules), voriconazole, posaconazole, or an echinocandin is recommended. The recommended duration of therapy is 14 to 21 days but depends

¹ Pappas PG, Kauffman CA, Andes DR, et al. Clinical practice guideline for the management of candidiasis: 2016 update by the Infectious Diseases Society of America. *Clin Infect Dis*. 2016;62(4):e1-e50

on severity of illness and patient factors, such as age and degree of immunocompromise. Changing from intravenous to oral therapy with fluconazole is recommended when the patient is able to tolerate oral intake. Suppressive therapy with fluconazole (3 times weekly) is recommended for recurrent infections.

Skin infections are treated with topical nystatin, miconazole, clotrimazole, naftifine, ketoconazole, econazole, or ciclopirox (see Topical Drugs for Superficial Fungal Infections, p 1037). Nystatin usually is effective and is the least expensive of these drugs.

Vulvovaginal candidiasis is treated effectively with many topical formulations, including clotrimazole or miconazole (available over the counter). Such topically applied azole drugs are more effective than nystatin. Oral azole agents also are effective and should be considered for recurrent or refractory cases (see Recommended Doses of Parenteral and Oral Antifungal Drugs, p 1026).

Nipple and ductal breast infections with candidiasis have been described with breastfeeding. Topical treatment as above may be adequate for nipple infection, but systemic treatment with fluconazole is often used in breast infections, with continuation of breastfeeding.

For chronic mucocutaneous candidiasis, fluconazole, itraconazole, and voriconazole are effective drugs. Relapses are common with any of these agents once therapy is terminated, and treatment should be viewed as a lifelong process that generally requires intermittent pulses of antifungal agents. Invasive infections in these patients with this condition are rare.

For management of asymptomatic candiduria, elimination of predisposing factors, such as indwelling bladder catheters, is strongly recommended. Antifungal treatment is not recommended unless patients are at high risk of candidemia, such as neutropenic patients and preterm infants. If candiduria occurs in a preterm infant, evaluation should be performed (blood cultures, cerebrospinal fluid evaluation, ophthalmologic examination, brain imaging, and abdominal ultrasonography) and treatment should be initiated.

For patients with symptomatic *Candida* cystitis, elimination of predisposing factors, such as indwelling bladder catheters, is strongly recommended, in addition to use of fluconazole for 2 weeks. Repeated bladder irrigations with amphotericin B (50 µg/mL of sterile water) have been used to treat patients with candidal cystitis. However, the comparative effectiveness of this procedure has not been established, and it does not treat disease beyond the bladder; for these reasons, it is not recommended routinely. Urinary catheters, if not able to be removed, should be replaced promptly in patients with candiduria. Echinocandins have poor urinary concentration.

Keratomyces is treated with corneal baths of voriconazole (1%) and always in conjunction with systemic therapy. Vision-threatening infections (near the macula or into the vitreous) require intravitreal injection of antifungal agents, usually amphotericin B or voriconazole, with or without vitrectomy, in addition to systemic antifungal agents.

Invasive Disease

General Recommendations. The echinocandins (caspofungin, micafungin, and anidulafungin) are all active in vitro against most *Candida* species and are recommended first-line drugs for invasive *Candida* infections beyond the neonatal period (see Antifungal Drugs for Systemic Fungal Infections, p 1017). Most *Candida* species are susceptible to amphotericin B, although *C lusitaniae*, *C auris*, and some strains of *C glabrata* and *C*

krusei exhibit decreased susceptibility or resistance (see Table 4.7, Fungal Species and Antifungal Drugs, p 1021). *C auris* is often resistant to fluconazole and amphotericin B, but most strains remain susceptible to echinocandins. Thus, echinocandins should be used as initial therapy for *C auris*, and susceptibility testing should be performed along with careful monitoring of patients for treatment effectiveness. Investigation for a deep focus of infection should be conducted for all patients with candidemia, regardless of species, when candidemia persists despite appropriate therapy.

Fluconazole resistance is seen in most *C krusei* isolates (which are intrinsically resistant), in more than 50% of *C glabrata* isolates, and approximately 90% of *C auris* isolates. Although voriconazole is effective against *C krusei*, it is often ineffective against *C glabrata* and *C auris*. Earlier studies suggested decreased susceptibility to echinocandins among *C parapsilosis*, but data now suggest echinocandin resistance is extremely rare. If an echinocandin is initiated empirically and *C parapsilosis* is isolated in a patient who is recovering, then the echinocandin can be continued. Removal of infected devices (eg, vascular or peritoneal catheters, ventriculostomy drains, shunts, nerve stimulators, prosthetic reconstructive devices) is absolutely necessary in addition to antifungal treatment. Breastfeeding may continue during treatment of the parent for candidiasis.

Neonatal Candidiasis. In extremely low birth weight infants, candidemia and candiduria have similar mortality of 28% and 26%, respectively, and mortality is 50% or greater with meningitis, peritonitis, and if multiple sites are involved. Comparatively, mortality is much lower (2%) for infants weighing >1000 g at birth. Infants are more likely than older children and adults to have meningitis as a manifestation of candidiasis. Although meningitis can occur in association with candidemia, approximately half of infants with *Candida* meningitis do not have a positive blood culture. Central nervous system disease in the infant typically manifests as meningoencephalitis and should be assumed to be present in the infant with candidemia and signs and symptoms of meningoencephalitis because of the high incidence of this complication.

All infants with cultures positive for *Candida* in the blood should have a lumbar puncture, brain imaging, echocardiography, dilated retinal examination, and ultrasonography (or other imaging) of the renal system, liver, and spleen during the first week after diagnosis. For term infants with candiduria alone, only ultrasonography of the renal system is needed.

Amphotericin B deoxycholate (first choice for infants), fluconazole, or an echinocandin (generally reserved for salvage therapy and once central nervous system infection is excluded), can be used in infants with systemic candidiasis. Amphotericin B deoxycholate is recommended for treatment at a dose of 1 mg/kg intravenously, daily, as the majority of neonatal infections are susceptible and resistance is rare. Fluconazole may be used for isolates susceptible to fluconazole in patients who are clinically stable. Therapy for candidemia without metastatic disease should continue for 2 weeks after documented clearance of *Candida* species from the blood by culture and resolution of signs attributable to candidemia. Congenital cutaneous candidiasis should receive systemic antifungal therapy for 2 weeks. Therapy for central nervous system infection is at least 3 weeks and should be continued until all signs, symptoms, and cerebrospinal fluid and imaging abnormalities, if present, have resolved. For central nervous system infections, end-organ dissemination, or prolonged candidemia >7 days, some experts recommend double coverage with a second antifungal agent until clinical improvement is achieved. Rescreening for end-organ dissemination

should be performed if blood cultures are persistently positive for *Candida* species. For candidemia, antifungal therapy plus prompt removal/replacement of central venous catheters is recommended within 24 hours of diagnosis and decreases both mortality and dissemination.

Lipid formulations of amphotericin B should be used with caution in infants, particularly in infants with urinary tract involvement. Published reports in adults and anecdotal reports in preterm infants indicate that lipid-associated amphotericin B preparations have failed to eradicate renal candidiasis, because these large-molecule drugs may not penetrate well into the renal parenchyma. It is unclear whether this is the reason for the inferior outcomes reported with the lipid formulations. Dosing may also be a factor, and if used lipid amphotericin B formulation can be dosed at 5 mg/kg daily. Flucytosine is not recommended routinely for infants because of concerns regarding toxicity and lack of efficacy.

Older Children and Adolescents. In neutropenic or nonneutropenic children and adults, an echinocandin (caspofungin, micafungin, anidulafungin) is preferred treatment according to guidelines, but fluconazole may be considered in those who are considered clinically stable and also are unlikely to have a fluconazole-resistant isolate. Transition from an echinocandin to fluconazole (usually in 5 to 7 days) is indicated in patients who are clinically stable, have isolates that are susceptible to fluconazole, and have negative blood cultures following initiation of antifungal therapy. Amphotericin B deoxycholate or lipid formulations are alternative therapies (see Antifungal Drugs for Systemic Fungal Infections, p 1017). In nonneutropenic patients with candidemia and no metastatic complications, treatment should continue for 2 weeks after documented clearance of *Candida* organisms from the bloodstream and resolution of clinical manifestations associated with candidemia.

In patients who are not critically ill, fluconazole is the alternative treatment for patients who have not had recent azole exposure, but voriconazole can be considered in situations in which additional mold coverage is desired. Duration of treatment for candidemia without metastatic complications is 2 weeks after documented clearance of *Candida* organisms from the bloodstream and resolution of symptoms attributable to candidemia. Avoidance or reduction of systemic immunosuppression is advised when feasible.

For chronic disseminated candidiasis (eg, hepatosplenic infection), initial therapy with lipid formulation amphotericin B or an echinocandin for several weeks is recommended, followed by oral fluconazole (only for patients who are unlikely to have a fluconazole-resistant isolate). Duration of therapy will vary based on resolution of clinical and radiographic findings as well as immune system recovery.

Management of Indwelling Catheters. Prompt removal of any infected vascular or peritoneal catheters is strongly recommended, although this recommendation is weaker for neutropenic children, because the source of candidemia in these patients is more likely to be gastrointestinal and it is difficult to determine the relative contribution of the catheter. Immediate replacement of a catheter over a wire in the same catheter site is not recommended. Replacement can be attempted once the infection is controlled.

Additional Assessments. Nonneutropenic patients with candidemia should have a dilated ophthalmologic examination within the first week after diagnosis. In neutropenic patients, dilated fundoscopic examinations should be performed within the first week after counts have recovered, because ophthalmologic findings of choroidal and

vitreal infection may not be apparent until recovery from neutropenia is achieved. Although there is emerging evidence that ophthalmologic evaluations may be low yield, they are recommended in guidelines from the Infectious Diseases Society of America.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended for all *Candida* species except *C. auris*, for which both Standard and Contact Precautions are recommended because of the high transmissibility of this species.

CONTROL MEASURES: Prolonged broad-spectrum antimicrobial therapy and use of systemic corticosteroids in susceptible patients promote overgrowth of *Candida* and predispose to invasive infection. Meticulous care of central intravascular catheters is recommended for any patient requiring long-term intravenous access.

Additional control measures are recommended for *C. auris*, because this organism is spread easily in health care facilities. Patients with *C. auris* should be placed in a single room whenever possible, with Standard and Contact Precautions implemented. Hand hygiene should be performed diligently, and the patient care environment and reusable equipment should be cleaned and disinfected thoroughly using products effective against *C. auris*. Communication of the patient's *C. auris* status should be clear to associated health care personnel and, if the patient is transferred, to the receiving health care facility. Surveillance and screening of other patients also should be considered to identify transmission so that infection control measures can be implemented for any other patients who may have *C. auris*.

Chemoprophylaxis. Invasive candidiasis in infants is associated with prolonged hospitalization and neurodevelopmental impairment or death in almost 75% of affected infants with extremely low birth weight (less than 1000 g). The poor outcomes, despite prompt diagnosis and therapy, make prevention of invasive candidiasis in this population desirable. A number of randomized controlled trials of fungal prophylaxis in extremely preterm infants have demonstrated significant reduction of invasive candidiasis in patients with risk factors and at high risk for *Candida*-associated mortality and neurodevelopmental impairment. Risk factors for invasive candidiasis in infants include extreme prematurity, gastrointestinal pathology, presence of a central venous catheter, exposure to third- or fourth-generation cephalosporins or carbapenems, postnatal steroids, and H2 blockers. Adherence to optimal infection control practices, including “bundles” for intravascular catheter insertion and maintenance and antimicrobial stewardship, can diminish infection rates and should be optimized as standard practice in a neonatal intensive care unit. Fluconazole is the preferred agent for prophylaxis and is recommended for extremely low birth weight infants (<1000 g) with factors that place them at significant risk for invasive candidiasis or who are in NICUs with significant rates (5%–10% or higher) of invasive candidiasis. Some experts recommend using additional criteria tailored to individual infant risk factors (eg, presence of central venous catheter, receipt of third- or fourth-generation cephalosporins or carbapenems, parenteral nutrition, gastrointestinal tract disease) to recommend fluconazole prophylaxis. The recommended regimen for extremely low birth weight infants is to initiate fluconazole prophylaxis intravenously shortly after birth at a dose of 3 or 6 mg/kg and then to administer it twice a week while requiring intravenous access (central or peripheral) for up to 6 weeks. Once infants tolerate enteral feeds, fluconazole can be transitioned to enteral administration, because fluconazole oral absorption is good, even in preterm

infants. This chemoprophylaxis dosage, dosing interval, and duration has not been associated with emergence of fluconazole-resistant *Candida* species in randomized trials.

Antifungal prophylaxis should be considered for children undergoing allogeneic hematopoietic cell transplantation and other highly myelosuppressive chemotherapy during the period of neutropenia. However, in patients with prolonged neutropenia, an antifungal prophylaxis agent with antimold activity is often preferred (see Table 4.7, p 1021). Fluconazole prophylaxis is recommended in certain solid organ transplant scenarios (eg, after prolonged surgical procedure for a liver transplant). Prophylaxis is not recommended routinely for other immunocompromised children, including children with HIV infection. Fluconazole prophylaxis can decrease the risk of mucosal (eg, oropharyngeal and esophageal) candidiasis in patients with advanced HIV disease. Increased incidence of breakthrough *C krusei* or *C glabrata* infections, species with increased resistance to fluconazole, has been reported in some patient populations that are frequently prescribed fluconazole.

Chancroid and Cutaneous Ulcers

CLINICAL MANIFESTATIONS: Chancroid is an acute ulcerative disease of the genitalia that occurs primarily in sexually active adolescents and adults. A clinical presentation with a painful genital ulcer and tender suppurative inguinal lymphadenopathy should raise suspicion for chancroid. An ulcer begins as an erythematous papule that becomes pustular and erodes over several days, forming a sharply demarcated, somewhat superficial lesion with a serpiginous border. The base of the ulcer is friable and can be covered with a gray or yellow, purulent exudate. Single or multiple ulcers can be present. Unlike a syphilitic chancre, which is typically painless and indurated, the chancroidal ulcer often is painful and nonindurated and can be associated with painful inguinal suppurative adenitis (bubo) ipsilateral to the lesion. Without treatment, ulcer(s) can spontaneously resolve, cause extensive erosion of the genitalia, or lead to scarring and phimosis, a painful inability to retract the foreskin of the penis.

In most male patients, chancroid manifests as a genital ulcer with or without inguinal tenderness; edema of the prepuce is common.¹ In female patients, most lesions are at the vaginal introitus, and symptoms include dysuria, dyspareunia, and vaginal discharge. People with anal infection may have pain on defecation or anal bleeding. Constitutional symptoms are unusual.

ETIOLOGY: Chancroid and cutaneous ulcers are caused by *Haemophilus ducreyi*, a gram-negative coccobacillus.

EPIDEMIOLOGY: Chancroid is a sexually transmitted infection. Chancroid is prevalent in some parts of Africa and the tropics but is uncommon in the United States, and when it does occur, it is usually imported from areas with endemic infection. Thus, recent travel to or from an area with endemic infection should raise suspicion for this diagnosis. Coinfection with syphilis or herpes simplex virus (HSV) occurs in up to 20% of patients. Chancroid is a well-established cofactor for acquisition and transmission of human immunodeficiency virus (HIV).

Because sexual contact is the major route of transmission in the United States, the diagnosis of chancroid ulcers in infants and young children, especially in the genital or

¹ The terms male and female refer to sex assigned at birth.

perineal region, is highly suspicious of sexual abuse. However, *H ducreyi* is recognized as a cause of nonsexually transmitted cutaneous ulcers in children and young adults in some tropical regions and, specifically, in countries where the cutaneous ulcer disease yaws, caused by *Treponema pallidum* subspecies *pertenue*, is endemic. The acquisition of a lower extremity ulcer attributable to *H ducreyi* in a child without genital ulcers and reported travel to a region with endemic yaws should not be considered evidence of sexual abuse.

For both chancroid and cutaneous ulcers, the **incubation period** is 1 to 10 days.

DIAGNOSTIC TESTS: Chancroid usually is diagnosed on the basis of clinical findings and by excluding other genital ulcerative diseases, such as syphilis, HSV infection, or lymphogranuloma venereum. Cutaneous ulcers can be diagnosed on the basis of clinical findings described, but clinical findings overlap, and mixed infections with *H ducreyi* and *T pallidum* subspecies *pertenue* (the cause of yaws) are common. Confirmation is made by isolation of *H ducreyi* from an ulcer (specimen should be taken from the base of the ulcer) or lymph node aspirate, although culture sensitivity is less than 80%. Because special culture media and conditions are required for isolation, laboratory personnel should be informed of the suspicion of *H ducreyi*. Approximately 30% to 40% of lymph node aspirates are culture positive. Nucleic acid amplification tests (NAATs) can provide a specific diagnosis but are not widely available. There is no NAAT for *H ducreyi* approved or cleared by the US Food and Drug Administration available in the United States. Such testing can be performed by clinical laboratories that have developed their own NAAT and have conducted CLIA verification studies.

TREATMENT: Genital strains of *H ducreyi* have been uniformly susceptible only to third-generation cephalosporins, macrolides, and quinolones. The prevalence of antibiotic resistance is unknown because of syndromic management of genital ulcers and the lack of diagnostic testing. Recommended regimens include azithromycin orally in a single dose, ceftriaxone intramuscularly in a single dose, ciprofloxacin orally for 3 days, or erythromycin orally for 7 days (see Table 4.4, p 1007, and Table 4.5, p 1014). Patients with HIV infection and those with an uncircumcised penis may require repeated or longer courses of therapy. In syndromic management approaches to genital ulcer disease, treatment will typically include syphilis as well as chancroid.

Clinical improvement occurs 3 to 7 days after initiation of therapy, and healing is complete in approximately 2 weeks. Adenitis often is slow to resolve and can require needle aspiration or surgical incision. Patients should be reexamined 3 to 7 days after initiating therapy to verify healing. If healing has not begun, the diagnosis may be incorrect or the patient may have an additional sexually transmitted infection (both of which necessitate further testing), the treatment may not have been used as instructed, or the *H ducreyi* strain causing the infection may be resistant to the prescribed antimicrobial therapy. Slow clinical improvement and relapses can occur after therapy, especially in people with HIV infection. Close clinical follow-up is recommended; retreatment with the original regimen usually is effective in patients who experience a relapse. In advanced cases, genital scarring and rectal or urogenital fistulas from suppurative buboes can result despite successful therapy.

Patients with chancroid should be evaluated for other sexually transmitted infections, including syphilis, HSV, chlamydia, gonorrhea, mpox, and HIV infection, at the time of diagnosis. Because chancroid is a risk factor for HIV infection and facilitates HIV transmission, if the initial HIV test result is negative, it should be repeated

3 months after the diagnosis of chancroid. Because syphilis and *H ducreyi* are frequently cotransmitted, serologic testing for syphilis also should be repeated 3 months after the diagnosis of chancroid. If the hepatitis B and human papillomavirus vaccine series have not been completed, these immunizations should be offered if appropriate for age. All people who had sexual contact with patients with chancroid within 10 days before onset of the patient's symptoms need to be examined and treated, even if they are asymptomatic.

Penicillin has long been used as empiric therapy for cutaneous ulcers in the tropics, but several beta-lactamase-producing cutaneous *H ducreyi* strains have been recovered. Cutaneous ulcers, therefore, should be treated with single-dose azithromycin (30 mg/kg, maximum 2 g) to cover both *T pallidum* subspecies *pertenue* (the cause of yaws) and *H ducreyi*. Cutaneous ulcers attributable to *H ducreyi* respond to single-dose azithromycin within 14 days. Given the environmental sources, it is unclear whether contacts of people with leg ulcers should be treated.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: Identification, examination, and treatment of sexual partners of patients with chancroid are important control measures. Regular condom use may decrease transmission, and penile circumcision is believed to be partially protective.

Chikungunya

CLINICAL MANIFESTATIONS: Most people infected with chikungunya virus become symptomatic. The disease most often is characterized by acute onset of high fever (typically $>39^{\circ}\text{C}$ [102°F]) and polyarthralgia. Other symptoms may include widespread maculopapular rash, headache, generalized myalgia, back pain, severe fatigue, arthritis, conjunctivitis, photophobia, anorexia, nausea, vomiting, diarrhea, and abdominal pain. Hemorrhagic manifestations are rare. Fever typically lasts for several days to a week and can be biphasic. Rash usually occurs after onset of fever, can be pruritic, and typically involves the trunk and extremities, but the palms, soles, and face may be affected. Joint symptoms are often severe and debilitating, are usually bilateral and symmetric, and occur most commonly in the hands and feet but can affect more proximal joints. Young children present with arthralgia less frequently than older children and adults. The term chikungunya derives from a word in the Kimakonde language from southeast Tanzania and northern Mozambique meaning “to become contorted,” in reference to the stooped appearance of affected people attributable to the joint pain. Clinical laboratory findings can include lymphopenia, thrombocytopenia, elevated creatinine, and elevated hepatic aminotransferases. Acute symptoms typically resolve within 7 to 10 days. Meningoencephalitis, myelitis, seizures, Guillain-Barré syndrome, and cranial nerve palsies occur rarely but appear to be the most common severe complications of chikungunya virus infection. Other rare complications include uveitis, retinitis, myocarditis, arrhythmias, pericarditis, pneumonia, respiratory failure, hepatitis, nephritis, bullous skin lesions, and hemorrhage. Perinatal infection may present with a sepsis-like syndrome. Acrocyanosis without hemodynamic instability, symmetrical vesicobullous lesions, generalized brown-to-black macular hyperpigmentation, and edema of the lower extremities may occur in newborn infants. People at risk for severe disease include neonates exposed perinatally, older adults (eg, >65 years), and

people with underlying medical conditions (eg, hypertension; diabetes mellitus; cardiovascular, liver, and kidney disease; and alcohol use disorder). Some patients might have relapse of rheumatologic symptoms (polyarthralgia, polyarthritis, and tenosynovitis) in the months following acute illness. Arthralgia is the most frequent chronic symptom. Studies report variable proportions of patients with persistent joint pains for months to years. Chronic chikungunya arthritis closely mimics classic rheumatoid arthritis and can be erosive with autoantibody positivity in some patients. Risk factors for chronic arthralgia are age >50 years, arthritis during the acute phase, severe or prolonged initial infection, and high viral load. Mortality is rare.

The similar epidemiology and possible cocirculation of chikungunya virus with dengue and Zika viruses demonstrate the increasing need to consider these diagnoses in travelers returning from tropical and subtropical regions of the Americas presenting with an acute febrile illness. Patients with coinfections may have more severe manifestations.

ETIOLOGY: Chikungunya virus is a single-stranded RNA virus in the *Alphavirus* genus of the *Togaviridae* family.

EPIDEMIOLOGY: Chikungunya virus is transmitted to humans primarily through the bites of infected mosquitoes, predominantly *Aedes aegypti* and *Aedes albopictus*. Humans are the primary host of chikungunya virus during epidemic periods. Following an initial infection, a person is likely to be protected from future infections. Bloodborne transmission is possible; cases have been documented among laboratory personnel handling infected blood and in a health care worker drawing blood from an infected patient. To date, there are no known reports of virus transmission through blood transfusion. Rare in utero transmission has been documented, mostly during the second trimester. Intrapartum transmission also has been documented when the mother was viremic around the time of delivery. There are no reports of infants infected with chikungunya virus through breastfeeding.

Before 2013, outbreaks of chikungunya infection were reported from countries in Africa, Asia, Europe, and the Indian and Pacific Oceans. In 2013, chikungunya virus was found for the first time in the Americas on islands in the Caribbean. The virus then spread rapidly throughout the Americas, with local transmission reported from 44 countries and territories and more than 1 million suspected cases reported by the end of 2014. Chikungunya virus disease cases were reported among US travelers returning from affected areas in the Americas beginning in 2014, and local transmission was identified in Florida, Puerto Rico, Texas, and the US Virgin Islands. Reports of cases in the United States can be found at www.cdc.gov/chikungunya/geo/index.html.

The **incubation period** typically is between 3 and 7 days (range, 1–12 days).

DIAGNOSTIC TESTS: Preliminary diagnosis is based on the patient's clinical features, places and dates of travel, and activities. Laboratory diagnosis generally is accomplished by testing serum to detect virus, viral nucleic acid, or virus-specific immunoglobulin (Ig) M and neutralizing antibodies. During the first week after onset of symptoms, chikungunya virus infection often can be diagnosed by performing a nucleic acid amplification test (NAAT) on serum. Chikungunya virus-specific IgM and neutralizing antibodies normally develop toward the end of the first week of illness. IgM levels tend to peak between 4 and 20 days after symptom onset and usually persist for 30 to 90 days, but

longer persistence has been documented. Therefore, a positive IgM test result on serum occasionally may reflect a past infection. A plaque-reduction neutralization test can be performed to quantitate virus-specific neutralizing antibodies and to discriminate between cross-reacting antibodies (eg, Mayaro, Ross River, and onyong nyong viruses). Immunohistochemical staining can detect specific viral antigen in fixed tissue.

Routine molecular and serologic testing for chikungunya virus is performed at commercial laboratories, several state health department laboratories, and Centers for Disease Control and Prevention (CDC) laboratories. Plaque-reduction neutralization tests and immunohistochemical staining are performed at the CDC and selected other reference laboratories.

TREATMENT: Although several therapeutic options have been or are being evaluated, including use of traditional antiviral compounds and monoclonal antibodies, currently there is no treatment available and approved for chikungunya. Management is supportive care and includes rest, fluids, analgesics, and antipyretics. In areas where dengue is endemic, acetaminophen is the preferred treatment for fever and joint pain. Nonsteroidal anti-inflammatory drugs should be avoided initially until a dengue diagnosis is ruled out to reduce the risk of hemorrhagic complications with dengue infection. Corticosteroids also should be avoided during the acute phase, because they can cause impairment in the natural recovery process and there is a risk of rebound effect after discontinuation. Patients with persistent joint pain may benefit during the chronic phase from the use of nonsteroidal anti-inflammatory drugs, corticosteroids, and physiotherapy. Disease-modifying antirheumatic drugs (DMARDs) such as methotrexate, sulfasalazine, chloroquine, and hydroxychloroquine, have been used in some patients with severe persistent arthritis.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: On November 9, 2023, the US Food and Drug Administration approved Ixchiq, the first chikungunya vaccine. Ixchiq is approved for individuals 18 years and older who are at increased risk of exposure to chikungunya virus. This live attenuated vaccine is administered as a single intramuscular dose. Recommendations for use of the vaccine by the CDC Advisory Committee on Immunization Practices are anticipated in 2024. Reduction of vectors in areas with endemic transmission is important to reduce risk of infection. Symptomatic febrile patients should be protected from mosquito bites to reduce further spread. Use of certain personal protective measures can help decrease risk of human infection, including using insect repellent, wearing long pants and long-sleeved shirts, staying in screened or air-conditioned dwellings, and limiting outdoor activities during peak vector feeding times (see Prevention of Mosquito-borne and Tick-borne Infections, p 207).

Breastfeeding. Chikungunya viral RNA has been documented in human milk during an acute chikungunya virus infection, but no infants have been found to be infected through breastfeeding.

Public Health Reporting. Chikungunya is a nationally notifiable disease. Health care professionals should report suspected chikungunya cases to their state or local health departments to facilitate diagnosis and mitigate risk of local transmission. State health departments should report laboratory-confirmed cases to the CDC through ArboNET, the national surveillance system for arboviral diseases.

CHLAMYDIAL INFECTIONS

Chlamydia pneumoniae

CLINICAL MANIFESTATIONS: Patients may be asymptomatic or mildly to moderately ill with a variety of respiratory tract diseases caused by *Chlamydia pneumoniae*, including pneumonia, acute bronchitis, prolonged cough, and less commonly, pharyngitis, laryngitis, otitis media, and sinusitis. A sore throat precedes the onset of cough by a week or more in some patients. The clinical course can be biphasic, culminating in atypical pneumonia. *C pneumoniae* can present as severe community-acquired pneumonia in immunocompromised hosts and has been associated with onset or acute exacerbation of respiratory symptoms in patients with asthma, cystic fibrosis, and sickle cell disease with acute chest syndrome. Rare cases of meningoencephalitis and myocarditis have been attributed to *C pneumoniae*.

Physical examination may reveal nonexudative pharyngitis, pulmonary rales, and bronchospasm. Chest radiography may reveal a variety of findings ranging from pleural effusion and bilateral infiltrates to a single patchy subsegmental infiltrate. Illness can be prolonged, and cough can persist for 2 to 6 weeks or longer.

ETIOLOGY: *C pneumoniae* is an obligate intracellular bacterium for which entry into mucosal epithelial cells is necessary for intracellular survival and growth. It exists in both an infectious nonreplicating extracellular form called an elementary body and a replicating intracellular form called a reticulate body. Reticulate bodies replicate within a protective intracellular membrane-bound vesicle called an inclusion.

EPIDEMIOLOGY: *C pneumoniae* infection is presumed to be transmitted from person to person via infected respiratory tract secretions. Infection typically peaks between 5 and 15 years of age but may occur earlier in life in tropical and resource-limited areas. In the United States, approximately 50% of adults have *C pneumoniae*-specific serum antibody by 20 years of age, indicating previous infection. Recurrent infection is common, especially in adults. Clusters of infection have been reported in groups of children and adults. There is no evidence of seasonality.

The mean **incubation period** is 21 days.

DIAGNOSTIC TESTS: Nucleic acid amplification tests (NAATs) are the preferred method for the diagnosis of an acute *C pneumoniae* infection because of their utility for rapid and accurate detection. Specimen types that can be assayed may vary according to the laboratory; thus, acceptable and preferred specimen types as well as storage and transport conditions should be confirmed with the laboratory prior to testing. Multiplex NAATs have been cleared by the US Food and Drug Administration for the diagnosis of *C pneumoniae* using nasopharyngeal swab samples. These tests have high sensitivity and specificity for acute infection. However, nasopharyngeal shedding can occur for months after acute disease, even with treatment.

C pneumoniae is difficult to culture but can be isolated from swab specimens obtained from the nasopharynx or oropharynx, from sputum or bronchoalveolar lavage fluid specimens, or from tissue biopsy specimens at specialized laboratories using cell cultures (www.cdc.gov/pneumonia/atypical/cpneumoniae/hcp/diagnostic.html). Immunohistochemistry, used to detect *C pneumoniae* in tissue specimens, requires control antibodies and tissues, in addition to skill in recognizing staining artifacts to avoid false-positive results.

Serologic testing for *C. pneumoniae* is problematic. The microimmunofluorescent antibody test is the most sensitive and specific serologic test for acute infection, but it is technically complex and its interpretation is subjective. A fourfold increase in immunoglobulin (Ig) G titer between acute and convalescent sera provides evidence of acute infection. Use of a single IgG titer in diagnosis of acute infection is not recommended, because IgG antibody may not appear until 6 to 8 weeks after onset of illness during primary infection and increases within 1 to 2 weeks after reinfection. In primary infection, IgM antibody appears approximately 2 to 3 weeks after onset of illness, and an IgM titer of 1:16 or greater is supportive of an acute infection. However, caution is advised when interpreting a single IgM antibody titer for diagnosis, because a single result can be either falsely positive because of cross-reactivity with other *Chlamydia* species or falsely negative in cases of reinfection, when IgM may not appear. Early antimicrobial therapy may suppress antibody responses. Past exposure is indicated by a stable IgG titer of 1:16 or greater.

TREATMENT: Most respiratory tract infections believed to be caused by *C. pneumoniae* are treated empirically. For suspected *C. pneumoniae* infections, treatment with macrolides (eg, azithromycin, erythromycin, or clarithromycin) is recommended. Doxycycline can be used without regard to patient age, but tetracycline should not be administered routinely to children younger than 8 years (see Tetracyclines, p 975). Fluoroquinolones (levofloxacin and moxifloxacin) are additional alternative drugs for patients who are unable to tolerate macrolide antibiotic agents but generally should not be used as first-line treatment. In vitro data suggest that *C. pneumoniae* is not susceptible to sulfonamides.

Duration of therapy typically is 10 to 14 days for erythromycin, clarithromycin, tetracycline, or doxycycline. With azithromycin, the treatment duration typically is 5 days. Duration of therapy for levofloxacin is 7 to 14 days and for moxifloxacin is 10 days. However, for all these antimicrobial agents, the optimal duration of therapy has not been established.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS: Standard precautions.

CONTROL MEASURES: Recommended prevention measures include employing respiratory hygiene (or cough etiquette), and frequent hand hygiene.

Chlamydia psittaci **(Psittacosis, Ornithosis, Parrot Fever)**

CLINICAL MANIFESTATIONS: Psittacosis (ornithosis) is an acute respiratory tract infection with systemic symptoms that often include fever, nonproductive cough, dyspnea, headache, myalgia, chills, and malaise. Infection often presents as atypical pneumonia in young or middle-aged adults with abrupt fever onset, headache, and dry cough, although symptoms can also include pharyngitis, diarrhea, constipation, nausea and vomiting, abdominal pain, arthralgia, rash (Horder spots, which are macular rashes similar to the rose spots of typhoid fever), and altered mental status. Extensive interstitial pneumonia can occur, with radiographic changes characteristically more severe than would be expected from physical examination findings. Rarely, infection with *Chlamydia psittaci* has been reported to affect organ systems other than the respiratory tract, resulting in arthritis, endocarditis, myocarditis, pericarditis, dilated

cardiomyopathy, thrombophlebitis, nephritis, hepatitis, cranial nerve palsy (including sensorineural hearing loss), transverse myelitis, meningitis, and encephalitis. Infection in pregnancy may be life-threatening to the pregnant person and cause fetal loss. Reports suggest a rare association of psittacosis with ocular adnexal marginal zone lymphomas involving orbital soft tissue, lacrimal glands, and conjunctiva.

ETIOLOGY: *C psittaci* is a gram-negative, obligate intracellular bacterial pathogen that exists in 2 forms. The extracellular form is called an elementary body and is infectious. The elementary body enters the epithelial host cell and then differentiates into a replicating reticulate body within a membrane-bound vesicle, or inclusion.

EPIDEMOLOGY: Psittacosis is worldwide in distribution and tends to occur sporadically in any season. Birds are the major reservoir of *C psittaci*. The term psittacosis commonly is used, although the term ornithosis more accurately describes the potential for nearly all domestic and wild birds, not just psittacine birds (eg, parakeets, parrots, macaws, cockatoos), to spread this infection. In the United States, a variety of birds including psittacine birds, poultry birds (eg, chickens, ducks, turkeys, pheasants), and pigeons have been reported as sources of human disease. Infected birds, whether they appear healthy or ill, may transmit the organism. Infection usually is acquired by direct contact or inhaling aerosolized excrement or respiratory secretions from the eyes or beaks of infected birds. Once dry, the organism remains viable for months, particularly at room temperature. Importation and illegal trafficking of exotic birds may be associated with disease in humans, because shipping, crowding, and other stress factors may increase shedding of the organism among birds with latent infection. Handling of plumage and mouth-to-beak contact are the modes of exposure described most frequently, although transmission has been reported through exposure to aviaries, poultry slaughter plants, bird exhibits, and lawn mowing. Excretion of *C psittaci* from birds may be intermittent or continuous for weeks or months. Pet bird owners and breeders, veterinarians, and workers at poultry slaughter plants, poultry farms, and pet shops may be at increased risk of infection. Laboratory personnel working with *C psittaci* also are at risk. Human-to-human transmission may occur but is rare.

The **incubation period** usually is 5 to 14 days but may be longer.

DIAGNOSTIC TESTS: The diagnosis of *C psittaci* disease historically has been based on clinical presentation and a positive serologic test result using microimmunofluorescence (MIF) with paired sera. Although the MIF test generally is more sensitive and specific than complement fixation (CF) tests, MIF still displays cross-reactivity with other *Chlamydia* species in some instances. Because of this, a titer less than 1:128 should be interpreted with caution. Paired acute- and convalescent-phase serum specimens obtained at least 2 to 4 weeks apart should be obtained and performed simultaneously within a single laboratory to ensure consistency of results.¹ Treatment with antimicrobial agents may suppress the antibody response and, in such cases, a third serum sample obtained 4 to 6 weeks after the acute-phase sample may be useful in confirming the diagnosis. Although serologic testing is more commonly used and available than molecular testing, serologic test results can often be ambiguous, subjective in their interpretation, and misleading because of the inherent limitations of this approach. If possible,

¹ National Association of State Public Health Veterinarians. Compendium of measures to control *Chlamydia psittaci* infection among humans (psittacosis) and pet birds (avian chlamydiosis). *J Avian Med Surg*. 2017;31(3). Available at: www.nasphv.org/Documents/PsittacosisCompendium.pdf

serologic testing should be considered a supportive test that augments the findings of other more reliable assays, such as nucleic acid amplification tests (NAATs), which can distinguish *C psittaci* from other chlamydial species. NAATs are available within specialized laboratories (www.cdc.gov/laboratory/specimen-submission/detail.html?CDC_TestCode=CDC-10153), but none are cleared by the US Food and Drug Administration for detection of *C psittaci* in clinical specimens. Commercial respiratory multiplex NAATs do not test for *C psittaci*. Because the organism is difficult to recover in culture and laboratory-acquired cases have been reported, culture generally is not recommended and should be attempted only by experienced personnel in laboratories in which strict containment measures to prevent spread of the organism are used. *C psittaci* currently is classified as an organism requiring biosafety level 3 biocontainment practices.

TREATMENT: Doxycycline is the drug of choice and can be used without regard to patient age. Erythromycin and azithromycin are alternative agents and are recommended for pregnant people. Therapy should continue for 10 to 14 days after fever abates. Most *C psittaci* infections are responsive to antimicrobial agents within 1 to 2 days. In patients with severe infection, intravenous doxycycline may be considered.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS: Standard precautions are recommended.

CONTROL MEASURES: All birds suspected to be the source of human infection should be seen by a veterinarian for evaluation and management. Birds with *C psittaci* infection should be isolated and treated with appropriate antimicrobial agents.¹ Birds suspected of dying from *C psittaci* infection should be transported to an animal diagnostic laboratory for testing as directed by the laboratory. Birds exposed to psittacosis should be also isolated and monitored by a veterinarian for signs of illness even if they do not appear ill. All potentially contaminated caging and housing areas should be disinfected thoroughly before reuse to eliminate any infectious organisms. People cleaning cages, handling birds confirmed with *C psittaci*, or handling birds exposed to those confirmed with *C psittaci* should wear personal protective equipment including a smock or coveralls, gloves, eyewear, designated footwear or shoe covers, a disposable hat, and a disposable N95 or higher respirator. *C psittaci* is susceptible to many but not all household disinfectants and detergents. Effective disinfectants include 1:1000 dilutions of quaternary ammonium compounds, freshly prepared 1:32 dilutions of household bleach (1/2 cup per gallon), or other oxidizing agents such as accelerated hydrogen peroxide-based disinfectants.

Public Health Reporting. Human psittacosis is a nationally notifiable disease. Please refer to the state or local health department for details on reporting cases.

Chlamydia trachomatis

CLINICAL MANIFESTATIONS: *Chlamydia trachomatis* is associated with a range of clinical manifestations, including neonatal conjunctivitis, nasopharyngitis, and pneumonia in young infants as well as genital tract infection, lymphogranuloma venereum (LGV), and trachoma in children, adolescents, and adults.

¹ National Association of State Public Health Veterinarians. Compendium of measures to control *Chlamydia psittaci* infection among humans (psittacosis) and pet birds (avian chlamydiosis). *J Avian Med Surg*. 2017;31(3). Available at: www.nasphv.org/Documents/PsittacosisCompendium.pdf

- **Neonatal chlamydial conjunctivitis** is characterized by ocular congestion, edema, and discharge developing a few days to several weeks after birth and lasting for 1 to 2 weeks and sometimes longer. In contrast to trachoma (described below), scars and pannus formation (vascularization of the normally avascular cornea) are rare.
- **Pneumonia** in young infants usually is an afebrile subacute illness typically occurring at age 1 to 3 months. A repetitive staccato cough, tachypnea, and rales in an afebrile 1-month-old infant are characteristic but not always present. Wheezing is uncommon. Hyperinflation usually accompanies infiltrates seen on chest radiographs. Nasal stuffiness and otitis media may occur. Untreated disease can linger or recur. Severe chlamydial pneumonia has occurred in infants and some immunocompromised adults.
- **Genitourinary tract** manifestations, such as vaginitis in prepubertal children; urethritis, cervicitis, endometritis, salpingitis, and pelvic inflammatory disease, with or without perihepatitis (Fitz-Hugh-Curtis syndrome) in postpubertal children and adolescents; urethritis and epididymitis; and reactive arthritis (with the classic triad, formerly known as Reiter syndrome, consisting of arthritis, urethritis, and bilateral conjunctivitis) can occur. Infection can persist for months to years. Reinfection is common. Infection often is asymptomatic.
- **Proctocolitis** may occur in individuals who engage in receptive anal intercourse. Symptoms can resemble those of inflammatory bowel disease, including mucoid or hemorrhagic rectal discharge, constipation, tenesmus, and/or anorectal pain. Stricture or fistula formation can follow severe or inadequately treated infection. Infection often is asymptomatic.
- **LGV** classically is an invasive lymphatic infection with an initial ulcerative lesion on the genitalia accompanied by tender, suppurative inguinal and/or femoral lymphadenopathy that typically is unilateral. The ulcerative lesion often resolves by the time the patient seeks care for the adenopathy.
- **Trachoma** is a chronic follicular keratoconjunctivitis with pannus formation that results from repeated and chronic infection. Blindness secondary to extensive local scarring and inflammation occurs in 1% to 15% of people with trachoma.

ETIOLOGY: *C trachomatis* is an obligate intracellular bacterial agent with at least 15 serologic variants (serovars) divided between the following biologic variants (biovars): oculogenital (serovars A–K) and LGV (serovars L1, L2, and L3). Trachoma usually is caused by serovars A through C, and genital and perinatal infections are caused by serovars B and D through K.

EPIDEMIOLOGY: *C trachomatis* is the most commonly reported notifiable condition in the United States, with highest rates among sexually active female¹ adolescents (ages 15–24 years). A significant proportion of these patients are asymptomatic, providing an ongoing reservoir for infection. Among sexually active 15- to 24-year-olds participating in the 2015–2018 cycles of the National Health and Nutrition Examination Survey, the estimated 2018 incidence was 8219 per 100 000 population among 15- to 24-year-old female individuals and 4122 per 100 000 among 15- to 24-year-old male individuals.² Among those tested for chlamydial infection through the STD

¹ The terms female, male, women, and men refer to sex assigned at birth.

² Kreisel KM, Weston EJ, St. Cyr SB, Spicknall IH. Estimates of the prevalence and incidence of chlamydia and gonorrhea among US men and women, 2018. *Sex Transm Dis.* 2021;48(4):222-231

Surveillance Network of the Centers for Disease Control and Prevention (CDC) in 2020, the highest proportion of patients testing positive were women 19 years and younger (27.6%) and men 19 years and younger who have sex with women only (35.2%).^{1,2}

Oculogenital serovars of *C trachomatis* can be perinatally transmitted to neonates during birth. Acquisition occurs in approximately 50% of infants born vaginally to infected individuals and in some infants born by cesarean delivery with membranes intact. In infants who contract *C trachomatis*, the risk of conjunctivitis is 25% to 50% and the risk of pneumonia is 5% to 30%. The nasopharynx is the anatomic site most commonly infected. Asymptomatic infection of the nasopharynx, conjunctivae, vagina, and rectum can be acquired at birth, and cultures from these sites of perinatal infection may remain positive for 2 to 3 years. Infection at these sites is not known to be communicable among infants and children. The degree of contagiousness of pulmonary disease is unknown but seems to be low.

Genital tract infection in adolescents and adults is sexually transmitted. The possibility of sexual abuse always should be considered in prepubertal children beyond infancy who have vaginal, urethral, or rectal chlamydial infection (see Table 2.5, p 183). Health care professionals are mandated to report suspected sexual abuse to their state child protective services agency.

LGV biovars are worldwide in distribution but are particularly prevalent in tropical and subtropical areas. Although disease occurs rarely in the United States, reports of outbreaks of LGV proctocolitis have been increasing among men who have sex with men (MSM). Perinatal transmission is rare. LGV is infectious during active disease. Little is known about the prevalence or duration of asymptomatic carriage.

Although rarely observed in the United States since the 1950s, trachoma is the leading infectious cause of blindness worldwide, causing up to 3% of the world's blindness. Trachoma is transmitted by transfer of ocular discharge and is generally confined to poor populations in resource-limited nations in Africa, the Middle East, Asia, and Latin America; the Pacific Islands; and remote aboriginal communities in Australia.

The **incubation period** of chlamydial illness is variable, depending on the type of infection, but usually is at least 1 week.

DIAGNOSTIC TESTS: Among **postpubertal individuals**, *C trachomatis* nucleic acid amplification tests (NAATs) are the most sensitive tests and are recommended for laboratory diagnosis. Commercial NAATs have been cleared by the US Food and Drug Administration (FDA) for testing vaginal (provider or patient collected), endocervical, penile urethral, throat, and rectal swab specimens; first-catch urine specimens; and liquid cytology specimens. The CDC recommends that *C trachomatis* urogenital infection be diagnosed in female individuals by vaginal or cervical swab specimens or first-catch urine. Patient-collected vaginal swab specimens are equivalent in sensitivity

¹ Centers for Disease Control and Prevention. 2018 STD Surveillance Report. Atlanta, GA: US Department of Health and Human Services; 2019. Available at: www.cdc.gov/nchhstp/newsroom/2019/2018-STD-surveillance-report.html

² Centers for Disease Control and Prevention. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(RR-4):1-187. Available at: www.cdc.gov/std/treatment-guidelines/chlamydia.htm

and specificity to those collected by a clinician using NAATs. Diagnosis of *C trachomatis* penile urethral infection can be made by testing first-catch urine or a urethral swab specimen. Patient collection of a penile meatal swab for *C trachomatis* testing may be a reasonable approach for patients who are either unable to provide urine or prefer to collect their own meatal swab over providing urine. NAATs have been demonstrated to have improved sensitivity and specificity compared with culture for the detection of *C trachomatis* at rectal and oropharyngeal sites. Data indicate that performance of NAATs on self-collected rectal swab specimens is comparable to those with clinician-collected rectal swab specimens. Most people with *C trachomatis* detected at oropharyngeal sites do not have oropharyngeal symptoms, and the clinical significance of oropharyngeal *C trachomatis* infection is unclear.

Newer NAAT-based point of care (POC), CLIA-waived tests perform well and are commercially available. Chlamydia POC tests can expedite treatment of infected people and their sex partners and limit unnecessary presumptive treatment at the time of clinical diagnosis and, therefore, improve antimicrobial stewardship.

Specimen collection for diagnosis of **neonatal chlamydial ophthalmia** should be obtained from the everted eyelid using a Dacron-tipped swab or the swab specified by the manufacturer's test kit; for culture and direct fluorescent antibody (DFA) assay, specimens must contain conjunctival cells, not exudate alone. For diagnosing **infant pneumonia** caused by *C trachomatis*, specimens should be collected from the posterior nasopharynx. Sensitive and specific methods used for diagnosis of both **neonatal ophthalmia and infant pneumonia** include cell culture and nonculture tests (eg, DFA assay and NAAT). DFA assay is the only nonculture FDA cleared test for the detection of chlamydia from conjunctival and oropharyngeal swab specimens; NAATs are not FDA cleared for the detection of chlamydia from these sites, but clinical laboratories may offer such testing once they verify the procedure according to CLIA regulations.

For the **evaluation of prepubertal children for suspected sexual abuse**, see STI Evaluation After Sexual Assault of a Prepubertal Child, p 184. Diagnosis of genitourinary tract chlamydial disease in a child should prompt examination for **other STIs**, including syphilis, gonorrhea, trichomoniasis, human immunodeficiency virus (HIV), hepatitis B virus, and hepatitis C virus and necessitates investigation for sexual abuse.

Serologic testing has little, if any, value in diagnosing uncomplicated genital *C trachomatis* infection.

A definitive **diagnosis of LGV** can be made only with LGV-specific molecular testing (eg, NAAT-based genotyping). These tests can differentiate LGV from non-LGV *C trachomatis* in rectal swab specimens; however, they are not widely available. Genital or oral lesion, rectal swab, and lymph node specimens (ie, lesion swab or bubo aspirate) can be tested for *C trachomatis* by NAAT or culture. NAAT is the preferred approach to testing, because it can detect both LGV strains and non-LGV *C trachomatis* strains. *Chlamydia* serologic testing (complement fixation or microimmunofluorescence) should not be routinely used to make a diagnosis of LGV, because the diagnostic utility of these methods has not been established, interpretation has not been standardized, and validation for clinical proctitis presentation has not been performed.

Diagnosis of **ocular trachoma** usually is made clinically in countries with endemic infection.

TREATMENT¹:

- **Neonates with chlamydial ophthalmia neonatorum** are treated with oral erythromycin base or ethylsuccinate (50 mg/kg/day in 4 divided doses daily) for 14 days. Data on azithromycin for treating neonatal chlamydial infection are limited; however, a short therapy course might be effective. Topical antibiotic therapy alone is inadequate for treating chlamydial ophthalmia neonatorum and is unnecessary when systemic treatment is administered.
- **Infants with chlamydial pneumonia** are treated with oral erythromycin base or ethylsuccinate (50 mg/kg/day in 4 divided doses daily) for 14 days or alternatively with azithromycin (20 mg/kg as a single daily dose) for 3 days.
- Because the efficacy of erythromycin treatment for ophthalmia neonatorum or infant pneumonia is approximately 80%, a second course of therapy might be required. Clinical follow-up of infants treated with either drug is recommended to determine whether initial treatment was effective. Neonates with documented chlamydial infection should be evaluated for possible gonococcal infection. An association between orally administered erythromycin and azithromycin and infantile hypertrophic pyloric stenosis (IHPS) has been reported in infants younger than 6 weeks. Infants treated with either of these antimicrobial agents should be followed for signs and symptoms of IHPS.
- Infants born to individuals known to have untreated chlamydial infection are at high risk of infection; however, prophylactic antimicrobial treatment is not indicated, because the efficacy of such treatment is unknown. Infants should be monitored clinically to ensure appropriate treatment if infection develops.
- For treatment of other **chlamydial infections in infants and children: For children who weigh <45 kg**, the recommended regimen is oral erythromycin base or ethylsuccinate, 50 mg/kg/day, divided into 4 doses daily for 14 days. Data are limited on the effectiveness and optimal dose of azithromycin for treatment of chlamydial infections in infants and children who weigh <45 kg. **For children who weigh ≥45 kg but who are younger than 8 years**, the recommended regimen is azithromycin, 1 g, orally, in a single dose. **For children 8 years and older**, the recommended regimen is azithromycin, 1 g, orally, in a single dose, or doxycycline, 100 mg, orally, twice a day for 7 days.
- For uncomplicated ***C trachomatis* anogenital tract infection in adolescents or adults**, oral doxycycline (100 mg, twice daily) for 7 days is recommended (see Table 4.4, p 1007). Alternatives include oral azithromycin in a single 1-g dose, or levofloxacin (500 mg orally, once daily) for 7 days. Doxycycline is more effective treatment for rectal *C trachomatis* infection, which cannot be predicted by reported sexual practices. Inadequately treated rectal *C trachomatis* infection among female individuals can increase risk for repeat urogenital *C trachomatis* infection through autoinoculation from the anorectal site. When nonadherence to a 7-day doxycycline regimen is a substantial concern, azithromycin, 1 g, is an alternative treatment option.
- **For pregnant people**, the recommended treatment is azithromycin (1 g, orally, as a single dose), with amoxicillin (500 mg, orally, 3 times/day for 7 days) as an alternative regimen.
- For **LGV**, doxycycline (100 mg, orally, twice daily for 21 days) is the preferred treatment. Azithromycin (1 g, once weekly for 3 weeks) and erythromycin (500 mg, orally, 4 times daily for 21 days) are alternative regimens. All persons who have been treated for LGV should be retested for chlamydia approximately 3 months after treatment.

¹Centers for Disease Control and Prevention. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(RR-4):1-187. Available at: www.cdc.gov/std/treatment-guidelines/chlamydia.htm

- Treatment for **trachoma** is azithromycin, orally, as a single dose of 20 mg/kg (maximum dose of 1 g), as recommended by the World Health Organization for all people diagnosed with trachoma as well as for all of their household contacts.

Follow-up Testing. Test of cure immediately following treatment is not recommended for **nonpregnant adult or adolescent** patients treated for uncomplicated chlamydial infection unless compliance is in question, symptoms persist, or reinfection is suspected. Test of cure (preferably by NAAT) is recommended approximately 4 weeks after treatment of **pregnant people**. Reinfection is common after initial infection and treatment, and all infected adolescents and adults, including pregnant people, should be retested for *C trachomatis* approximately 3 months following initial treatment, regardless of whether patients believe their sex partners were treated. If retesting at 3 months is not possible, patients should be retested when they next present for health care in the 12 months after initial treatment.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES:

Pregnancy. Identification and treatment of people with *C trachomatis* genital tract infection during pregnancy and before delivery can prevent peripartum acquisition of disease in the infant. The CDC and US Preventive Services Task Force (USPSTF) recommend that all pregnant people aged ≤ 24 years of age as well as those older than 24 years who are at increased risk for chlamydia (eg, those who have a new sex partner; more than one sex partner; a sex partner with concurrent partners, or a sex partner who has an STI) should be routinely screened for *C trachomatis* at the first prenatal visit. Pregnant people who remain at increased risk for chlamydial infection also should be retested during the third trimester to prevent postnatal complications in the birthing person and chlamydial infection in the neonate.

Neonatal Chlamydial Conjunctivitis. Recommended topical prophylaxis with erythromycin or tetracycline for all newborn infants for prevention of gonococcal ophthalmia will not prevent neonatal chlamydial conjunctivitis or extraocular infection (see Neonatal Ophthalmia Prevention, p 1129).

Contacts of Infants With *C trachomatis* Conjunctivitis or Pneumonia. Birthing parents of infected infants should be evaluated and presumptively treated for *C trachomatis*, as should their sex partners.

Routine Screening.¹⁻⁴ All sexually active female individuals (≤ 24 years) should be tested at least annually for chlamydial infection, even if no symptoms are present or barrier contraception is reported. Rectal chlamydial testing for female patients can be considered on the basis of reported sexual behaviors and exposure with shared clinical

² US Preventive Services Task Force. Screening for chlamydia and gonorrhea: US Preventive Services Task Force recommendation statement. *JAMA*. 2021;326(10):949-956

³ Centers for Disease Control and Prevention. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(RR-4):1-187. Available at: www.cdc.gov/std/treatment-guidelines/chlamydia.htm.

⁴ www.cdc.gov/std/treatment-guidelines/screening-recommendations.htm

decision making between the patient and the provider. In addition, opt-out chlamydia screening (ie, the patient is notified that testing will be performed unless the patient declines, regardless of reported sexual activity) for adolescent and young female adults can be considered during clinical encounters. Opt-out chlamydia screening may substantially increase screening, be cost-saving, and identify infections among patients who do not disclose sexual behavior.

Although evidence is insufficient to recommend routine screening for *C trachomatis* in sexually active male individuals, annual screening should be considered in clinical settings serving populations of male young adults with high prevalence of chlamydia (eg, correctional facilities, military recruits, STI clinics, high school clinics, adolescent clinics) or in populations with high burden of infection. Sexually active young MSM should be screened at least annually for rectal and urethral chlamydia if they engaged in receptive or insertive anal intercourse, respectively (regardless of condom use during exposure). Screening practices may be suboptimal because of inadequate disclosure or inadequate sexual history taking; thus, testing may be considered at rectal or pharyngeal sites in those who do not report exposure at these sites. More frequent chlamydia screening every 3 to 6 months is recommended if risk behaviors persist or if they or their sex partners have multiple partners.

Postexposure Prophylaxis. Doxycycline, 200 mg, administered within 24 to 72 hours of condomless sex (doxy-PEP) has been shown in studies to reduce the incidence of syphilis, chlamydia, and gonorrhea among cisgender men who have sex with men (MSM) and transgender women with a recent history of these infections.

Management of Sex Partners.¹ All people with sexual contact in the 60 days preceding diagnosis or onset of symptoms of patients with *C trachomatis* infection (whether symptomatic or asymptomatic), nongonococcal urethritis, cervicitis, epididymitis, or pelvic inflammatory disease should be evaluated and treated for *C trachomatis* infection. The patient's last sex partner should be treated even if last sexual contact was more than 60 days before diagnosis in the index case. If concerns exist that sex partners who are referred for evaluation and treatment will not seek care, expedited partner therapy (EPT), which is the practice of the index patient delivering the prescriptions or medications to the patient's sex partner without the health care provider first examining the partner, can be considered. To clarify the legal status of EPT in each state, refer to the CDC website (www.cdc.gov/std/ept/legal/).

Efforts should be made to educate partners about symptoms of chlamydia and to encourage partners to seek clinical evaluation. MSM with chlamydia have a high risk for coexisting STIs, especially undiagnosed HIV, among partners, and data are limited regarding EPT effectiveness in reducing persistent or recurrent chlamydia among MSM. Thus, shared clinical decision making for MSM regarding EPT is recommended.

Patients and contacts should abstain from unprotected intercourse until treatment of both partners is complete (ie, after completion of a multiple-dose treatment or for 7 days after single-dose therapy).

LGV. Nonspecific preventive measures for LGV are the same as measures for STIs in general and include education, case reporting, condom use, and avoidance of sexual contact with infected people. Partners exposed to an LGV-infected person within the

¹ Centers for Disease Control and Prevention. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(RR-4):1-187. Available at: www.cdc.gov/std/treatment-guidelines/chlamydia.htm

60 days before the patient's symptom onset should be tested and presumptively treated for chlamydia with doxycycline, 100 mg, orally, 2 times/day for 7 days.

Trachoma. Prevention methods recommended by the World Health Organization for global elimination of blindness attributable to trachoma by 2030 include surgery, antimicrobial agents, face washing, and environmental improvement (SAFE). Azithromycin (20 mg/kg, maximum 1 g), once a year as a single oral dose, is used in mass drug administration campaigns for trachoma control.

CLOSTRIDIAL INFECTIONS

Botulism and Infant Botulism

(*Clostridium botulinum*)

CLINICAL MANIFESTATIONS: Botulism is a neuromuscular disorder typically characterized by an acute, afebrile, symmetric, descending, flaccid paralysis that can progress to respiratory distress or failure. Paralysis is caused by blockade of neurotransmitter release at the voluntary motor and autonomic neuromuscular junctions. Four naturally occurring forms of human botulism exist: infant, foodborne, wound, and adult intestinal colonization. Cases of iatrogenic botulism, which result from injection of excess therapeutic or cosmetic botulinum toxin, have been reported, and botulinum neurotoxins are considered a potential agent of bioterrorism. Symptoms of botulism can occur abruptly, within hours of exposure, or evolve gradually over several days and may include diplopia, dysphagia, dysphonia, and dysarthria. Loss of facial expression and/or pooling of oropharyngeal secretions may be present. Cranial nerve palsies are followed by symmetric, descending, flaccid paralysis of somatic musculature in patients who remain fully alert. In children, dysphagia and dysarthria are the most frequent cranial nerve symptoms, and generalized weakness is reported more than paralysis in the early stage of illness.

Infant botulism, which occurs predominantly in infants younger than 6 months (range, 1 day–14 months), is preceded by or begins with constipation and manifests as decreased movement, loss of facial expression, poor feeding or poor suck, ptosis, weak cry, diminished gag reflex, ocular palsies, loss of head control, and progressive descending generalized weakness and hypotonia. Some reports suggest that sudden infant death could result from rapidly progressing infant botulism.

ETIOLOGY: Botulism occurs after absorption of botulinum toxin into the circulation from a mucosal (eg, gastrointestinal) or wound surface. Infant botulism results after ingested spores of *Clostridium botulinum* or when related neurotoxicogenic clostridial species colonize the intestine and then germinate, multiply, and produce botulinum toxin. There are 7 classic antigenic toxin types (A–G) of *C. botulinum*. Type H toxin is a hybrid of types A and F. Non-*botulinum* species of *Clostridium* may rarely produce these neurotoxins and cause disease. The most common botulinum toxin serotypes associated with naturally occurring illness are types A, B, E, and rarely F. Most cases of infant botulism result from toxin types A and B, but a few cases of types E and F have been caused by *Clostridium butyricum* (type E), *C. botulinum* (type E), and *Clostridium baratii* (type F). *C. botulinum* spores are ubiquitous in soils and dust worldwide and have been isolated from the home environment and vacuum cleaner dust of infant botulism cases.

EPIDEMIOLOGY: Infant botulism cases may occur in breastfed infants before or after the first introduction of nonhuman milk substances; the source of spores usually is not identified. Honey has been identified as an avoidable source of spores. No case of infant botulism has been proven to be caused by consumption of corn syrup. Rarely, intestinal botulism can occur in older children and adults, usually after intestinal surgery and exposure to antimicrobial agents (www.cdc.gov/botulism/infant-botulism.html).

Foodborne botulism results when food that carries spores of *C botulinum* is preserved or stored improperly under anaerobic conditions that permit germination, multiplication, and toxin production. Illness follows ingestion of the food containing preformed botulinum toxin. Home processing of foods (eg, home canning) and inadequate refrigeration of cooked foods are the most common causes of foodborne botulism in the United States, followed by rare outbreaks associated with commercially processed foods, restaurant-associated foods, and wine produced in prisons (“pruno” or “hooch”).

Wound botulism results when *C botulinum* contaminates traumatized tissue, germinates, multiplies, and produces toxin. Gross trauma or crush injury can be a predisposing event. In recent years, “skin popping” and self-injection of drugs such as heroin (including black tar heroin) and rarely methamphetamines have been associated with most cases.

Immunity to botulinum toxin does not develop after infection. Botulism is not transmitted from person-to-person. The usual **incubation period** for foodborne botulism is 12 to 48 hours (range, 6 hours–10 days). In infant botulism, the **incubation period** is estimated at 3 to 30 days from the time of ingestion of spores. For wound botulism, the **incubation period** is 4 to 14 days from time of injury until onset of symptoms.

DIAGNOSTIC TESTS: Appropriate specimens for culture and botulinum toxin detection should be obtained as soon as a diagnosis of botulism is suspected. Because results of laboratory testing may require several days, treatment with antitoxin should be initiated urgently for all forms of botulism on the basis of clinical suspicion. To increase the likelihood of diagnosis in foodborne botulism, all suspect foods should be collected, and serum and stool or enema specimens should be obtained from all people with suspected illness. In foodborne cases, the length of time serum specimens may have detectable toxin varies, and in some cases can be longer than 10 days after illness onset.

Enriched selective media are required to isolate *C botulinum* from stool and foods. Laboratory confirmation of infant botulism is made by demonstrating botulinum toxin in serum or feces or botulinum toxin-producing organisms in feces or enema fluid. Wound botulism is confirmed by demonstrating botulinum toxin-producing organisms in the wound or tissue or toxin in the serum. Foodborne botulism is confirmed by demonstrating botulinum toxin in food, serum, or stool or botulinum toxin-producing organism in stool. Confirmation can also occur when a symptomatic patient consumed the same food as a laboratory-confirmed patient.

A toxin neutralization bioassay in mice (available only at specialized public health laboratories) and an in vitro mass spectrometry assay can be used to detect botulinum toxin in serum, stool, enema fluid, gastric aspirate, or suspect foods. A nucleic acid amplification test (NAAT) available at some reference laboratories can detect botulinum neurotoxin genes (*BaNT*) in clostridial species in cultures (www.cdc.gov/mmwr/volumes/70/rr/rr7002a1.htm). For additional information on testing for botulinum toxin, consult your state health department.

Although toxin can be demonstrated in serum in some infants with botulism (13% in 1 study), this requires a large volume of serum, ideally collected before administration of antitoxin. Stool is the best specimen for diagnosis; enema effluent also can be useful. If constipation makes obtaining a stool specimen difficult, an enema of sterile, nonbacteriostatic water should be administered promptly.

Ancillary testing can be helpful when evaluating children with suspected botulism. Cerebrospinal fluid findings are generally normal in botulism. Brain imaging may help to exclude strokes or some inflammatory conditions. Tensilon (edrophonium) testing, which yields positive results in myasthenia gravis, usually yields negative results in botulism. The most prominent electromyographic finding in botulism is an incremental increase of evoked muscle potentials at high-frequency nerve stimulation (20–50 Hz). In addition, a characteristic pattern of brief, small-amplitude, overly abundant motor action potentials may be seen after stimulation of muscle, but its absence does not exclude the diagnosis.

TREATMENT:

Involvement of Public Health Authorities. When botulism of any type is suspected, it should be reported to the state health department; all states maintain a 24-hour telephone service. The Centers for Disease Control and Prevention (CDC) Clinical Emergency Botulism Service can also be contacted at 770-488-7100. Public health agencies can provide guidance on collection, storage, and shipping requirements for all necessary clinical specimens (and possible food sources, when relevant).

Meticulous Supportive Care. Meticulous supportive care, in particular respiratory and nutritional support, constitutes a fundamental aspect of therapy in all forms of botulism. Recovery from botulism may take weeks to months.

Antitoxin for Infant Botulism. Immediate administration of antitoxin is the key to successful therapy, because antitoxin treatment ends the toxemia and stops further uptake of toxin. However, because botulinum neurotoxin becomes internalized in the nerve ending, administration of antitoxin does not reverse paralysis.

Human-derived antitoxin should be administered immediately. Human botulism immune globulin for intravenous use (BIG-IV, which goes by the brand name BabyBIG) is licensed by the US Food and Drug Administration (FDA) for treatment of infant botulism caused by *C. botulinum* type A or type B. BabyBIG is produced and distributed by the California Department of Public Health (CDPH). If the patient's clinical findings are consistent with infant botulism, immediately contact the Infant Botulism Treatment and Prevention Program (IBTPP) of the CDPH to arrange for shipment of BabyBIG (24-hour telephone number: 510-231-7600; www.infantbotulism.org). BabyBIG significantly decreases days of mechanical ventilation, days of intensive care unit stay, and total length of hospital stay by almost 1 month and is cost-saving. BabyBIG is first-line therapy for infant botulism. As with other immune globulin intravenous preparations, routine live-virus vaccines should be delayed for 6 months after receipt of BabyBIG because of potential interference with immune responses (see Table 1.11, p 69).

Equine-derived heptavalent botulinum antitoxin (BAT; see below) was licensed by the FDA in 2013 for treatment of adult and pediatric botulism and is available through the CDC. BAT has been used, on a case by case basis, to treat patients with type F infant botulism, as this antitoxin is not contained in BabyBIG.

Antitoxin for Noninfant Forms of Botulism. BAT is the only botulinum antitoxin approved in the United States for treatment of noninfant botulism. BAT contains antitoxins against botulinum toxin types A–G and has been “despeciated” by enzymatic removal of the Fc immunoglobulin fragment, resulting in a product that is >90% Fab and F(ab')₂ immunoglobulin fragments. This reduces but does not fully eliminate allergic reactions. As a precaution, epinephrine and antihistamine treatments should be available for any patient receiving BAT. It is possible that an infant could develop botulism from a food source or wound infection (“botulism in an infant” rather than “infant botulism”), such that BAT may be the appropriate antitoxin preparation. BAT is provided by the CDC with the product information that includes specific, detailed instructions for intravenous administration of antitoxin. Additional information may be found on the CDC website (www.cdc.gov/botulism/ and www.cdc.gov/botulism/resources.html).

Antimicrobial Agents. Antimicrobial therapy is not prescribed in infant botulism unless clearly indicated for a concurrent infection. Aminoglycoside agents can potentiate the paralytic effects of the toxin and should be avoided. Given theoretical concerns of toxin release from antibiotic-induced bacterial cell death, providers should consider delaying the use of antibiotics in wound botulism until after antitoxin is administered, depending on the clinical situation. The role for antimicrobial therapy in the adult intestinal colonization form of botulism, if any, has not been established.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS: Standard precautions are recommended.

CONTROL MEASURES:

- Honey should not be given to children younger than 12 months because of the possibility of contaminating *C botulinum* spores. Many foods and commercial products contain honey, and the honey is included in a variety of ways. Because the details of each manufacturing process vary, the California Department of Public Health is unable to comment on the likelihood that the honey-containing food product may contain viable *C botulinum* spores (www.infantbotulism.org/general/faq.php). Prudence would dictate that these types of foods also should be avoided during the first 12 months of life. Botulism is not transmitted by human milk, and breastfeeding parents may consume honey.
- Prophylactic antitoxin is not recommended for asymptomatic people who have ingested a food known to contain botulinum toxin. Physicians treating a patient who has been exposed to toxin or is suspected of having any type of botulism should contact their state health department immediately. People exposed to toxin who are asymptomatic should have close medical observation in nonsolitary settings.
- Education regarding safe practices in food preparation and home-canning methods should be promoted. Use of a pressure cooker (at 116°C [240.8°F]) is necessary to kill spores of *C botulinum*. Bringing the internal temperature of foods to 85°C (185°F) for 10 minutes will destroy the toxin. Cooked and leftover foods should be refrigerated in order limit the opportunity for toxin production. Time, temperature, and pressure requirements vary with altitude and the product being heated. Food containers that appear to bulge may contain gas produced by *C botulinum* and should be discarded. Other foods that appear to have spoiled should not be eaten or tasted (https://nchfp.uga.edu/publications/publications_usda.html).

Public Health Reporting. Botulism is a nationally notifiable disease, and it is required by law to be reported immediately to local and state health departments. Immediate reporting of suspected cases is particularly important, because a single case could be the harbinger of many more cases, as with foodborne botulism, and because of possible use of botulinum toxin as a bioterrorism weapon.

Clostridial Myonecrosis (Gas Gangrene)

CLINICAL MANIFESTATIONS: Disease onset is heralded by acute and progressive pain at the site of the wound, often initially out of proportion to the appearance of the affected area. Later, there is edema, increasing exquisite tenderness, and exudate. Systemic findings include tachycardia disproportionate to the degree of fever, pallor, and diaphoresis. Crepitus is suggestive but not pathognomonic of *Clostridium* infection and is not always present. Tense bullae containing thin, serosanguineous, or dark fluid develop in the overlying skin and areas of green-black cutaneous necrosis appear. Fluid in the bullae has a foul odor. Disease can progress rapidly with development of hypotension, renal failure, and alterations in mental status. Diagnosis is based on clinical manifestations, including the characteristic appearance of necrotic muscle at surgery. Untreated clostridial myonecrosis, also known as gas gangrene, can lead to disseminated myonecrosis, suppurative visceral infection, septicemia, and death within hours.

Nontraumatic gas gangrene usually is caused by *Clostridium septicum* and is a complication of bacteremia, which is the result of an occult gastrointestinal mucosal lesion (most commonly colon cancer) or a complication of neutropenic colitis, leukemia, or diabetes mellitus.

ETIOLOGY: Clostridial myonecrosis is caused by *Clostridium* species, most often *Clostridium perfringens*. Other *Clostridium* species (eg, *Clostridium sordellii*, *C septicum*, *Clostridium novyi*) have also been associated with myonecrosis. These organisms are large, gram-positive, spore-forming, anaerobic bacilli with blunt ends. Disease manifestations are caused by potent clostridial exotoxins. Mixed infection with other gram-positive and gram-negative bacteria is common.

EPIDEMIOLOGY: Clostridial myonecrosis usually results from contamination of deep open wounds. The sources of *Clostridium* species are soil, contaminated foreign bodies, and human and animal feces. Dirty surgical or traumatic wounds, particularly those with retained foreign bodies or significant amounts of devitalized tissue, predispose to disease. Cases have occurred in people who inject drugs, in association with contaminated black tar heroin. Rarely, nontraumatic gas gangrene occurs in immunocompromised people, most frequently in those with underlying malignancy, neutrophil dysfunction, or diseases associated with bowel ischemia.

The **incubation period** from the time of injury is 6 hours to 4 days.

DIAGNOSTIC TESTS: Anaerobic cultures of wound exudate, involved soft tissue and muscle, and blood should be performed. Matrix-assisted laser desorption/ionization–time-of-flight (MALDI-TOF) devices have an approved indication from the US Food and Drug Administration to identify *C perfringens*. Because *Clostridium* species are ubiquitous, their recovery from a wound is not diagnostic unless typical clinical manifestations are present. A Gram-stained smear of wound discharge demonstrating

characteristic gram-positive bacilli and few, if any, polymorphonuclear leukocytes suggests clostridial infection. Tissue specimens (not swab specimens) for anaerobic culture must be obtained to confirm the diagnosis. Because some pathogenic *Clostridium* species are exquisitely sensitive to oxygen, care should be taken when collecting and processing a sample to optimize anaerobic growth conditions. A radiograph of the affected site might demonstrate gas in the tissue, but this is a nonspecific finding that is not always present. Occasionally, blood cultures are positive and are considered diagnostic.

TREATMENT:

- Prompt and complete surgical excision of necrotic tissue and removal of foreign material is essential. Repeated surgical débridement may be required to ensure complete removal of all infected tissue. Vacuum-assisted wound closure can be used following multiple débridements.
- Management of shock, fluid and electrolyte imbalance, hemolytic anemia, and other complications is crucial.
- High-dose penicillin G should be administered intravenously (see Table 4.3, p 993). Clindamycin, metronidazole, meropenem, ertapenem, and chloramphenicol are alternative drugs for patients with a serious penicillin allergy or for treatment of polymicrobial infections. The combination of penicillin G and clindamycin may be superior to penicillin alone because of the theoretical benefit of clindamycin inhibiting toxin synthesis.
- Hyperbaric oxygen may be beneficial, but efficacy data from adequately controlled clinical studies are not available.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: Prompt and careful débridement, copious lavage of contaminated wounds, and removal of foreign material should be performed.

Penicillin G (50 000 U/kg per day) or clindamycin (20–30 mg/kg per day) has been used for prophylaxis in patients with grossly contaminated wounds, but there are no data on recommended duration or the effectiveness of such preventative measures.

***Clostridioides difficile* (Formerly *Clostridium difficile*)**

CLINICAL MANIFESTATIONS: *Clostridioides difficile* (formerly *Clostridium difficile*) is associated with a wide spectrum of gastrointestinal illness, ranging from asymptomatic colonization (common, especially in young infants) to severe and prolonged colitis with shock. In children, *C difficile* infections are rarely fatal. Mild to moderate illness is characterized by watery diarrhea, low-grade fever, and abdominal pain. In the past, hospital onset of symptoms was believed to be the most common presentation. However, recent studies have found that *C difficile* often is diagnosed in nonhospitalized children. Pseudomembranous colitis is characterized by diarrhea with mucus in feces, abdominal cramps and pain, fever, and systemic toxicity. Toxic megacolon (acute dilatation of the colon) should be considered in children who develop marked abdominal tenderness and distension with minimal diarrhea and may be associated with hemodynamic instability. Other complications of *C difficile* disease include intestinal perforation, hypotension, shock, and death. Complicated infections are less common in children than adults. Severe or fatal disease is more likely to occur in neutropenic children with leukemia, infants with Hirschsprung disease, and patients with inflammatory bowel

disease. Extraintestinal manifestations of *C difficile* infection are uncommon but can include bacteremia, wound infections, and reactive arthritis. Clinical illness attributable to *C difficile* is considered very rare in children younger than 12 months.

C difficile colonization occurs when there are no attributable clinical symptoms but test results are positive for *C difficile* organism or its toxins. *C difficile* disease occurs when attributable clinical symptoms are present in the setting of tests which are positive for *C difficile* organisms or its toxins.

ETIOLOGY: *C difficile* is a spore-forming, obligate anaerobic, gram-positive bacillus. Some strains produce exotoxins (toxins A and B), which are responsible for the clinical manifestations of disease when there is overgrowth of *C difficile* in the intestine.

EPIDEMIOLOGY: *C difficile* is shed in feces. People can acquire infection from the stool of other colonized or infected people through the fecal-oral route. Any surface (including hands), device, or material that has become contaminated with feces may also transmit *C difficile* spores. Hospitals, nursing homes, and child care facilities are major reservoirs for *C difficile*. Risk factors for acquisition of the bacterium include prolonged hospitalization and exposure to an infected person either in the hospital or the community. Risk factors for *C difficile* disease include antimicrobial therapy, repeated enemas, proton pump inhibitor therapy, prolonged placement of feeding tubes (including nasogastric, gastrostomy, and jejunostomy tubes), underlying bowel disease, gastrointestinal tract surgery, renal insufficiency, and immunocompromised state. *C difficile* colitis has been associated with exposure to almost every antimicrobial agent; amoxicillin, clindamycin, cephalosporins, carbapenems, and fluoroquinolones are the agents most frequently associated with *C difficile* infection, particularly for recurrent *C difficile* disease and infections with epidemic strains. The ribotype 027 (formerly known as NAP-1/BI/027) strain is a virulent strain of *C difficile* because of increased toxin production and is associated with an increased risk of severe and recurrent disease. Ribotype 027 strains of *C difficile* have emerged as a cause of outbreaks among adults and are reported sporadically in children.

C difficile disease and associated hospitalizations among children ≥ 1 year of age and adults in the United States decreased 24% from 2011 to 2017, after adjustment for more sensitive diagnostic testing (nucleic acid amplification tests [NAATs]). The overall decrease was driven by a 36% decrease in health care-associated cases, while community-associated cases did not change. The incidence of pediatric community-associated *C difficile* disease may be twice as frequent as health care-associated disease.

Asymptomatic intestinal colonization with *C difficile* (including toxin-producing strains) is common in children younger than 2 years; up to 50% of healthy infants are colonized. Colonization rates drop to 5% to 12% in healthy children 5 to 18 years. The rate of asymptomatic colonization with *C difficile* in hospitalized adults ranges from 3% to 26%.

The **incubation period** is unknown; colitis usually develops 5 to 10 days after initiation of the causative antimicrobial therapy but can occur on the first day of treatment and up to 10 weeks after therapy cessation.

DIAGNOSTIC TESTS: Endoscopic findings of pseudomembranes (2- to 5-mm, raised yellowish plaques) and hyperemic, friable rectal mucosa suggesting pseudomembranous colitis are highly correlated with *C difficile* disease. More commonly, the diagnosis of *C difficile* disease is based on laboratory detection of *C difficile* toxin(s) or toxin gene(s)

in a diarrheal stool specimen. In general, laboratory tests for *C difficile* should not be ordered for a patient who is having formed stools unless ileus or toxic megacolon is suspected. Similarly, *C difficile* tests should not be ordered on a patient who is receiving laxatives or stool softeners or has evidence suggestive of a viral or noninfectious cause of diarrhea. Notwithstanding the availability of several test methods, there currently is no generally agreed on gold standard laboratory test method for the diagnosis of *C difficile* disease.

Molecular assays using NAATs have become the most common diagnostic test for toxigenic strains of *C difficile* in both adult and pediatric hospitals. NAATs detect genes responsible for the production of toxins A and B, rather than free toxins A and B in the stool, which instead are detected by enzyme immunoassay (EIA). EIAs for the toxins are rapid, performed easily, and highly specific for diagnosis of *C difficile* disease, but their sensitivity is relatively low. The cell culture cytotoxicity assay, which also tests for toxin in stool, is more sensitive than the EIA but is labor intensive and has a long turnaround time, limiting its usefulness in the clinical setting.

NAATs combine excellent sensitivity and analytic specificity and provide results to clinicians in times comparable to EIAs. However, detecting toxin gene(s) in patients who are only colonized with *C difficile* is common and likely contributes to misdiagnosis of *C difficile* disease in children with other causes of diarrhea, leading to unnecessary antibiotic treatment for *C difficile*. Several steps can be taken to reduce the likelihood of misdiagnosis/overdiagnosis of *C difficile* disease related to use of highly sensitive NAATs. Age should be considered, because colonization with *C difficile* in infants younger than 12 months is common and symptomatic infection in this age group is not believed to occur; therefore, *C difficile* diagnostic testing on samples from children younger than 12 months is discouraged unless other infectious and noninfectious causes of diarrhea have been excluded and should be limited to infants with significant diarrhea and underlying Hirschsprung disease, other severe motility disorders, or evidence of pseudomembranous colitis or in an outbreak situation.

Likewise, testing should not be performed routinely in toddlers with diarrhea who are 12 through 23 months of age unless other infectious or noninfectious causes have been excluded. For children 24 months and older, testing is recommended if there is new onset of prolonged and worsening diarrhea and risk factors (eg, inflammatory bowel disease, immunocompromising condition) or a recent course of antibiotics or health care exposures. Because shedding of *C difficile* in the stool can persist for several months after treatment and symptom resolution, tests of cure should not be performed. Rather, response to therapy should be based on symptom resolution.

A 2- or 3-stage approach to testing for *C difficile* increases the positive predictive value compared with 1-stage testing. Multistep algorithms have been suggested by the Infectious Diseases Society of America guidelines¹ that incorporate testing for stool toxin (EIA); testing for glutamate dehydrogenase (GDH), an enzyme expressed by both toxigenic and nontoxigenic strains of *C difficile*; and NAAT depending on whether the laboratory has prespecified criteria for which stool samples to test (eg, diarrheal stool samples on patients who are not receiving laxatives). This approach could include a NAAT alone or EIA as part of a multistep algorithm (GDH plus EIA, GDH plus EIA

¹ McDonald LC, Gerding DN, Johnson S, et al. Clinical practice guidelines for *Clostridium difficile* infection in adults and children: 2017 update by the Infectious Diseases Society of America (IDSA) and Society for Healthcare Epidemiology of America (SHEA). *Clin Infect Dis*. 2018;66(7):e1-e48

arbitrated by NAAT, or NAAT plus toxin). If diagnostic stewardship is not performed, the testing would include EIA as part of a multistep algorithm as outlined above (and not NAAT alone).

TREATMENT: A central tenet to control *C difficile* disease is the discontinuation of precipitating antimicrobial therapy. Stopping these agents allows for reemergence of healthy commensal gut flora, which prevent *C difficile* infection. A variety of therapies are available; use of a particular treatment modality is dependent on severity of illness, the number of recurrences of infection, tolerability of adverse effects, and cost. Recommended therapies for first occurrence, first recurrence, and second recurrence are provided in Table 3.3. Drugs that decrease intestinal motility should not be administered. Asymptomatic patients should not be treated.

When using oral vancomycin, some experts recommend oral administration of the intravenous formulation of vancomycin to reduce costs and risk of recurrence. The intravenous formulation is less expensive than the product available for oral use. Intravenously administered vancomycin is not effective for *C difficile* disease.

Fidaxomicin is approved by the US Food and Drug Administration for treatment of *C difficile*-associated diarrhea in adults and children 6 months and older. Studies have demonstrated equivalent efficacy to oral vancomycin, although subjects with life-threatening and fulminant infection, hypotension, septic shock, peritoneal signs, significant dehydration, or toxic megacolon were excluded. Secondary outcomes from trials in both children and adults suggest a lower *C difficile* recurrence rate in individuals receiving fidaxomicin versus vancomycin. On the basis of these limited data in children, fidaxomicin may be considered for treatment of the initial *C difficile* episode. However, given equivalent efficacy to oral vancomycin and the significantly higher cost of fidaxomicin, many experts limit use of fidaxomicin for treatment of *C difficile* recurrences. No comparative data of fidaxomicin versus metronidazole are available.

Up to 20% of patients experience a recurrence after discontinuing therapy, but infection usually responds to a second course of the same treatment. Metronidazole should not be used for treatment of a second recurrence or for prolonged therapy, because neurotoxicity is possible. A variety of tapered or pulsed regimens of oral vancomycin have been used to treat recurrent disease (Table 3.3).

Fecal transplant (intestinal microbiota transplantation) appears to be safe and effective in adults as well as children. In a multicenter retrospective study of 335 children with a *C difficile* infection that had been unresponsive to antibiotic treatment, 81% had a successful outcome following a single fecal transplant. In 2022, the US Food and Drug Administration approved Rebyota, a fecal microbiota product, with the indication to prevent recurrent *C difficile* infections in individuals 18 years or older, following successful antibiotic treatment of *C difficile* infection. Rebyota is not indicated for the treatment of *C difficile* infection. Bezlotoxumab, a human monoclonal antibody that neutralizes *C difficile* toxin B, is approved to reduce the recurrence of infection in at-risk adults receiving *C difficile*-directed antibacterial treatment. Pharmacokinetic and safety data support a dose of 10 mg/kg dose in children 1 to <18 years of age, although pediatric efficacy data are not yet available. These or other therapies may be appropriate for third recurrences of disease in children, especially in consultation with an infectious disease or gastroenterology expert. Cholestyramine is not recommended. Other potential adjunctive therapies

of unclear efficacy include immune globulin therapy and probiotics (particularly *Saccharomyces boulardii* and kefir).

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, contact precautions and a private room (if feasible) are recommended at the time that disease is suspected through resolution of diarrhea.

Table 3.3. Treatments for *Clostridioides difficile* Disease

Severity	Recommendation
First Occurrence	
Mild-moderate	Metronidazole, 30 mg/kg/day, PO, every 6 h (preferred), every 6 h for 10 days (maximum 500 mg/dose) OR Vancomycin, 40 mg/kg/day, PO, every 6 h for 10 days (maximum 125 mg/dose) <u>For pregnant/breastfeeding or metronidazole-intolerant patients:</u> Vancomycin, 40 mg/kg/day, PO, every 6 h for 10 days (maximum 125 mg/dose) <u>In patients for whom oral therapy cannot reach colon:</u> To above regimen, ADD vancomycin, 500 mg/100 mL normal saline enema, as needed every 8 h until improvement
Severe ^a	Vancomycin, 40 mg/kg/day, PO, every 6 h for 10 days (maximum 125 mg/dose)
Severe and complicated ^b	<u>If no abdominal distension (use both for 10 days):</u> Vancomycin, 40 mg/kg/day, PO, every 6 h (maximum 125 mg/dose) PLUS metronidazole, 30 mg/kg/day, IV, every 6 h (maximum 500 mg/dose) <u>If complicated with ileus or toxic colitis and/or significant abdominal distension (use all for 10 days):</u> Vancomycin, 40 mg/kg/day, PO, every 6 h (maximum 500 mg/dose) PLUS metronidazole, 30 mg/kg/day, IV, every 6 h (maximum 500 mg/dose) PLUS vancomycin, 500 mg/100 mL normal saline enema, as needed every 8 h until improvement
Severity	Recommendation
First Recurrence	
Mild-moderate	Same regimen as for first occurrence (see above)
Severe	Vancomycin, 40 mg/kg/day, PO, every 6 h (maximum 125 mg/dose)

Table 3.3. Treatments for *Clostridioides difficile* Disease, continued

Severity	Recommendation
	Second (or Additional) Recurrence
All	Vancomycin, PO, as pulsed or prolonged tapered dose with one of the following regimens: • Vancomycin orally, 10 mg/kg/dose (maximum 125 mg/dose) 4 times a day for 7 days, then 3 times a day for 7 days, then twice a day for 7 days, then once daily for 7 days, then once every other day for 7 days, then every 72 hours for 7 days OR • Vancomycin, orally, 10 mg/kg/dose (maximum 125 mg/dose) 4 times a day for 14 days, then twice a day for 7 to 14 days, then once daily for 7 to 14 days, then every 2 to 3 days for 2 to 8 weeks OR • Vancomycin, orally, 10 mg/kg/dose (maximum 125 mg/dose) 4 times a day for 14 days, then rifaximin, orally, 400 mg, 3 times a day for 14 days (note that rifaximin dosing in pediatric patients is not well described; it is poorly water-soluble and minimally absorbed and should be avoided if the patient recently has received rifaximin for <i>C difficile</i> disease or another indication). OR Fidaxomicin^c weight band dosing^d twice daily for 10 days OR Fecal microbiota product or transplantation, in eligible patients

PO indicates orally; IV, intravenously.

^aSevere: not well defined in children, but should be considered in the presence of leukocytosis, leukopenia, or worsening renal function.

^bSevere and complicated: intensive care unit admission, hypotension or shock, pseudomembranous colitis by endoscopy, ileus, toxic megacolon.

^cMay be considered for treatment of the initial *C difficile* episode. However, given high cost and equivalent efficacy to oral vancomycin, many experts limit use to treatment of *C difficile* recurrences.

^dPer dose: 4 kg to <7 kg, 80 mg; 7 kg to <9 kg, 120 mg; 9 kg to <12.5 kg, 160 mg; ≥12.5 kg, 200 mg

CONTROL MEASURES: Exercising meticulous hand hygiene, properly handling contaminated waste (including diapers), disinfecting fomites, and limiting use of antimicrobial agents are the best available methods for control of *C difficile* infection. Gloves and gowns should be worn for all in-room care to prevent hand contamination and perform hand hygiene immediately after glove removal. Because no single method of hand hygiene will eliminate all *C difficile* spores, using gloves to prevent hand contamination remains critical for preventing *C difficile* transmission via the hands of health care personnel. During an outbreak, after contact with a *C difficile*-infected patient, optimal hand hygiene includes removing gloves and washing hands with soap and

water instead of alcohol-based hand sanitizers. In nonoutbreak hospital settings, either handwashing with soap and water or use of alcohol-based hand sanitizers is adequate; this is supported by data showing hospitals relying on alcohol-based hand hygiene do not have more frequent *C difficile* outbreaks.

Thorough cleaning of hospital rooms and bathrooms of patients with *C difficile* disease, as well as disinfection of reusable equipment with which infected patients had contact, is essential. Because *C difficile* spores are difficult to kill with standard hospital disinfectants approved by the US Environmental Protection Agency, many health care facilities have instituted the use of disinfectants with sporicidal activity (eg, hypochlorite).

Children with *C difficile* diarrhea should be excluded from child care settings until stools are contained in the diaper, and for the child who is continent, until stool frequency is no more than 2 stools above that child's normal frequency.

***Clostridium perfringens* Foodborne Illness**

CLINICAL MANIFESTATIONS: *Clostridium perfringens* foodborne illness is characterized by a sudden onset of watery diarrhea and moderate-to-severe crampy, mid-epigastric pain. Symptoms usually resolve within 24 hours. The shorter incubation period, shorter duration of illness, and absence of fever in most patients differentiate *C perfringens* foodborne disease from shigellosis and salmonellosis. As compared with foodborne illnesses associated with heavy metals, *Staphylococcus aureus* enterotoxins, *Bacillus cereus* emetic toxin, and fish and shellfish toxins, *C perfringens* foodborne illness is infrequently associated with vomiting. Diarrheal illness caused by *B cereus* diarrheal enterotoxins can be indistinguishable from that caused by *C perfringens* (see Appendix VI, Clinical Syndromes Associated With Foodborne Diseases, p 1150). Necrotizing colitis and death from constipation have been described in patients with disease attributable to *C perfringens* type A who received antidiarrheal medications. Enteritis necroticans (also known as pigbel) results from hemorrhagic necrosis of the midgut and is a cause of severe illness and death attributable to *C perfringens* infection caused by contamination with *Clostridium* strains carrying a β toxin. Rare cases have been reported in the highlands of Papua New Guinea and in Thailand; protein malnutrition is an important risk factor. Additionally, enteritis necroticans attributed to *C perfringens* type C has been reported in a child with poorly controlled diabetes in the United States who consumed chitterlings (pig intestine).

ETIOLOGY: Typical illness is caused by a heat-labile *C perfringens* enterotoxin, produced during sporulation in the small intestine. *C perfringens* type F (formerly *cpe*-positive type A), which produces α toxin and enterotoxin, commonly causes foodborne illness. Enteritis necroticans is caused by *C perfringens* type C, which produces a β toxin that causes necrotizing small bowel inflammation.

EPIDEMIOLOGY: *C perfringens* is a gram-positive, spore-forming bacillus that is ubiquitous in the environment and the intestinal tracts of humans and animals and is commonly present in raw meat and poultry. Spores of *C perfringens* that survive cooking can germinate and multiply rapidly during slow cooling, when stored at temperatures from 20°C to 60°C (68°F–140°F), and during inadequate reheating. At an optimum temperature, *C perfringens* has one of the fastest rates of growth of any bacterium. Illness results from consumption of food containing high numbers of vegetative organisms

(>10⁵ colony forming units [CFU]/g) that produce enterotoxin in the intestine of the consumer.

Ingestion of the organism is commonly associated with foods prepared by restaurants or caterers or in institutional settings (eg, schools and camps) where food is prepared in large quantities, cooled slowly, and may be stored inappropriately for prolonged periods. Beef, poultry, gravies, and dried or precooked foods are commonly implicated sources. Most outbreaks occur in November or December, often linked to consumption of popular holiday foods. Illness is not transmissible from person-to-person.

The **incubation period** is 6 to 24 hours, usually 8 to 12 hours.

DIAGNOSTIC TESTS: Because the fecal flora of healthy people commonly includes *C perfringens*, counts of *C perfringens* of 10⁶ CFU/g of feces or greater obtained within 48 hours of onset of illness support the diagnosis in symptomatic people. The diagnosis also can be supported by detection of enterotoxin in stool. *C perfringens* can be confirmed as the source of an outbreak if 10⁶ CFU/g are isolated from stool, enterotoxin is demonstrated in the stool of 2 or more ill people, or the concentration of organisms is at least 10⁵ CFU/g in the implicated food. Although *C perfringens* is an anaerobe, special transport conditions are unnecessary. Whole stool, rather than rectal swab specimens, should be obtained, transported in ice packs, and tested within 24 hours. For enumeration and enterotoxin testing, obtaining stool specimens in bulk without added transport media is required.

TREATMENT: *C perfringens* foodborne illness is typically self-limited. Oral rehydration or, occasionally, intravenous fluid and electrolyte replacement may be indicated to prevent or treat dehydration. Antimicrobial agents are not indicated.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: Preventive measures depend on limiting proliferation of *C perfringens* in foods by cooking foods thoroughly and maintaining food at warmer than 60°C (140°F) or cooler than 7°C (45°F). Meat dishes should be served hot. Leftovers should be reheated to at least 74°C (165°F). Foods should never be held at room temperature to cool; they should be refrigerated in shallow containers after removal from warming devices or serving tables as soon as possible and within 2 hours of preparation. Information on recommended safe food handling practices, including time and temperature requirements during cooking, storage, and reheating, can be found at www.foodsafety.gov.

Coccidioidomycosis

CLINICAL MANIFESTATIONS: Coccidioidomycosis, also called Valley fever, is an infection caused by fungi of the genus *Coccidioides*. Primary pulmonary infection is acquired by inhaling fungal conidia and is asymptomatic or self-limited in 60% to 65% of infected children and adults. Constitutional symptoms, including extreme fatigue and weight loss, are common and can persist for weeks or months. Symptomatic disease can resemble community-acquired pneumonia or other respiratory illnesses, with malaise, fever, cough, myalgia, arthralgia, headache, and chest pain. Pleural effusion, empyema, and mediastinal involvement are more common in children.

Acute infection may be associated only with cutaneous abnormalities, such as erythema multiforme, an erythematous maculopapular rash, or erythema nodosum manifesting as bilateral symmetrical violaceous nodules usually overlying the shins. Chronic pulmonary lesions are rare, but approximately 5% of infected people develop asymptomatic pulmonary radiographic residua (eg, cysts, nodules, cavitory lesions, coin lesions).

Nonpulmonary primary infection is rare and usually follows trauma associated with contamination of wounds by arthroconidia. Cutaneous lesions and soft tissue infections often are accompanied by regional lymphadenitis.

Disseminated (extrapulmonary) infection occurs in less than 1% of infected people; common sites of dissemination include skin, bones, joints, and the central nervous system (CNS). Meningitis is invariably fatal if untreated. Congenital (transplacental) infection is rare but can occur, with resultant pulmonary coccidioidomycosis soon after birth.

ETIOLOGY: *Coccidioides* species are dimorphic fungi. In soil, *Coccidioides* organisms exist in the mycelial phase as mold that grows as branching, septate hyphae. Infectious arthroconidia (ie, spores) produced from hyphae become airborne, infecting the host after inhalation or, rarely, inoculation. In tissues, arthroconidia enlarge to form spherules; mature spherules release hundreds to thousands of endospores that develop into new spherules and continue the tissue cycle. Molecular studies have divided the genus *Coccidioides* into 2 species: *Coccidioides immitis*, confined mainly to California and Washington, and *Coccidioides posadasii*, encompassing the remaining areas of distribution of the fungus within certain deserts of the southwestern United States, northern Mexico, and areas of Central and South America.

EPIDEMIOLOGY: *Coccidioides* species are found mostly in soil in areas of the southwestern United States with endemic infection, including California, Arizona, New Mexico, west and south Texas, southern Nevada, and Utah; northern Mexico; and throughout certain parts of Central and South America. Areas of endemicity can extend beyond traditionally defined ranges, which are expanding because of climate change.

In areas with endemic coccidioidomycosis, clusters of cases can follow dust-generating events, such as storms, seismic events, archaeological digging, and recreational and construction activities, including building of solar farms. The majority of cases occur without a known preceding event.

Infection is believed to provide lifelong immunity. Person-to-person transmission of coccidioidomycosis does not occur except in rare instances of cutaneous infection with actively draining lesions, donor-derived transmission via an infected organ, or congenital infection following in utero exposure. People with impairment of T-lymphocyte-mediated immunity caused by a congenital immune defect or human immunodeficiency virus (HIV) infection, individuals with defects in the interleukin-12/interferon- γ and STAT3 pathways, or those receiving immune-modulating medications (eg, tumor necrosis factor [TNF] alpha antagonists) are at major risk for severe primary coccidioidomycosis, disseminated disease, or relapse of past infection. Higher rates of severe or disseminated disease have been reported in people of African or Filipino ancestry, individuals in the third trimester of pregnancy and those postpartum, and children younger than 1 year. Cases may occur in people who do not reside in regions with endemic infection but who previously have visited these areas, including months or even years previously. In regions without endemic infection, careful

travel histories should be obtained from people with symptoms or findings compatible with coccidioidomycosis.

The **incubation period** typically is 1 to 3 weeks in primary infection. Disseminated infection may develop years after primary infection.

DIAGNOSTIC TESTS: Diagnosis of coccidioidomycosis is best established using serologic, histopathologic, and culture methods. Nucleic acid amplification tests (NAATs) have been developed; one is now FDA approved for use in lower respiratory tract specimens. Antigen tests have also been developed.

Serologic tests are useful in the diagnosis and management of infection. One approach is to test first with enzyme immunoassay (EIA), which is highly sensitive and provides relatively rapid results, and if EIA is positive to then perform the more specific immunodiffusion test. The immunoglobulin (Ig) M response can be detected by EIA or immunodiffusion methods. IgM is detected in the first and third weeks in approximately 50% and 90% of primary infections, respectively, but a positive EIA IgM result alone should be interpreted with caution because of the low specificity of this test. IgG response can be detected 4 to 8 weeks after symptom onset by EIA, immunodiffusion, or complement fixation (CF) tests. Immunodiffusion is considered more specific, whereas CF is more sensitive. A combination of both CF and immunodiffusion tests is often helpful in diagnosis, although both immunodiffusion and especially CF are known to cross-react with *Histoplasma* organisms. Serum antibodies detected by CF usually are of low titer and are transient if the disease is asymptomatic or mild; persistent high titers ($\geq 1:16$) occur with severe disease and are almost always seen in disseminated infection. Cerebrospinal fluid (CSF) antibodies also are detectable by immunodiffusion or CF testing. Increasing serum and CSF titers indicate progressive disease, and decreasing titers usually suggest improvement. False-positive titers can occur in patients with cryptococcal meningitis. Antibody titers detected by CF may not be reliable in immunocompromised patients; low or nondetectable titers in immunocompromised patients should be interpreted with caution. Among infants whose birthing parent had active coccidioidomycosis during pregnancy, serologic testing of infants during the first 3 months of life is not recommended, and serologic test results should be interpreted with caution during the first year of life.

Spherules are as large as 80 μm in diameter and can be visualized with 100x to 400x magnification in infected body fluid specimens (eg, pleural fluid, bronchoalveolar lavage) and biopsy specimens of skin lesions or organs. Silver or period-acid Schiff staining can be performed on biopsy specimens. The presence of a mature spherule with endospores is pathognomonic of infection.

Isolation of *Coccidioides* species in culture establishes the diagnosis, even in patients with mild symptoms. When a specimen from a patient suspected of having coccidioidomycosis is sent for culture, the diagnostic laboratory should be alerted as biosafety level 3 facilities are required. Culture of organisms is possible on a variety of artificial media but is hazardous to laboratory personnel, because spherules can convert to arthroconidia-bearing mycelia on culture plates. Suspect cultures should be sealed and handled using appropriate safety equipment and procedures. A DNA probe can identify *Coccidioides* species in cultures.

At least 1 commercial laboratory offers an EIA test for urine, serum, plasma, CSF, or bronchoalveolar lavage fluid for detection of *Coccidioides* antigen. Antigen test results may be positive in patients with more severe forms of disease (sensitivity, 71%)

in a study of immunosuppressed patients. Cross-reactions may occur in patients with dimorphic fungal diseases (eg, coccidioidomycosis, histoplasmosis, paracoccidioidomycosis, sporotrichosis, *Emergomyces africanus* disease, and talaromycosis [formerly penicilliosis]); clinical and epidemiologic distinctions aid in differentiating these entities. Using serologic and antigen testing together may improve sensitivity and early detection of infection in progressive coccidioidomycosis.

TREATMENT^{1,2}: Antifungal therapy is not recommended routinely for uncomplicated asymptomatic primary infection in people without risk factors for severe disease. Although most mild cases will resolve without therapy, some experts believe that treatment may reduce illness duration or risk of severe complications. Most experts recommend treatment of coccidioidomycosis with fluconazole for 3 to 6 months for people at risk of severe disease or people with severe primary infection. During pregnancy, amphotericin B (including lipid formulations) is the treatment of choice over fluconazole and other azole antifungals, as fluconazole has been demonstrated to be a teratogen in early pregnancy. Dosing of antifungal medication is in Antifungal Drugs for Systemic Fungal Infections, p 1017. Follow-up every 1 to 3 months for up to 2 years, either to document radiographic resolution or to identify residual abnormalities or pulmonary or extrapulmonary complications, is recommended. For diffuse pneumonia, defined as bilateral reticulonodular or miliary infiltrates, amphotericin B or high-dose fluconazole is recommended. Amphotericin B is used more frequently in the presence of severe hypoxemia or rapid clinical deterioration. The total length of therapy for diffuse pneumonia is 1 year.

Oral fluconazole or itraconazole is the recommended initial therapy for disseminated infection not involving the CNS. Amphotericin B is recommended as alternative therapy if lesions are progressing or are in critical locations, such as the vertebral column, or in fulminant infections, because it is believed to result in more rapid improvement.

Consultation with a specialist for treatment of patients with CNS disease caused by *Coccidioides* species is recommended. High-dose oral fluconazole (adult dose: 400–1200 mg/day, see Antifungal Drugs for Systemic Fungal Infections, p 1017) is recommended for treatment of patients with CNS infection. Patients who respond to azole therapy should continue this treatment indefinitely (for the remainder of their lives). For CNS infections that are unresponsive to oral azoles or are associated with severe basilar inflammation, intrathecal amphotericin B deoxycholate therapy can be used to augment the azole therapy. A subcutaneous reservoir can facilitate administration into the cisternal space or lateral ventricle. Hydrocephalus is a common complication of coccidioidal meningitis and nearly always requires a shunt for decompression.

There are reports of success with voriconazole, posaconazole, and isavuconazole in treatment of coccidioidomycosis, but this has not been established in children. These newer agents may be administered in certain clinical settings, such as therapeutic failure in severe coccidioidal disease (eg, meningitis). When used, these newer azoles

¹ Galgiani JN, Ampel NM, Blair JE, et al. 2016 Infectious Diseases Society of America (IDSA) clinical practice guideline for the treatment of coccidioidomycosis. *Clin Infect Dis*. 2016;63(6):e112–e146

² Thompson GR III, Le T, Chindamporn A, et al. Global guideline for the diagnosis and management of the endemic mycoses: an initiative of the European Confederation of Medical Mycology in cooperation with the International Society for Human and Animal Mycology. *Lancet Infect Dis*. 2021;21(12):e364–e374

should be administered in consultation with experts experienced with their use in treatment of coccidioidomycosis.

The duration of antifungal therapy is variable and depends on the site(s) of involvement, clinical response, and mycologic and immunologic test results. In general, therapy is continued until clinical and laboratory evidence indicates that active infection has resolved. Treatment for disseminated coccidioidomycosis is at least 6 months but for some patients may be extended to 1 year or longer. The role of subsequent suppressive azole therapy is uncertain, except for patients with CNS infection, osteomyelitis, or underlying human immunodeficiency virus (HIV) infection or for solid organ transplant recipients. Coccidioidal meningitis requires lifelong therapy. The duration of suppressive therapy also may be lifelong for other high-risk groups.¹

Surgical consultation for potential excision or débridement is recommended for patients with pulmonary cavitary lesions who do not respond to antifungal therapy, whose cavities persist >2 years, or who have rupture of infection into the plural space. Surgical débridement or excision of lesions in bone, pericardium, and other sites has been advocated for localized, symptomatic, persistent, resistant, or progressive lesions. In some localized infections with sinuses, fistulae, or abscesses, amphotericin B has been instilled locally or used for irrigation of wounds. Antifungal prophylaxis for solid organ transplant recipients may be considered if they reside in areas with endemicity and have prior serologic evidence or a history of coccidioidomycosis. Patients should be advised to avoid pregnancy while receiving fluconazole, which is known to be teratogenic. Breastfeeding while receiving fluconazole is considered likely safe for the infant.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended. Care should be taken in handling, changing, and discarding dressings, casts, and similar materials through which arthroconidial contamination could occur.

CONTROL MEASURES: Coccidioidomycosis is a reportable disease in many states and some countries. Measures to control dust are recommended in areas with endemic infection, including construction sites, archaeological project sites, or other locations where activities cause excessive soil disturbance. Immunocompromised people residing in or traveling to areas with endemic infection should be counseled to avoid exposure to activities that may aerosolize spores in contaminated soil.

Coronavirus Disease 2019 (COVID-19)

CLINICAL MANIFESTATIONS: Children infected with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) generally have mild disease or may be asymptomatic, although severe and even fatal infections occur. The most common presenting symptoms of acute coronavirus disease 2019 (COVID-19) in children are fever and cough; other symptoms include shortness of breath, sore throat, headache, myalgia, fatigue, congestion, and rhinorrhea. Gastrointestinal symptoms such as nausea, vomiting, diarrhea, and poor appetite may occur without respiratory symptoms. Loss

¹ Panel on Opportunistic Infections in HIV-Exposed and HIV-Infected Children. Guidelines for the Prevention and Treatment of Opportunistic Infections in Children With and Exposed to HIV. Department of Health and Human Services. Available at: <https://clinicalinfo.hiv.gov/en/guidelines/hiv-clinical-guidelines-pediatric-opportunistic-infections/whats-new>

of smell (anosmia) or taste (ageusia), when it occurs, tends to be more specific for COVID-19 as opposed to other causes of respiratory illness and is more common in adolescents and adults with COVID-19 than in younger children. Conjunctivitis and rashes have also been reported. Children who have obesity or medical comorbidities are at risk for more severe disease. Complications of COVID-19 include respiratory failure, acute respiratory distress syndrome (ARDS), myocarditis, acute kidney injury, shock, coagulopathy, multiorgan failure, and neurologic complications (eg, encephalitis, encephalopathy, seizures, stroke). Diabetic ketoacidosis and intussusception also have been reported. Laboratory findings may be normal (typically the case for uncomplicated COVID-19 in children) or may include lymphopenia, leukopenia, elevated C-reactive protein or procalcitonin, and elevated alanine aminotransferase and aspartate aminotransferase. Chest imaging may be normal or there may be unilateral or bilateral lung involvement with multiple areas of consolidation and ground glass opacities in children who have moderate to severe disease. After the acute illness, some children, including some who experienced mild disease, have a variety of ongoing physical, neurologic, and psychiatric symptoms, often termed “long COVID,” post-acute sequelae of COVID-19 (PASC), or post-COVID conditions.

Multisystem inflammatory syndrome in children (MIS-C) is a severe postinfectious complication of SARS-CoV-2 infection that generally occurs 2 to 6 weeks following infection; preceding infections are often mild or asymptomatic. The Centers for Disease Control and Prevention (CDC) and the Council for State and Territorial Epidemiologists (CSTE) have developed a surveillance case definition for MIS-C (https://cdn.ymaws.com/www.cste.org/resource/resmgr/ps/ps2022/22-ID-02_MISC.pdf); note that a surveillance case definition is not meant to be a clinical case definition and is used for public health reporting. Children with MIS-C present with fever, clinical severity requiring hospitalization or resulting in death, evidence of systemic inflammation by C-reactive protein of ≥ 3.0 mg/dL, and new-onset manifestation in 2 or more of the following systems: cardiac, mucocutaneous, shock, gastrointestinal, or hematologic. Patients also have evidence of recent SARS-CoV-2 infection (ie, a positive SARS-CoV-2-specific molecular test or SARS-CoV-2-specific antigen, in a clinical specimen up to 60 days prior to or during hospitalization or in a postmortem specimen, or serologic evidence of SARS-CoV-2 associated with the current illness) or a history of close contact with a confirmed or probable case of COVID-19 in the 60 days prior to hospitalization. The symptoms of MIS-C overlap with other infectious and noninfectious etiologies, and alternative diagnoses should be ruled out as part of the diagnostic evaluation. Many of these children present with severe abdominal pain and many have Kawasaki disease-like features. A large proportion of children with MIS-C have echocardiographic abnormalities including diminished cardiac function and coronary artery abnormalities and many have elevated troponin, B-type natriuretic peptide (BNP), or proBNP.

ETIOLOGY: SARS-CoV-2, the virus that causes COVID-19, is an enveloped, non-segmented single stranded RNA virus of the coronavirus family. The spike proteins of coronaviruses project from the virion to resemble a corona (Latin for “crown”) on electron microscopy. SARS-CoV-2 and SARS-CoV-1 (which circulated 2002-2004) are lineage B betacoronaviruses. SARS-CoV-2 has a high rate of mutations in the spike protein and multiple variants and subvariants have circulated since the pandemic began.

EPIDEMIOLOGY: SARS-CoV-2 emerged in late 2019 in Wuhan, China. Infection spread rapidly over the ensuing months around the world. The World Health Organization (WHO) declared a global pandemic on March 11, 2020. By December 20, 2022, 3 years after the outbreak in Wuhan was recognized, nearly 655 million cases were confirmed and approximately 6.7 million deaths were reported globally. In the United States, there were nearly 100 million COVID-19 cases, with 17% occurring in children younger than 18 years. By December 14, 2022, there were nearly 1.1 million deaths overall in the United States attributable to COVID-19, including at least 1575 children. By February 2022, the CDC estimated that approximately 75% of children had serologic evidence of previous infection with SARS-CoV-2. Current data on cases and deaths are available at <https://covid.cdc.gov/covid-data-tracker/#datatracker-home>.

The risk of COVID-19 infection, hospitalization, or death is increased for American Indian/Alaska Native people, Black people, and Hispanic people compared with white, non-Hispanic people.

MIS-C is a rare diagnosis; by January 30, 2023, 9344 cases were reported to CDC, including 76 deaths. The median age of patients with MIS-C in the United States was 9 years, 60% of cases were in male children, and 57% of cases occurred in Hispanic or Black children. Ninety-eight percent of MIS-C cases had laboratory-confirmed SARS-CoV-2 infection and 2% had a recent exposure to someone with COVID-19.

SARS-CoV-2 is transmitted efficiently between people, including from presymptomatic, symptomatic, and asymptomatic infected individuals. Transmission occurs primarily by respiratory droplets and fine particles that are inhaled or deposited on mucous membranes generally when within 6 feet of an infectious person, although transmission via aerosols can occur beyond that distance. A person can also self-inoculate eyes, nose, and mouth. The CDC provides information on factors that increase or decrease the risk of transmission (www.cdc.gov/coronavirus/2019-ncov/your-health/risks-exposure.html), taking into account the length of time, cough/heavy breathing, symptoms, use of N95 or higher respirators/high-quality masks, ventilation/filtration, and distance. Crowded, enclosed, and poorly ventilated spaces are particularly effective environments for the transmission of SARS-CoV-2. Infected people are believed to be infectious 2 days prior to symptom onset through 10 days after symptom onset, with the viral load highest earlier in the course of infection. The risk of transmission may be further impacted by the degree of symptomatology and severity of disease as well as immune status (eg, history of vaccination, previous infection) of the infected and/or exposed individual.

Health care-associated transmission occurs with SARS-CoV-2 and is a concern for health care personnel and patients. Adherence to infection prevention guidance is important. Outbreaks of SARS-CoV-2 infection occur readily in congregate settings (eg, long-term care facilities, group homes, prisons, shelters, congregate workplaces, dormitories) and households.

Perinatal transmission of SARS-CoV-2 is infrequent, occurring in approximately 2% of infants born to SARS-CoV-2 positive persons, increasing to approximately 20% if the pregnant person has evidence of acute COVID-19 infection at delivery. Perinatal transmission is believed to be driven primarily through transmission of respiratory droplets and fine particles in the postnatal period. Transplacental or intrapartum transmission appears possible but is extremely rare. Although SARS-CoV-2-specific

antibodies have been detected in human milk, SARS-CoV-2 is not believed to be transmissible via human milk.

The **incubation period** is 2 to 14 days (median, 5 days for the original SARS-CoV-2 strain). The period may differ by variant (eg, median is 3 days for the Omicron variant).

DIAGNOSTIC TESTS: There are a variety of nucleic acid amplification tests (NAATs) and antigen detection tests for the diagnosis of acute SARS-CoV-2 infections from respiratory samples (which can include nasopharyngeal, nasal, oropharyngeal, saliva, or lower respiratory specimens depending on the specific NAAT). Some molecular assays for SARS-CoV-2 are part of a multiplex test. Antigen tests, which generally have decreased sensitivity relative to molecular tests (especially for asymptomatic persons), are typically faster and cheaper than NAATs and are frequently used in point-of-care testing (nasopharyngeal or nasal specimen). In addition, a variety of over-the-counter tests that have received emergency use authorization (EUA) or clearance from the US Food and Drug Administration (FDA) are available. Serologic testing for SARS-CoV-2 can be used to indicate history of infection and can support a diagnosis of MIS-C. Prior infection results in antibody production against anti-spike (anti-S) and anti-nucleocapsid (anti-N), while prior vaccination results in antibody production against anti-spike (anti-S) alone.

The CDC (www.cdc.gov/coronavirus/2019-ncov/hcp/testing-overview.html and www.cdc.gov/coronavirus/2019-ncov/lab/resources/antigen-tests-guidelines.html) and FDA (www.fda.gov/medical-devices/covid-19-emergency-use-authorizations-medical-devices/in-vitro-diagnostics-euas) websites have more information on SARS-CoV-2 assays, including information about performance and when a confirmatory test is recommended. The FDA provides updated information about whether a diagnostic test may fail to detect a particular variant of SARS-CoV-2 (www.fda.gov/medical-devices/coronavirus-covid-19-and-medical-devices/sars-cov-2-viral-mutations-impact-covid-19-tests?utm_medium=email&utm_source=govdelivery).

TREATMENT OF COVID-19: Treatment of COVID-19 has evolved rapidly across the pandemic. The Infectious Diseases Society of America provides updated information on treatment for COVID-19 (www.idsociety.org/practice-guideline/covid-19-guideline-treatment-and-management/). There are no placebo-controlled randomized trials in children and there are limited data from observational studies; treatment recommendations for children, therefore, are generally extrapolated from trials performed in adults.

Nirmatrelvir plus ritonavir, which goes by the brand name Paxlovid, is an oral antiviral medication combination that initially received EUA from the FDA for people 12 years or older (weighing ≥ 40 kg) who are at high risk for severe COVID-19. Full approval for use in adults was granted on May 25, 2023. Nirmatrelvir plus ritonavir reduces hospitalization and all-cause mortality in high-risk adults.

Remdesivir is an intravenous antiviral drug that is approved by the FDA for the treatment of COVID-19 in hospitalized or nonhospitalized adult and pediatric (28 days of age and older and weighing at least 3 kg) patients with mild to moderate COVID-19 symptoms and high risk for progression to severe COVID-19, including hospitalization or death. Some experts administer remdesivir to hospitalized children requiring supplemental oxygen, particularly early in the course of illness, and to children who are

outpatients with mild-moderate COVID-19 who are at high risk for severe disease. The latter therapy is administered as a 3-day course and should be given within 7 days of symptom onset versus the 5-day course given to hospitalized patients.

Additional therapies have been used in hospitalized patients. Dexamethasone is recommended in the NIH treatment guidelines for children with COVID-19 who require high-flow oxygen, noninvasive ventilation, invasive mechanical ventilation, or extracorporeal membrane oxygenation (ECMO). Dexamethasone has not been evaluated in, and may be harmful to, profoundly immunocompromised children and should be considered only on a case-by-case basis. The FDA has issued an EUA for baricitinib in children 2 years or older and a full approval for the treatment of COVID-19 in hospitalized adults requiring supplemental oxygen, noninvasive or invasive mechanical ventilation, or ECMO. It is administered daily for 14 days or until hospital discharge, whichever comes first. The FDA also issued an EUA for tocilizumab for children 2 years or older and a full approval for the treatment of COVID-19 in hospitalized adults who are receiving systemic corticosteroids and require supplemental oxygen, noninvasive or invasive mechanical ventilation, or ECMO. Experience with these agents in children is limited, and consultation with an expert in the treatment of severe COVID-19 in children is recommended.

Anti-SARS-CoV-2 monoclonal therapies have been developed for use in patients who have mild to moderate COVID-19 and are at high risk for progression to severe COVID-19, are within 7 days of symptom onset, and meet the age criteria for the particular product. However, the high proportion of circulating variants and subvariants resistant to the therapies has precluded their use since the end of 2022. Additional monoclonal therapies may become available. The CDC COVID data tracker (<https://covid.cdc.gov/covid-data-tracker/#variant-proportions>) provides information on currently circulating variants.

The FDA also has issued an EUA for use of high-titer anti-SARS-CoV-2 convalescent plasma for the treatment of COVID-19 in ambulatory or hospitalized patients who have immunosuppressive disease or are on immunosuppressive therapy not associated with treatment of COVID-19. Safety and effectiveness of COVID-19 convalescent plasma in the pediatric population have not been evaluated.

TREATMENT OF MIS-C: The American College of Rheumatology provides guidance on the evaluation and treatment of MIS-C (<https://assets.contentstack.io/v3/assets/bltee37abb6b278ab2c/blt08209081de21d613/covid-19-clinical-guidance-pediatric-patients-mis-c.pdf>). Currently, there are no trials evaluating the efficacy of treatment options. A multidisciplinary approach with the involvement of pediatric specialists in cardiology, rheumatology, infectious disease, hematology, immunology, and critical care is recommended to guide individual management. In addition to supportive care, expert consensus recommendations include treating hospitalized patients with immune globulin intravenous (2 g/kg, based on ideal body weight, maximum 100 g; if patient has cardiac dysfunction, dose can be 1 g/kg per day for 2 days) and low-dose methylprednisolone (1–2 mg/kg/day). Therapeutic options for refractory cases include high-dose methylprednisolone (10–30 mg/kg/day) and immunomodulating agents (anakinra, infliximab). Most experts also treat patients with MIS-C with low-dose aspirin (3–5 mg/kg/day, maximum 81 mg). Higher-intensity anticoagulation in patients at high risk for thrombosis or with severe cardiac dysfunction should be considered on a case-by-case basis in consultation with relevant

subspecialists. Patients with coronary artery aneurysms should be managed per the American Heart Association (AHA) guideline for Kawasaki disease (<https://doi.org/10.1161/CIR.0000000000000484>).

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

The CDC recommends standard, airborne, droplet, and contact precautions for health care providers caring for patients who are potentially infected with SARS-CoV-2. These precautions include N95 or higher respiratory protection, gown, gloves, and eye protection (face shield or goggles). Aerosol-generating procedures should be performed in an airborne infection isolation room. Caregivers providing delivery room care for newborn infants of infected pregnant persons should utilize all such precautions. Patients should wear a face mask for source control when other people are in the room, if they are 2 years or older and can tolerate the mask.

CONTROL MEASURES: Please refer to the latest CDC guidance for the most up-to-date recommendations.

Infected Persons in the Community. The CDC recommends an isolation period for people with SARS-CoV-2 infection of at least 5 days (with day 0 being the first day of symptoms or a positive test result for those who never develop symptoms) for those with asymptomatic infection or mild disease if they are afebrile for at least 24 hours by the end of that period without the use of fever-reducing medicine and their symptoms are improving, and if they can continue to wear a face mask through 10 days after symptom onset (www.cdc.gov/coronavirus/2019-ncov/hcp/duration-isolation.html). A test-based strategy may be used to cease face mask use sooner (www.cdc.gov/coronavirus/2019-ncov/your-health/isolation.html). Patients with moderate disease are advised to isolate for 10 days after symptom onset. Patients with severe disease or severe immunocompromise may shed viable virus longer (the CDC recommends extending transmission-based precautions to 20 days after symptom onset for these patients; some severely immunocompromised people may continue to shed well beyond this time period [some for months] and require testing to determine end of isolation).

Exposed Persons in the Community. For people in the community who have a known exposure to someone with COVID-19, the CDC recommends that they wear a well-fitting face mask for 10 days whenever they are around another person or are in public, watch for symptoms, and if they have no symptoms, test at day 6 (day of exposure is day 0). They should take care not to be around those who are at risk for severe disease. If they develop symptoms, they should immediately isolate and test (www.cdc.gov/coronavirus/2019-ncov/your-health/if-you-were-exposed.html).

Vaccines. The incidence of COVID-19, hospitalization, and death is higher in unvaccinated people than in vaccinated people. Studies have found that people have better protection when they are up to date on COVID-19 vaccination, even with a history of a prior infection, and vaccination is recommended for people who have previously had COVID-19 (once clinically improved and no longer in isolation), including people with PASC. COVID-19 vaccine is protective against MIS-C (www.cdc.gov/mmwr/volumes/71/wr/mm7102e1.htm).

COVID-19 vaccine authorization, approvals, and recommendation are updated frequently; refer to the CDC (www.cdc.gov/vaccines/covid-19/clinical-considerations/covid-19-vaccines-us.html) and FDA (www.fda).

gov/emergency-preparedness-and-response/coronavirus-disease-2019-covid-19/covid-19-vaccines) websites for the most up-to-date information and recommendations on vaccines and their recommended intervals for administration.

As of December 2023, 3 COVID-19 vaccines are available in the United States. Two are mRNA vaccines (Pfizer-BioNTech and Moderna) that can be used in persons 6 months and older, and one (Novavax) is an adjuvanted protein vaccine that can be used in persons 12 years and older. The CDC should be consulted for the latest recommendations (**www.cdc.gov/vaccines/covid-19/clinical-considerations/interim-considerations-us.html#table-01**). For information on interchangeability of mRNA COVID-19 vaccines, see **www.cdc.gov/vaccines/covid-19/clinical-considerations/interim-considerations-us-appendix.html#appendix-a**.

Pregnancy. The CDC, the American College of Obstetricians and Gynecologists, and the Society for Maternal-Fetal Medicine recommend COVID-19 vaccines for people who are pregnant, might become pregnant, were recently pregnant, or are currently breastfeeding. There is an increased risk of severe COVID-19 and death during pregnancy and an increased risk for adverse pregnancy and neonatal outcomes. Accumulating data have confirmed the safety and effectiveness of COVID-19 vaccination in people who are pregnant as well as conveyance of protection for the newborn infant.

Additional Doses for Immunocompromised Patients. People who are moderately or severely immunocompromised may require additional doses of COVID-19 vaccine (**www.cdc.gov/coronavirus/2019-ncov/vaccines/recommendations/immuno.html**). People eligible for additional doses include those who are receiving active cancer treatment for tumors or cancers of the blood, those who received an organ transplant and are taking medicine to suppress the immune system, those who received a hematopoietic cell transplant within the last 2 years or are taking medicine to suppress the immune system, those with moderate or severe primary immunodeficiency (such as DiGeorge syndrome, Wiskott-Aldrich syndrome), those with advanced or untreated HIV infection, and those with active treatment with high-dose corticosteroids or other drugs that may suppress an immune response.

Adverse Events. The most common adverse events following COVID-19 vaccination observed in clinical trials and vaccine safety surveillance are local and systemic reactions that are generally mild and transient. Anaphylaxis has rarely been reported after COVID-19 vaccines. Appropriate medical treatment for severe allergic reactions must be immediately available at any site administering the vaccine. The CDC recommends an observation period after COVID-19 vaccination (**www.cdc.gov/vaccines/covid-19/clinical-considerations/managing-anaphylaxis.html**).

Rare cases of myocarditis and pericarditis have been reported in adolescents and young adults following receipt of mRNA vaccines, most often following the second dose. COVID-19 vaccination reduces the risk of myocarditis caused by SARS-CoV-2 infection. The risk of myocarditis is up to 6 times higher after SARS-CoV-2 infection than after mRNA vaccines. Postvaccine myocarditis is milder, requiring shorter hospital stays (1–2 days) compared with myocarditis caused by SARS-CoV-2 infection. Pediatricians should consider myocarditis and pericarditis in adolescents or young adults with acute chest pain, shortness of breath, or palpitations and report any suspected cases after COVID-19 vaccination to VAERS. In adolescents and adults, the risk of postvaccination myocarditis and pericarditis might be reduced with an interval

longer than 4 weeks, but extending the interval beyond 8 weeks has not been shown to provide additional benefit. For more information see www.cdc.gov/vaccines/covid-19/clinical-considerations/myocarditis.html.

Special Situations:

- COVID-19 infection: The primary series vaccination of people with current SARS-CoV-2 infection should be deferred until the person has recovered from the acute illness and no longer requires isolation.
- Patients with MIS-C: A multicenter study was published in early 2023 in which 185 children with MIS-C who received at least 1 dose of COVID-19 vaccine following MIS-C were followed, and no serious adverse effects including myocarditis or the return of MIS-C were detected. Many experts consider the benefits of vaccination (reduced risk of severe disease from COVID-19, including a potential recurrence of MIS-C after reinfection) to outweigh potential risks when clinical recovery from MIS-C has been achieved (including return to baseline cardiac function) and it has been at least 90 days since the diagnosis of MIS-C.
- Other vaccines: COVID-19 vaccines can be administered at the same time as other vaccines. Patients who receive mpox vaccine (JYNNEOS or ACAM2000) may consider waiting 4 weeks before getting a COVID-19 vaccine (see Mpox, p 606). Those who previously received COVID-19 vaccines can receive an mpox vaccine (when indicated) without a minimum interval between vaccines.

Preexposure Prophylaxis. Long-acting monoclonal antibody combinations available earlier in the pandemic no longer have activity against currently circulating variants of SARS-CoV-2. Additional products may be developed in the future, however.

Nonpharmaceutical Control Measures. Nonpharmaceutical measures that make up layered mitigation include use of well-fitting, high-quality face masks for anyone 2 years and older (www.cdc.gov/coronavirus/2019-ncov/prevent-getting-sick/types-of-masks.html); the CDC has guidance on when to use face masks depending on COVID-19 levels in the community (www.cdc.gov/coronavirus/2019-ncov/your-health/covid-by-county.html) or if exposed to or infected with COVID-19. Other nonpharmaceutical mitigation measures include avoiding crowds, improving ventilation, exercising hand hygiene, and following recommendations for testing and isolation. Local or state public health agencies also may provide guidance for specific locations on mitigation measures. Additional guidance can be found on the CDC website (www.cdc.gov/coronavirus/2019-ncov/prevent-getting-sick/prevention.html).

Schools. For recommendations on exposed and infected children during the COVID-19 pandemic, refer to CDC (www.cdc.gov/coronavirus/2019-ncov/community/schools-childcare/child-care-guidance.html), state, and local health department guidance.

Care of Exposed Newborn Infants. Infants born to SARS-CoV-2 positive people may room in during the birth hospitalization. The parent should perform hand hygiene and use a well-fitting, high-quality face mask when providing hands-on care to the infant for the duration of time the parent is infectious. Consideration may be given to testing the well newborn infant for SARS-CoV-2 before discharge from the birth hospital, to facilitate precautions and pediatric monitoring in the community. Infants born to parents with COVID-19 who require neonatal intensive care for any reason should be cared for with standard, airborne, droplet, and contact precautions. Testing at the

beginning and end of the incubation period for COVID-19 may facilitate management of the exposed infant in the intensive care setting.

Breastfeeding. The CDC recommends breastfeeding even if the nursing parent has COVID-19. Precautions should be taken including washing hands with soap and water (or using 60% alcohol-based hand sanitizer) prior to breastfeeding or expressing milk and wearing a well-fitting, high-quality mask when in close proximity to the child. Breast pump equipment and all feeding items should be cleaned and sanitized between uses. The infant is considered exposed and should follow recommended precautions. For further information about COVID-19 and breastfeeding, see www.cdc.gov/breastfeeding/breastfeeding-special-circumstances/maternal-or-infant-illnesses/covid-19-and-breastfeeding.html.

Public Health Reporting. COVID-19 is a nationally notifiable disease. Please refer to the state or local health department for details on reporting cases.

Coronaviruses, Including MERS-CoV and SARS-CoV-1

CLINICAL MANIFESTATIONS: Human coronaviruses (HCoV) 229E, OC43, NL63, and HKU1 are associated most frequently with an upper respiratory tract infection characterized by rhinorrhea, nasal congestion, sore throat, sneezing, and cough; fever may also occur. Symptoms are generally self-limited and typically peak on day 3 or 4 of illness. HCoV infections also may be associated with acute otitis media, croup, or asthma exacerbations. Less frequently, HCoV are associated with lower respiratory tract infections, including bronchiolitis and pneumonia, primarily in younger patients or in those who are immunocompromised. Asymptomatic infections can occur.

MERS-CoV, the virus associated with the Middle East respiratory syndrome (MERS) that emerged in 2012, can cause severe disease, but asymptomatic infections and mild disease may also occur. Most cases have been identified in male adults with comorbidities. Infections in children are uncommon and typically are milder than in adults. Patients initially present with fever, myalgia, and chills followed by a nonproductive cough and dyspnea a few days later. Approximately 25% of patients may experience vomiting, diarrhea, or abdominal pain. Rapid deterioration of oxygenation with respiratory distress and progressive unilateral or bilateral airspace infiltrates on chest imaging may follow and may further progress to respiratory failure requiring mechanical ventilation. Acute kidney injury can also occur. The case fatality rate for MERS is high, estimated at approximately 35%, although this may partially reflect surveillance bias for more severe disease. Laboratory abnormalities may include thrombocytopenia, lymphopenia, and increased lactate dehydrogenase (LDH) concentration, particularly among severely infected individuals.

Severe acute respiratory syndrome coronavirus 1 (SARS-CoV-1) was responsible for the 2002–2003 global outbreak of SARS, which was associated with severe respiratory symptoms, although a spectrum of disease including asymptomatic infections and mild disease also occurred. Infections in children were generally less severe than in adults and typically presented with fever, cough, and rhinorrhea. Adolescents with SARS had clinical courses more closely resembling those of adult disease, presenting with fever, myalgia, headache, and chills. No deaths in children from SARS-CoV-1 infection were documented. The overall case fatality rate was 10% but was generally higher in older adults.

ETIOLOGY: Coronaviruses are enveloped, nonsegmented, single-stranded, positive-sense RNA viruses named after their crown (or Latin “corona”)-like surface projections observed on electron microscopy that correspond to spike proteins. Coronaviruses are classified in the subfamily *Orthocoronavirinae* of the *Coronaviridae* family. Coronaviruses are generally host specific and can infect humans as well as a variety of different animals. Four distinct genera in the subfamily *Orthocoronavirinae* have been described: *Alphacoronavirus*, *Betacoronavirus*, *Gammacoronavirus*, and *Deltacoronavirus*. HCoV-229E and NL63 belong to the genus *Alphacoronavirus*. HCoV-OC43 and HKU1 belong to lineage A, SARS-CoV-1 and SARS-CoV-2 belong to lineage B, and MERS-CoV belongs to lineage C of the genus *Betacoronavirus*.

EPIDEMIOLOGY: HCoV-229E, OC43, NL63, and HKU1 can be found worldwide. They typically cause disease in the winter and spring months in temperate climates. Seroprevalence data for these HCoVs suggest that exposure is common in early childhood, with approximately 90% of adults being seropositive for HCoV-229E, OC43, and NL63 and 60% being seropositive for HCoV HKU1. The modes of transmission for HCoV-229E, OC43, NL63, and HKU1 have not been well studied. However, on the basis of studies of other respiratory tract viruses, it is likely that transmission occurs primarily via a combination of droplet and direct and indirect contact spread. HCoV-229E and OC43 are most likely to be transmitted during the first few days of illness, when symptoms and respiratory viral loads are at their highest.

MERS-CoV likely evolved from bat coronaviruses and infected dromedary camels in parts of the Middle East and Africa, where serologic and molecular detection of MERS-CoV have been reported. MERS-CoV cases in humans continue mostly in the Middle East, primarily linked to close contact with camels or an infected person. Human-to-human transmission generally occurs in health care settings and less frequently in household settings. Transmission is thought to occur most commonly through droplet and contact spread, although airborne spread may occur. Updated figures on global cases can be found on the World Health Organization website (www.who.int/emergencies/mers-cov/en/).

SARS-CoV-1 likely evolved from a natural reservoir of SARS-CoV-like viruses in horseshoe bats through civet cats or other intermediate animal hosts in wet markets in China. Public health interventions ultimately aborted the epidemic. Human SARS-CoV-1 infection was last reported in 2004.

The **incubation period** for HCoV-229E is 2 to 5 days (median, 3 days). Further study is needed to confirm the incubation periods for HCoV-OC43, NL63, and HKU1. The **incubation period** for MERS-CoV is estimated to be 2 to 14 days (median 5 days). The **incubation period** for SARS-CoV-1 is 2 to 14 days (typically 2–7 days).

DIAGNOSTIC TESTS: Multiplex assays for detection of respiratory pathogens by nucleic acid amplification are commercially available that include HCoV-229E, OC43, NL63, HKU1, and SARS-CoV-2 as targets. Notably, multiple respiratory viruses can be detected concurrently in some patients and detection of HCoV does not always implicate it as the cause of a patient's symptoms. State public health departments should be contacted for evaluation of suspected cases of MERS-CoV using a nucleic acid amplification test (NAAT). Guidance regarding testing for MERS-CoV (including specimen collection, typically upper respiratory, lower respiratory, and

serum) is available on the CDC MERS website (www.cdc.gov/coronavirus/mers/guidelines-clinical-specimens.html). State public health departments should be consulted for suspect cases of SARS-CoV-1.

TREATMENT: Infections attributable to HCoV HKU1, OC43, 229E, and NL63 are treated with supportive care. Investigational therapy for MERS includes anti-MERS monoclonal antibodies. A report of the combination of lopinavir-ritonavir plus subcutaneous interferon-beta-1b indicated clinical benefit, but further evaluation is needed. Remdesivir has activity against MERS-CoV and SARS-CoV-1 using in vitro systems and against SARS-CoV-1 in a mouse model. Remdesivir also has activity against SARS-CoV-2 (see Coronavirus Disease 2019 [COVID-19], p 324).

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Airborne, droplet, and contact precautions are recommended for patients with suspected or known MERS-CoV infection (or SARS-CoV-1 infection if it reemerges). This includes eye protection (face shield or goggles), N95 or higher respirator (or medical mask if not available), gown, and gloves; for aerosol-generating procedures, an N95 or higher respirator should be used. Airborne infection isolation rooms should be prioritized for aerosol-generating procedures. A well-ventilated single-occupancy room with a closed door may be used if aerosol-generating procedures are not performed.

For other HCoV infections, in addition to standard precautions, health care professionals should use droplet and contact precautions when examining and caring for infants and young children.

CONTROL MEASURES: Practicing appropriate hand and respiratory hygiene can help curb spread of all respiratory tract viruses, including coronaviruses. Cleaning and disinfection of high-touch environmental surfaces using standard disinfectants should decrease the potential for indirect transmission of coronaviruses via fomites.

MERS-CoV transmission within hospitals and households can be averted with case identification and the use of infection control and public health measures, including contact tracing. However, preventing the transmission of MERS-CoV from camels to humans is more challenging, given the prevalent use of camels in some Middle East countries. Most experts believe that intermittent sporadic cases will continue because of zoonotic transmission. Several candidate vaccines are currently in trials for both humans and camels.

Public Health Reporting. Suspect cases of MERS or SARS-CoV-1 infection should be reported promptly to your state or local health department.

***Cryptococcus neoformans* and *Cryptococcus gattii* Infections (Cryptococcosis)**

CLINICAL MANIFESTATIONS: Primary pulmonary infection is acquired by inhalation of aerosolized *Cryptococcus* fungal propagules found in contaminated soil or organic material (eg, trees, rotting wood, and bird guano), and infection often is asymptomatic or mild. When symptomatic, pulmonary disease is characterized by cough, chest pain, and constitutional symptoms. Chest radiographs may reveal solitary or multiple masses; patchy, segmental, or lobar consolidation, which often is multifocal; or a nodular or reticulonodular pattern with interstitial changes. Pulmonary cryptococcosis may present as acute respiratory distress syndrome (ARDS) and can mimic *Pneumocystis*

pneumonia. Hematogenous dissemination occurs particularly to the central nervous system (CNS) but also to bones, skin, and other body sites. Disseminated cryptococcosis is generally rare in children and almost always occurs in children with defects in T-lymphocyte-mediated immunity, including children with leukemia or lymphoma, those taking corticosteroids, children with congenital immunodeficiency such as hyperimmunoglobulin M syndrome or severe combined immunodeficiency syndrome, those with acquired immunodeficiency syndrome (AIDS) from advanced human immunodeficiency virus (HIV) infection, or those who have undergone solid organ transplantation. Several anatomic sites usually are infected, but manifestations of involvement at one site predominate. Cryptococcal meningitis, the most common and serious form of cryptococcal disease in children, often follows an indolent course but symptoms can be more acute in severely immunosuppressed patients. Symptoms are often typical of those of meningitis, meningoencephalitis, or space-occupying lesions but sometimes manifest only as subtle, nonspecific findings such as fever, headache, or behavioral changes. Cryptococcal fungemia without apparent organ involvement occurs in patients with HIV infection but is rare in children.

ETIOLOGY: There are more than 30 species of *Cryptococcus*, but only 2, *Cryptococcus neoformans* species complex and *Cryptococcus gattii* species complex, are regarded as consistent human pathogens. These 2 species have been divided into approximately 10 genotypes or sibling species but clinically are referred to together as cryptococcosis. Further taxonomic studies and disease correlations are anticipated in the future to aid in understanding the clinical relevance of these groups.

EPIDEMIOLOGY: *C. neoformans* species complex is isolated primarily from soil contaminated with pigeon or other bird droppings and causes most human infections, especially infections in immunocompromised hosts. *C. neoformans* infects 5% to 10% of adults with AIDS, but cryptococcal disease is rare in HIV-infected and non-HIV-infected children. *C. gattii* species complex is associated with certain trees and the surrounding soil and has emerged as disease manifesting as a respiratory syndrome with or without neurologic findings in individuals from British Columbia, Canada, and the Pacific Northwest region of the United States, but primarily as meningitis and meningoencephalitis in other regions of the United States. A high frequency of disease also has been reported in Aboriginal people in Australia and in the central province of Papua New Guinea. *C. gattii* causes disease in both immunocompetent and immunocompromised individuals, and cases have been reported in children. Person-to-person transmission generally does not occur with cryptococcal species; although rare, transmission from donor organ and tissue grafts has been reported. The prevalence of cryptococcal disease is lower in children compared with adults and even less in children younger than 6 years compared with older children.

The **incubation period** for *C. neoformans* is unknown but likely variable; dissemination often represents reactivation of latent disease acquired previously. The **incubation period** for *C. gattii* is estimated at 8 weeks to 13 months based on outbreak investigations, but these figures also are imprecise.

DIAGNOSTIC TESTS: The cerebrospinal fluid (CSF) profile of cryptococcal meningoencephalitis is characterized by low cell counts, low glucose, and elevated protein. Opening pressure may be markedly elevated, especially in HIV-infected individuals.

Laboratory diagnosis of cryptococcal infection is best performed using cryptococcal antigen (CrAg) detection methods or by culture. The latex agglutination test, lateral flow immunoassay, and enzyme immunoassay for detection of cryptococcal capsular polysaccharide antigen (galactoxylomannan) in serum or CSF specimens are excellent rapid diagnostic tests in patients with suspected meningitis. CrAg is detected in CSF or serum specimens from more than 95% of patients with cryptococcal meningitis. Antigen test results can be falsely negative when antigen concentrations are very high (prozone effect), which can be addressed by dilution of samples. CrAg assays are less useful in following response to therapy than they are in diagnosis, because CrAg can remain high even after viable yeasts can no longer be detected. Accuracy, ease of use, and cost have made the lateral flow immunoassay, which shows good agreement with standard CrAg testing, a common test in both resource-abundant and resource-limited settings and has allowed preemptive management strategies for adults in areas with high incidence of HIV infection.

Definitive diagnosis requires isolation of the yeast from body fluid or tissue specimens. Encapsulated yeast cells can be visualized using India ink or other stains of CSF and bronchoalveolar lavage specimens, but this method has limited sensitivity and is not recommended as a stand-alone rapid test. CSF specimens may contain only a few yeast cells, and a large quantity of CSF may be needed to recover organisms in culture. Automated blood culture systems are acceptable for growing *Cryptococcus*. Sabouraud dextrose agar is useful for isolation of *Cryptococcus* organisms from sputum, bronchopulmonary lavage, tissue, or CSF specimens. Differentiation between *C. neoformans* species complex and *C. gattii* species complex can be made by the use of the selective medium L-canavanine, glycine, bromothymol blue (CGB) agar. A matrix-assisted laser desorption/ionization–time-of-flight (MALDI-TOF) mass spectrometer can identify yeasts to species complex level accurately and rapidly. Nucleic acid amplification tests (NAATs) are commercially available but may miss low burden cryptococcal central nervous system infections. Focal pulmonary or skin lesions can be biopsied for fungal staining and culture. Although there are CLIA standards for in vitro cryptococcal susceptibility testing, there are no break point minimum inhibitory concentration (MIC) interpretations; therefore, generally, a threefold increase in MIC from original to relapse isolate is evidence for direct resistance.

TREATMENT: Practice management guidelines for cryptococcal disease are available.^{1–3} No pediatric trials have been performed, so optimal dosing and duration of therapy for children with cryptococcal infection have not been determined precisely. *C. neoformans* and *C. gattii* infections are treated similarly. Amphotericin B deoxycholate (1 mg/kg/day) or liposomal amphotericin B (5–6 mg/kg/day) are indicated in combination with oral flucytosine (25 mg/kg/dose, 4 times/day when renal function

¹ Perfect J, Dismukes WE, Dromer F, et al. Clinical practice guidelines for the management of cryptococcal disease: 2010 update by the Infectious Diseases Society of America. *Clin Infect Dis*. 2010;50(3):291–322

² Panel on Opportunistic Infections in HIV-Exposed and HIV-Infected Children. Guidelines for the Prevention and Treatment of Opportunistic Infections in Children with and Exposed to HIV. Available at: <https://clinicalinfo.hiv.gov/en/guidelines/hiv-clinical-guidelines-pediatric-opportunistic-infections/whats-new>

³ World Health Organization. Guidelines for diagnosing, preventing, and managing cryptococcal disease among adults, adolescents and children living with HIV. Available at: www.who.int/publications/i/item/9789240052178

is normal) as first-line induction therapy for pediatric patients with meningeal and/or other serious cryptococcal infections (see Antifungal Drugs for Systemic Fungal Infections, p 1017). Among HIV-positive adults with cryptococcal meningitis, induction with a single high dose of parenteral liposomal amphotericin B (10 mg/kg) plus 14 days of oral flucytosine (100 mg/kg/day) and oral fluconazole (1200 mg/day) demonstrated noninferiority to parenteral amphotericin B deoxycholate (1 mg/kg/day) plus oral flucytosine (100 mg/kg/day) for 7 days, followed by oral fluconazole (1200 mg/day) for 7 days. Frequent monitoring of blood counts and/or serum peak flucytosine concentrations (with a target of 40 to 60 µg/mL 2 hours after the dose) are recommended to prevent neutropenia. If flucytosine cannot be administered, amphotericin B alone has been successfully used in pediatric cryptococcosis, or amphotericin B can be combined with fluconazole for the induction phase of therapy. Ideally, a lumbar puncture should be performed after 2 weeks of therapy to document microbiologic clearance. Patients in whom culture is positive after 2 weeks of therapy will require a more prolonged induction treatment course.

Patients with meningitis should receive induction combination therapy for at least 2 weeks and until a repeat CSF culture is negative, followed by consolidation therapy with fluconazole (10–12 mg/kg/day; maximum 800 mg per day) for a minimum of 8 weeks.

For any relapse, primary induction antifungal therapy should be restarted for 4 to 10 weeks, CSF cultures should be repeated every 2 weeks until sterile, and antifungal susceptibility of the relapse isolate should be determined and compared with the original isolate. Monitoring of serum CrAg is not useful to determine response to therapy in patients with cryptococcal meningitis.

Increased intracranial pressure occurs frequently despite microbiologic response and often is associated with clinical deterioration. Significant elevation of intracranial pressure is a major source of morbidity and should be managed with frequent repeated lumbar punctures or placement of a lumbar drain in those with high intracranial pressures and symptoms. Immune reconstitution inflammatory syndrome (IRIS) is described in children, and although there are no guidelines for specific management of IRIS in children, a patient should be monitored closely for signs and symptoms associated with symptomatic central nervous system IRIS and a steroid taper should be considered for management. In antiretroviral-naïve HIV-infected patients with newly diagnosed cryptococcal meningitis or disseminated disease, delay in potent antiretroviral therapy is recommended until the end of the first 2 weeks of induction therapy; further delays in initiating combined antiretroviral therapy, especially in resource-limited settings, should be individualized.¹

Children with HIV infection who have completed initial therapy for cryptococcosis should receive long-term (at least 1 year) secondary prophylaxis therapy with fluconazole (6 mg/kg daily; maximum dose 200 mg). The safety of discontinuing secondary prophylaxis for cryptococcosis after immune reconstitution with combined antiretroviral therapy (ART) has not been studied in children. However, on the basis of adult data and experience, discontinuing suppressive/maintenance therapy for cryptococcosis

¹ Panel on Opportunistic Infections in HIV-Exposed and HIV-Infected Children. Guidelines for the Prevention and Treatment of Opportunistic Infections in Children with and Exposed to HIV. Available at: <https://clinicalinfo.hiv.gov/en/guidelines/hiv-clinical-guidelines-pediatric-opportunistic-infections/whats-new>

(after receiving secondary prophylaxis for at least 1 year) can be considered for asymptomatic children ≥ 6 years of age, with increase in their CD4+ T-lymphocyte counts to ≥ 100 cells/mm³ and an undetectable viral load after receiving ART for ≥ 3 months.¹ Secondary prophylaxis therapy should be reinitiated if the CD4+ T-lymphocyte count decreases to < 100 cells/mm³. Most experts would not discontinue secondary prophylaxis for patients younger than age 6 years and thus individualized management plans need to be made.

Patients with less severe nonmeningeal disease (pulmonary disease) can be treated with fluconazole alone, but data on use of fluconazole for children with *C. neoformans* infection are limited; itraconazole is a potential alternative. Another potential treatment option for patients in whom amphotericin B treatment is not possible is combination therapy with fluconazole and flucytosine; this combination has superior efficacy compared with fluconazole alone for severe disease. Echinocandins are not active against cryptococcal infections and should not be used.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: None.

Cryptosporidiosis

CLINICAL MANIFESTATIONS: Cryptosporidiosis commonly presents with frequent, nonbloody, watery diarrhea, although infection can be asymptomatic. Other symptoms include abdominal cramps, fatigue, fever, vomiting, anorexia, and weight loss. In an immunocompetent person, symptomatic cryptosporidiosis is self-limited, usually resolving within 2 to 3 weeks. *Cryptosporidium* infection is a common cause of moderate to severe diarrhea and poor growth among young children in resource-limited countries.

In an immunocompromised person, such as a child who has received a solid organ transplant or has advanced human immunodeficiency virus (HIV) disease, cryptosporidiosis can result in profuse diarrhea lasting weeks to months, which can lead to severe, even life-threatening dehydration, malnutrition, and wasting. The diagnosis of cryptosporidiosis should be considered in any immunocompromised person with diarrhea. Extraintestinal (eg, pulmonary or biliary tract) cryptosporidiosis has been reported in immunocompromised people and is associated with CD4+ T-lymphocyte counts less than 50/mm³.

ETIOLOGY: Cryptosporidia are oocyst-forming coccidian protozoa. Approximately 20 *Cryptosporidium* species or genotypes have been reported to infect humans, but *Cryptosporidium hominis* and *Cryptosporidium parvum* cause more than 90% of cases of human cryptosporidiosis. Oocysts are excreted in feces of an infected host and as few as 10 oocysts can cause infection. *Cryptosporidium* oocysts can tolerate extreme

¹ Panel on Opportunistic Infections in HIV-Exposed and HIV-Infected Children. Guidelines for the Prevention and Treatment of Opportunistic Infections in Children with and Exposed to HIV. Available at: <https://clinicalinfo.hiv.gov/en/guidelines/hiv-clinical-guidelines-pediatric-opportunistic-infections/whats-new>

environmental conditions and can survive in water and soil for several months. Even in properly chlorinated pools, *Cryptosporidium* oocysts can survive for more than 7 days.

EPIDEMIOLOGY: *Cryptosporidium* organisms can be transmitted between humans and to humans via contaminated water or food or from infected animals. Extensive water-borne disease outbreaks have been associated with contamination of drinking water and recreational water (eg, pools, lakes, and splash pads). *Cryptosporidium* infection is the leading cause of outbreaks associated with treated recreational water venues (eg, swimming pools and splash pads), responsible for 76 (49%) of 155 US outbreaks during 2015–2019 for which an infectious cause was identified, and 84% of all cases from those 155 outbreaks.

In children, the incidence of cryptosporidiosis is greatest during summer and early fall, corresponding to the outdoor swimming season. The incidence of reported cryptosporidiosis is highest in children 1 through 4 years of age.

Foodborne transmission can occur; *Cryptosporidium* organisms have been detected on raw produce and in raw or unpasteurized apple cider and milk. People can acquire infections from pets, livestock, and from animals found in petting zoos, particularly preweaned bovine calves, lambs, and goat kids. *Cryptosporidium* organisms can spread by person-to-person transmission and result in outbreaks in child care settings and are a cause of travelers' diarrhea. (www.cdc.gov/parasites/crypto/audience-travelers.html).

The **incubation period** of *Cryptosporidium* species usually is 2 to 10 days. Recurrence of symptoms has been reported frequently. In immunocompetent people, oocyst shedding usually ceases within 2 weeks after symptoms completely abate. In immunocompromised people, the period of oocyst shedding can continue for months.

DIAGNOSTIC TESTS: Molecular methods are being used increasingly for diagnosis of cryptosporidiosis and are now the standard of care. Nucleic acid amplification tests (NAATs) that target multiple gastrointestinal tract pathogens in a single assay have a sensitivity of 97% and a specificity of 98% for *Cryptosporidium* organisms.

Nonmolecular testing, including direct fluorescent antibody (DFA) detection of oocysts in stool and enzyme immunoassays (EIAs) or rapid point-of-care lateral flow immunochromatographic tests targeting cryptosporidial antigens in stool, can provide rapid results, but their potential false-positive results and low positive predictive values still necessitate molecular confirmation. The detection of oocysts on microscopic examination of stool specimens can be accomplished by direct wet mount if concentration of the oocysts is high. Alternatively, the formalin ethyl acetate stool concentration method can be used followed by staining of the stool specimen with a modified Kinyoun acid-fast stain. Oocysts generally are small (4–6 μm in diameter) and can be missed in a rapid scan of a slide. At least 3 stool specimens collected on separate days should be examined before considering test results to be negative, because shedding can be intermittent. Organisms also can be identified in intestinal fluid, tissue samples, or biopsy specimens.

TREATMENT: Supportive therapy with volume and electrolyte repletion is recommended for all patients with cryptosporidiosis. Immunocompetent people might not need specific therapy. If treatment of diarrhea associated with cryptosporidiosis is

indicated, a 3-day course of nitazoxanide oral suspension has been approved by the FDA for non-HIV-infected, immunocompetent people 1 year or older (see Table 4.11, Drugs for Parasitic Infections, p 1068).

In children with HIV infection, nitazoxanide alone in a 3-day course is generally ineffective in the treatment of *Cryptosporidium* diarrhea. Improvement in CD4+ T-lymphocyte count associated with antiretroviral therapy can lead to resolution of symptoms and cessation of oocyst shedding. For this reason, administration of combination antiretroviral therapy (ART) is the primary treatment for cryptosporidiosis in patients with HIV infection. Given the seriousness of cryptosporidiosis in immunocompromised people, a 14-day course of nitazoxanide can be considered in immunocompromised HIV-infected children in conjunction with immune restoration with ART.¹ In immunocompromised children, including some children with HIV infection, paromomycin or azithromycin have been used in case series with some success as single agents, in combination, or in combination with nitazoxanide (either agent or both). There are little data on the use of paromomycin or azithromycin in immunocompetent children with *Cryptosporidium* diarrhea, so they should be considered for use primarily in immunocompromised children, and should be used in immunocompetent children only if nitazoxanide has failed or is not available.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, contact precautions are recommended for diapered or incontinent people for the duration of illness. Hydrogen peroxide is preferred over bleach for environmental cleaning because of the organism's extreme chlorine tolerance.

CONTROL MEASURES: Appropriate control and prevention measures should be implemented promptly to prevent pathogen transmission. In general, these measures include the following, and other measures might be indicated depending on suspected source and mode of transmission:

- Wash hands frequently with soap and water. Alcohol-based hand sanitizers are not effective against *Cryptosporidium* species.
- Do not swim or participate in recreational water activities if sick with diarrhea. If cryptosporidiosis is diagnosed, wait 2 weeks after diarrhea has stopped completely before participating in recreational water activities.
- Avoid swallowing recreational water. Additional information on healthy swimming can be found at **www.cdc.gov/healthyswimming**.
- Do not consume food or drink that might be contaminated, such as water from lakes or rivers; inadequately treated water (eg, while traveling in areas with unsafe water); fruits or vegetables washed in water that might be contaminated; or unpasteurized milk or apple cider.
- If immunocompromised, avoid contact with farm animals and their feces (see **www.cdc.gov/parasites/crypto/gen_info/prevent_ic.html**).

Public Health Reporting. Cryptosporidiosis cases are reportable to local, state, and territorial health departments.

¹ Panel on Opportunistic Infections in HIV-Exposed and HIV-Infected Children. Guidelines for the Prevention and Treatment of Opportunistic Infections in Children with and Exposed to HIV. Available at: **<https://clinicalinfo.hiv.gov/en/guidelines/hiv-clinical-guidelines-pediatric-opportunistic-infections/whats-new>**

Cutaneous Larva Migrans

CLINICAL MANIFESTATIONS: Cutaneous larva migrans refers to a classic skin rash caused by zoonotic hookworms. It is a clinical diagnosis based on advancing serpiginous tracks in the skin with associated intense pruritus. Certain zoonotic nematode larvae may penetrate intact skin and produce pruritic, reddish papules at the site of skin entry. Humans usually are “dead-end” hosts for these parasites, and the larvae are unable to progress beyond the skin and eventually die. As the larvae migrate through skin, advancing up to 20 millimeters per day, intensely pruritic serpiginous tracks are formed, a condition also referred to as creeping eruption. Bullae may develop later as a complication of the larval migration. Larval activity can continue for several weeks, but the infection typically is self-limiting. Rarely complications such as Loeffler (also spelled Löffler) syndrome (pulmonary infiltration with peripheral eosinophilia) have been reported.

ETIOLOGY: Infective larvae of cat and dog hookworms (most often *Ancylostoma braziliense*, also *Ancylostoma caninum*, *Ancylostoma ceylanicum*, and *Uncinaria stenocephala*) cause cutaneous larva migrans. Other skin-penetrating nematodes can cause similar pruritic serpiginous skin rashes (eg, larva currens caused by *Strongyloides* species and “ground itch” of *Necator americanus*).

EPIDEMIOLOGY: Cutaneous larva migrans is a disease of children, utility workers, gardeners, sunbathers, and others who come in contact with soil or sand contaminated with cat and dog feces. Locally acquired cases in the United States are mostly in the Southeast. Most US cases are not acquired locally but occur among travelers to tropical and subtropical regions, particularly those who have walked barefoot or have had unprotected skin contact on beaches.

The **incubation period** typically is short, with signs and symptoms developing several days after larval penetration of the skin. Rarely, onset may be weeks to months after exposure.

DIAGNOSTIC TESTS: The diagnosis is made clinically, and biopsies are not indicated. Biopsy specimens typically demonstrate an eosinophilic inflammatory infiltrate, but the migrating parasite is not visualized. Eosinophilia and increased immunoglobulin (Ig) E serum concentrations occur in some cases. Enzyme immunoassay or Western blot analysis using antigens of *A caninum* have been developed in research laboratories, but these assays are not available for routine diagnostic use.

TREATMENT: The disease usually is self-limited with spontaneous cure after several weeks, but treatment can decrease symptoms and hasten their resolution. Orally administered albendazole or ivermectin is the recommended therapy (see Drugs for Parasitic Infections, p 1068). Repeated application of topical 10% albendazole may be useful in young children who cannot take oral medication, but it is not available commercially and must be formulated at a pharmacy. Outside the United States, topical thiabendazole has also been used successfully for treatment of localized larvae.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS: Standard precautions are recommended.

CONTROL MEASURES: Skin contact with moist soil or sand contaminated with animal feces should be avoided. Beaches should be kept free of dog and cat feces. Regular veterinary care of dogs and cats is recommended.

Cyclosporiasis

CLINICAL MANIFESTATIONS: Watery diarrhea is the most common symptom of cyclosporiasis and can be profuse and protracted. Anorexia, nausea, substantial weight loss, flatulence, abdominal cramping and bloating, and prolonged fatigue can occur. Low-grade fever occurs in approximately 50% of patients and vomiting, body aches, headaches, and other influenza-like symptoms also may occur. Biliary tract disease has been reported. Infection usually is self-limited, but untreated people may have remitting, relapsing symptoms for weeks to months. Asymptomatic infection has been documented, most commonly in settings where cyclosporiasis is endemic.

ETIOLOGY: *Cyclospora cayetanensis* is a coccidian protozoan; oocysts (rather than cysts) are passed in stools and must then sporulate before they are infectious. In the laboratory, sporulation occurs at temperatures between 22°C and 32°C for 1 to 2 weeks; the exact conditions that support sporulation in the natural environment are unknown.

EPIDEMIOLOGY: *C. cayetanensis* is endemic in many resource-limited countries and has been reported as a cause of travelers' diarrhea. Foodborne and waterborne outbreaks have been reported. Most outbreaks in the United States and Canada for which a food vehicle and its source have been identified have been associated with consumption of imported fresh produce (eg, basil, cilantro, raspberries, sugar snap peas, lettuce). There has been a trend in the United States of seasonal increases in reported cases from May through August in recent years; many cases occur among people without a history of international travel. Recent increases in case numbers reported in the United States might be attributable, in part, to increased use of commercially available molecular testing panels.

Humans are the only known hosts for *C. cayetanensis*. Direct person-to-person transmission is unlikely because excreted oocysts take at least 1 to 2 weeks (estimated) under favorable environmental conditions to sporulate and become infective. Oocysts are resistant to most disinfectants used in food and water processing and can remain viable for prolonged periods in cool, moist environments.

The **incubation period** typically is 1 week but can range from 2 days to 2 weeks or more.

DIAGNOSTIC TESTS: Diagnosis is made by identification of oocysts (8–10 µm in diameter) in stool, intestinal fluid/aspirates, or intestinal biopsy specimens. Oocysts may be shed in low concentrations, even by people with profuse diarrhea. This constraint underscores the utility of repeated stool examinations, sensitive recovery methods (eg, concentration procedures including formalin-ethyl acetate sedimentation or sucrose centrifugal flotation), and detection methods that highlight the organism. Oocysts are autofluorescent and are variably acid fast after modified acid-fast staining of stool specimens. Molecular diagnostic assays (eg, nucleic acid amplification tests) are available commercially as part of a multiplex gastrointestinal panel and at the Centers for Disease Control and Prevention.

TREATMENT: Trimethoprim-sulfamethoxazole, typically for 7 to 10 days, is the drug of choice (see Table 4.11, Drugs for Parasitic Infections, p 1068); immunocompromised patients may need longer courses of therapy. No highly effective alternatives have been identified for people who cannot tolerate trimethoprim-sulfamethoxazole (www.cdc.gov/parasites/cyclosporiasis/health_professionals/tx.html), but case reports suggest that nitazoxanide might be an effective alternative for patients who

cannot tolerate sulfa drugs. Data from patients with human immunodeficiency virus (HIV) infection in Haiti have suggested that ciprofloxacin also may be effective, but anecdotal reports among immunocompetent patients do not support its efficacy.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, contact precautions are recommended for diapered or incontinent persons.

CONTROL MEASURES: Avoiding food or water that may be contaminated with feces is the best known way to prevent cyclosporiasis. Fresh produce should be avoided in high-risk settings or should be washed thoroughly before it is eaten, although this may not eliminate risk for transmission completely.

Public Health Reporting. Cyclosporiasis is a nationally notifiable disease. Please refer to the state or local health department for details on reporting cases.

Cystoisosporiasis (Formerly Isosporiasis)

CLINICAL MANIFESTATIONS: Watery, nonbloody diarrhea is the most common symptom of cystoisosporiasis; diarrhea can be profuse and protracted, even in immunocompetent people. Manifestations are similar to those caused by other enteric protozoa (eg, *Cryptosporidium* and *Cyclospora* species) and can include abdominal pain, cramping, flatulence, anorexia, nausea, vomiting, weight loss, and low-grade fever. Severity of infection ranges from self-limiting in immunocompetent hosts to chronic, debilitating, sometimes life-threatening diarrheal infection with wasting in immunocompromised patients, particularly but not exclusively among people infected with human immunodeficiency virus (HIV). Biliary tract disease (cholecystitis/cholangiopathy) and reactive arthritis also have been reported. Peripheral eosinophilia may occur.

ETIOLOGY: *Cystoisospora belli* (formerly *Isospora belli*) is a coccidian protozoan; oocysts (rather than cysts) are passed in stools.

EPIDEMIOLOGY: Infection occurs predominantly in tropical and subtropical regions of the world and results from ingestion of sporulated oocysts in food or water contaminated with human feces. Humans are the only known host for *C. belli* and shed noninfective oocysts in feces. These oocysts must mature (sporulate) outside the host in the environment to become infective. Therefore, direct person-to-person transmission of *Cystoisospora* is unlikely. Under favorable conditions, sporulation can be completed in 1 to 2 days and perhaps more quickly in some settings. Oocysts probably are resistant to most disinfectants and can remain viable for prolonged periods in a cool, moist environment.

The **incubation period** averages 1 week but may range from several days to 2 or more weeks.

DIAGNOSTIC TESTS: Identification of oocysts in feces or in duodenal aspirates is diagnostic, as is finding developmental stages of the parasite in biopsy specimens (eg, of the small intestine). Oocysts in stool are elongate and ellipsoidal (length, 25 to 35 μm). Oocysts can be shed in low numbers, even by people with profuse diarrhea. This underscores the utility of repeated stool examinations, sensitive recovery methods (eg, concentration methods), and the need for detection methods that highlight the organism (eg, oocysts stain bright red with modified acid-fast staining techniques and autofluoresce when viewed by ultraviolet fluorescence microscopy). Nucleic acid amplification tests (NAATs) have been developed for detecting *Cystoisospora* DNA in feces but

are not widely available. Like *Cryptosporidium* and *Cyclospora* species, *Cystoisospora* organisms usually are not detected by routine stool ova and parasite examination. Therefore, the laboratory should be notified specifically when any coccidian parasite is suspected on clinical grounds so that special microscopic methods are used in addition to traditional ova and parasite examination.

TREATMENT: Treatment has been studied predominantly in patients with HIV infection. In the immunocompetent host, treatment may not be necessary, as symptoms usually are self-limited. If symptoms do not begin to resolve by 5 to 7 days, and in immunocompromised patients, trimethoprim-sulfamethoxazole (TMP-SMX) is the drug of choice (see Table 4.11, Drugs for Parasitic Infections, p 1068). Immunocompromised patients may need higher doses and a longer duration of therapy. Pyrimethamine (plus leucovorin, to prevent myelosuppression) is an alternative for people who cannot tolerate (or whose infection does not respond to) trimethoprim-sulfamethoxazole. Ciprofloxacin is less effective than trimethoprim-sulfamethoxazole. Nitazoxanide has been reported to be effective, but data are limited.

In adolescents and adults coinfecting with HIV with CD4+ T-lymphocyte counts of <200 cells/mm³, secondary prophylaxis with TMP-SMX is recommended to prevent recurrent disease. In adults, secondary prophylaxis may be discontinued once the CD4+ T-lymphocyte count is >200 cells/mm³ for >6 months as a result of antiretroviral therapy. In children, a reasonable time to discontinue secondary prophylaxis would be after sustained improvement (for >6 months) in CD4+ T-lymphocyte count or CD4+ T-lymphocyte percentage from CDC immunologic category 3 to category 1 or 2 in response to antiretroviral therapy (<https://clinicalinfo.hiv.gov/en/guidelines/pediatric-opportunistic-infection/isosporiasis-cystoisosporiasis> and www.cdc.gov/mmwr/preview/mmwrhtml/rr6303a1.htm?s_cid=rr6303a1_e). These individuals should be monitored closely for recurrent symptoms. Supportive treatment for dehydration and/or malnutrition associated with severe diarrheal illness may be required.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, contact precautions are recommended for diapered and incontinent people.

CONTROL MEASURES: Preventive measures include avoiding fecal exposure (eg, food, water, skin, and fomites contaminated with stool), practicing hand and personal hygiene, and thorough washing of fruits and vegetables before eating.

Cytomegalovirus Infection

CLINICAL MANIFESTATIONS: Manifestations of acquired human cytomegalovirus (CMV) infection vary with age and immunocompetence of the host. Asymptomatic infections are the most common, particularly in children. An infectious mononucleosis-like syndrome with prolonged fever and mild hepatitis, occurring in the absence of heterophile antibody production (“monospot negative”), may occur in adolescents and adults. End-organ disease, including pneumonia, colitis, retinitis, meningoencephalitis, or transverse myelitis, or a CMV syndrome characterized by fever, thrombocytopenia, leukopenia, and mild hepatitis may occur in immunocompromised hosts, including people receiving treatment for malignant neoplasms, people infected with human

immunodeficiency virus (HIV), and people receiving immunosuppressive therapy for solid organ or hematopoietic cell transplantation. Less commonly, patients treated with biologic response modifiers (see Biologic Response Modifying Drugs Used to Decrease Inflammation, p 104) can exhibit CMV end-organ disease, such as retinitis and hepatitis.

Congenital CMV infection has a spectrum of clinical manifestations but usually is not evident at birth (asymptomatic congenital CMV infection). Approximately 10% of infants with congenital CMV infection exhibit clinical findings that are evident at birth (symptomatic congenital CMV disease), with manifestations including jaundice attributable to direct hyperbilirubinemia, petechiae attributable to thrombocytopenia, purpura, hepatosplenomegaly, microcephaly, intracerebral (typically periventricular) calcifications, and retinitis. Developmental delays can occur among affected infants in later infancy and early childhood. Death attributable to congenital CMV is estimated to occur in 3% to 10% of infants with symptomatic disease or 0.3% to 1.0% of all infants with congenital CMV infection.

Congenital CMV infection is the leading nongenetic cause of sensorineural hearing loss (SNHL) in children in the United States. Approximately 20% of all hearing loss at birth and 25% of all hearing loss at 4 years of age is attributable to congenital CMV infection. SNHL is the most common sequela following congenital CMV infection, with SNHL occurring in up to 50% of children with congenital infections that are symptomatic at birth and up to 15% of those with asymptomatic infections. Approximately 40% of infected children who ultimately develop SNHL will not have hearing loss detectable within the first month of life, illustrating the risk of late-onset SNHL in these populations. Approximately 50% of children with CMV-associated SNHL continue to have further deterioration (progression) of their hearing loss over time.

Infection acquired during the intrapartum period from cervical secretions or in the postpartum period from human milk usually is not associated with clinical illness in term infants. In preterm infants, however, postpartum infection resulting from human milk or from transfusion from CMV-seropositive donors has been associated with hepatitis, interstitial pneumonitis, colitis, hematologic abnormalities including thrombocytopenia, neutropenia, leukopenia, and a viral sepsis syndrome.

ETIOLOGY: Human CMV, also known as human herpesvirus 5, is a member of the herpesvirus family (*Herpesviridae*), the beta-herpesvirus subfamily (*Betaherpesvirinae*), and the *Cytomegalovirus* genus. The viral genome contains double-stranded DNA that range in size from 196 000 to 240 000 bp encoding at least 166 proteins and is the largest of the human herpesvirus genomes.

EPIDEMIOLOGY: CMV is highly species-specific, and only human CMV has been shown to infect and cause disease in humans. The virus is ubiquitous, and CMV strains exhibit extensive genetic diversity. Transmission occurs horizontally (by direct person-to-person contact with virus-containing secretions), vertically (from mother to infant before, during, or after birth), and via transfusions of blood, platelets, and white blood cells from infected donors. CMV also can be transmitted with solid organ or hematopoietic cell transplantation. Infections have no seasonal predilection. CMV persists in leukocytes and tissue cells after a primary infection, with intermittent virus shedding; symptomatic reinfection can occur throughout the lifetime of the infected person, particularly under conditions of immunosuppression. Reinfection with other strains of CMV can occur in seropositive hosts, including pregnant people. In the

United States, there appears to be 3 periods in life when there is an increased incidence of CMV acquisition: early childhood, adolescence, and the childbearing years.

Horizontal transmission probably is the result of exposure to saliva, urine, or genital secretions from infected individuals. Spread of CMV in households and child care centers is well documented. Excretion rates from urine or saliva in children 1 to 3 years of age who attend child care centers usually range from 30% to 40% but can be as high as 70%. In addition, children who attend child care frequently excrete large quantities of virus for prolonged periods. Young children can transmit CMV to their parents, including those who may be pregnant, and other caregivers, including child care staff (see *Children in Group Child Care and Schools*, p 145). In adolescents and adults, sexual transmission occurs, as evidenced by detection of virus in seminal and cervical fluids. As such, CMV is considered to be a sexually transmitted infection (STI).

CMV-seropositive healthy people have latent CMV in their leukocytes and tissues; hence, blood transfusions and organ transplantation can result in transmission. Severe CMV disease following transfusion or solid organ transplantation is more likely to occur if the recipient is CMV seronegative before transplantation. In contrast, among nonautologous hematopoietic cell transplant (HCT) recipients, CMV-seropositive individuals who receive transplants from seronegative donors are at greatest risk of disease when exposed to CMV after transplantation, likely because of the failure of the transplanted graft to provide immunity to the recipient. Latent CMV may reactivate in immunosuppressed individuals and result in disease if immunosuppression is severe (eg, in patients with acquired immunodeficiency syndrome [AIDS] or solid organ or HCT recipients).

Vertical transmission of CMV to an infant occurs in one of the following time periods: (1) in utero (congenital), by transplacental passage of parental bloodborne virus; (2) at birth (perinatal), by passage through an infected genital tract; or (3) following birth (postnatal), via ingestion of CMV-positive human milk. Approximately 5 per 1000 live-born infants are infected in utero and excrete CMV at birth, making this the most common congenital viral infection in the United States. Significant racial and ethnic differences exist in the prevalence of congenital CMV, with the highest prevalence of CMV in Black newborn infants (9.5/1000 live births) and lower prevalence in non-Hispanic white infants (2.7/1000 live births) and Hispanic white infants (3.0/1000 live births). In utero fetal infection can occur in pregnant people with no preexisting CMV immunity (primary infection) or in pregnant people with preexisting antibodies to CMV (nonprimary infection) either by acquisition of a different viral strain during pregnancy or by reactivation of an existing infection. Congenital infection and associated sequelae can occur irrespective of the trimester when the pregnant person is infected, but severe sequelae are associated more commonly with infection acquired during the first trimester. Damaging fetal infections and sequelae can occur following both primary and nonprimary infections in the pregnant person. It is estimated that more than three quarters of infants with congenital CMV infection in the United States are born to a person with nonprimary infection; in nations with near-universal CMV seroprevalence, most damaging congenital CMV infections occur in infants born to people with nonprimary infection.

Among infants who acquire infection perinatally from cervical secretions or postnatally from human milk, preterm infants born before 32 weeks' gestation and with a birth weight less than 1500 g are at greater risk of developing CMV disease than are full-term infants. Most infants who acquire CMV from ingestion of human milk from

a CMV-seropositive parent do not develop clinical illness or sequelae, likely because of the presence of passively transferred antibody.

The **incubation period** for horizontally transmitted CMV infections is highly variable. Infection usually manifests 3 to 12 weeks after blood transfusions and between 1 and 4 months after organ transplantation. For vertical transmission through human milk in preterm infants, the median time to onset of CMV viremia is 7 weeks (range, 3–24 weeks).

DIAGNOSTIC TESTS: The diagnosis of CMV disease is confounded by the ubiquity of the virus, the high rate of asymptomatic excretion, the frequency of reactivated infections, reinfection with different strains of CMV, the development of serum immunoglobulin (Ig) M CMV-specific antibodies in some episodes of reactivation and reinfection, and concurrent infection with other pathogens.

Viral DNA can be detected by nucleic acid amplification tests (NAATs) in tissues and some fluids, including cerebrospinal fluid (CSF), amniotic fluid, human milk, aqueous and vitreous humor fluids, urine, saliva and other respiratory secretions, and peripheral blood. Detection of CMV DNA by NAAT in blood does not necessarily indicate acute infection or disease, especially in immunocompetent people. Several quantitative NAATs for detection of CMV have been cleared by the US Food and Drug Administration (FDA). These assays are sensitive, use standardized international units for reporting, provide rapid results compared with culture, and generally are the preferred method for detecting CMV DNA. The same specimen type should always be used when testing any given patient over time. Antigenemia assays also have been cleared by the FDA, but they are labor intensive and require timely processing of specimens to obtain accurate results. Because of these drawbacks, molecular assays are preferred.

CMV can be isolated in conventional cell culture from urine, saliva, peripheral blood leukocytes, human milk, semen, cervical secretions, and other tissues and body fluids. Recovery of virus from a target organ provides supportive evidence that the disease is caused by CMV infection. Standard viral cultures must be maintained for more than 28 days before considering such cultures negative. Shell vial culture coupled with staining of cells using immunofluorescence antibody techniques for immediate early antigen provides results within 24 to 36 hours but is not available in many laboratories.

Various serologic assays, including immunofluorescence assays, latex agglutination assays, and enzyme immunoassays, are available for detecting both IgG and IgM CMV-specific antibodies. Single serum specimens for IgG antibody testing are useful in screening for past infection in individuals at risk for CMV reactivation or for screening potential organ transplant donors and recipients. For diagnosis of suspected recent infection, testing for CMV IgG in paired sera obtained at least 2 weeks apart and testing for IgM in a single serum specimen may be useful. Determination of low-avidity CMV IgG in the presence of CMV IgM in a pregnant person can suggest more recent infection.

Fetal CMV infection can be diagnosed by detection of CMV DNA in amniotic fluid. Congenital infection with CMV requires detection of CMV or CMV DNA in urine, saliva, blood, or CSF obtained within 3 weeks of birth; detection beyond this initial period of life could reflect postnatal acquisition of virus. NAATs of saliva swab specimens from neonates have been shown to be >95% sensitive for the identification of congenital CMV infection. Positive saliva swab specimen test results requires confirmation with testing of urine because of potential contamination of saliva with CMV in human milk. The analytical sensitivity of CMV NAAT of dried blood spots is lower;

limiting use of this type of specimen for widespread screening for congenital CMV infection. A positive NAAT result from a neonatal dried blood spot confirms congenital infection, but a negative result does not rule out congenital infection. Differentiation between congenital and perinatal infection is difficult at later than 3 weeks of age unless clinical manifestations of the former, such as chorioretinitis or periventricular calcifications, are present. At least 1 commercial assay has been cleared by the FDA for detection of CMV DNA from saliva of neonates within the first 3 weeks of life. IgM serologic methods have reduced sensitivity and specificity and may yield false-positive results, making serologic diagnosis of congenital CMV infection unreliable.

Targeted CMV newborn screening, in which infants who do not pass their newborn hearing screening are tested for CMV in saliva or urine within the first 2 to 3 weeks of life, is mandated in several states, and many birth hospitals have implemented targeted screening programs as standard of care. Universal screening of all newborn infants for CMV has been undertaken in Ontario and Saskatchewan, Canada, beginning in 2019 and 2022, respectively, and in 2022 Minnesota became the first state to add congenital CMV to its newborn screening program.

TREATMENT: Intravenous ganciclovir (see Non-HIV Antiviral Drugs, p 1044) is approved for induction and maintenance treatment of retinitis caused by acquired or recurrent CMV infection in immunocompromised adult patients, including people living with HIV, and for prophylaxis and treatment of CMV disease in adult transplant recipients. Valganciclovir, the oral prodrug of ganciclovir, is approved for treatment (induction and maintenance) of CMV retinitis in immunocompromised adult patients, including people living with HIV, and for prevention of CMV disease in kidney, kidney-pancreas, or heart transplant recipients at high risk of CMV disease. Valganciclovir also is approved for prevention of CMV disease in pediatric kidney transplant patients 4 months and older and for pediatric heart transplant patients 1 month and older. Ganciclovir and valganciclovir are used to treat CMV infections of other sites (esophagus, colon, lungs) and for preemptive treatment of immunosuppressed adults with CMV antigenemia or viremia. Valganciclovir is available in both tablet and powder for oral solution formulations. Oral ganciclovir and ganciclovir ocular implants are no longer available in the United States.

Neonates with moderately to severely symptomatic congenital CMV disease with or without central nervous system (CNS) involvement have improved audiologic and neurodevelopmental outcomes at 2 years of age when treated with oral valganciclovir for **6 months** (see Non-HIV Antiviral Drugs, p 1044). The dose should be adjusted each month to account for weight gain. Neonates with isolated SNHL have improved audiologic outcomes when treated with oral valganciclovir for **6 weeks**, with treatment begun by 13 weeks following birth. Treatment of mildly symptomatic neonates has not been studied. Treatment recommendations by degree of symptomatology are provided in Table 3.4. Infants with asymptomatic congenital CMV infection should not receive antiviral treatment outside the confines of a research study.

Therapy can be accomplished using oral valganciclovir for the entire treatment course, because drug exposure following appropriate dosing of valganciclovir is the same as that achieved with intravenous ganciclovir. If an infant is unable to absorb medications reliably from the gastrointestinal tract (eg, because of necrotizing enterocolitis or other bowel disorders), intravenous ganciclovir can be used initially. Significant neutropenia occurs in approximately 20% of infants treated with oral

Table 3.4. Classification of Congenital Cytomegalovirus Disease Severity and Treatment Recommendations

CMV Disease Severity	Signs and Symptoms	Treatment
Moderately to severely symptomatic	One or more of the following: • Single severe or multiorgan disease (eg, significant liver enzyme abnormalities and marked hepatosplenomegaly) or life-threatening organ dysfunction • Multiple persistent (eg, ≥ 2 weeks) manifestations attributable to congenital CMV infection: thrombocytopenia, petechiae, hepatomegaly, splenomegaly, hepatitis (increased aminotransferases or direct bilirubin) • Central nervous system involvement such as microcephaly, radiographic abnormalities (ventriculomegaly, intracerebral calcifications, white matter changes, periventricular echogenicity, cortical or cerebellar malformations, migration abnormalities), abnormal cerebrospinal fluid indices for age, chorioretinitis, or the detection of CMV DNA in cerebrospinal fluid • Greater than 2 mild disease manifestations (see below)	Valganciclovir ^a (see Non-HIV Antiviral Drugs, p 1044) given orally for 6 months ; treatment should be started within the first 13 weeks following birth ^b
Asymptomatic with isolated sensorineural hearing loss	No clinically apparent signs to suggest congenital CMV disease, but sensorineural hearing loss	Valganciclovir (see Non-HIV Antiviral Drugs, p 1044) may be offered and given orally for 6 weeks ; treatment should be started within the first 13 weeks following birth ^b
Mildly symptomatic	Two or fewer transient (eg, < 2 weeks) or clinically insignificant findings (eg, petechiae, mild hepatomegaly, thrombocytopenia, raised levels of alanine aminotransferase)	There are insufficient data to recommend routine treatment, but it may be considered on a case by case basis in consultation with a pediatric infectious diseases expert
Asymptomatic	No apparent signs to suggest congenital CMV disease, and normal hearing	Therapy not recommended outside of a research study

Modified from Rawlinson W, Boppana S, Fowler KB, et al. Congenital cytomegalovirus infection in pregnancy and the neonate: consensus recommendations for prevention, diagnosis, and therapy. *Lancet Infect Dis*. 2017;17(6):e177-e188; and Luck SE, Wieringa JW, Blázquez-Gamero D, et al. Congenital cytomegalovirus: a European expert consensus statement on diagnosis and management. *Pediatr Infect Dis J*. 2017;36(12):1205-1213.

^aIf an infant is unable to absorb medications reliably from the gastrointestinal tract (eg, because of necrotizing enterocolitis or other bowel disorders), intravenous ganciclovir can be used initially (see Non-HIV Antiviral Drugs, p 1044).

^bAntiviral treatment can start from birth through 12 weeks 6 days following delivery.

valganciclovir and in approximately 65% of infants treated with parenteral ganciclovir. Absolute neutrophil counts should be measured weekly for 6 weeks, then at 8 weeks, then monthly for the duration of antiviral treatment; serum alanine aminotransferase concentration should be measured monthly during treatment. When it occurs, neutropenia is more common during the first 4 to 6 weeks of therapy; if the absolute neutrophil count reproducibly drops below 500 cells/mm³, either treatment can be held until counts recover above 750 cells/mm³, or granulocyte colony-stimulating factor can be administered once daily for 1 to 3 consecutive days.

Patients with symptomatic or asymptomatic congenital CMV infection should have serial audiologic assessments throughout childhood. The American Academy of Pediatrics *Bright Futures: Guidelines for Health Supervision of Infants, Children, and Adolescents*, 4th Edition, recommends hearing screening/assessment at 4, 6, 9, 12, 15, 18, 24, and 30 months of age for children with congenital CMV, in addition to the standard hearing testing recommended for all children at 4, 5, 6, 8, and 10 years of age.

Preterm infants with perinatally acquired CMV infection can have symptomatic, end organ disease (eg, pneumonitis, hepatitis, thrombocytopenia). Antiviral treatment has not been studied in this population. If such patients are treated with parenteral ganciclovir, a reasonable approach is to treat for 2 weeks and then reassess responsiveness to therapy. If clinical data suggest benefit of treatment, an additional 1 to 2 weeks of parenteral ganciclovir can be considered if symptoms and signs have not resolved. Valganciclovir generally is not a reasonable alternative in this setting, given the degree of illness these infants experience and the corresponding effect that this potentially could have on gastrointestinal tract absorption of valganciclovir and first-pass hepatic metabolism to ganciclovir.

In HCT recipients, the combination of immune globulin intravenous (IGIV) or CMV immune globulin intravenous (CMV-IGIV) and intravenous ganciclovir has been reported to be synergistic in treatment of CMV pneumonia. Unlike CMV-IGIV, IGIV products have varying anti-CMV antibody concentrations from lot to lot, are not tested routinely for their quantities of anti-CMV antibodies, and do not have a specified titer of antibodies to CMV that have correlated with efficacy.

Valganciclovir and foscarnet have been approved for treatment and maintenance therapy of CMV retinitis in adults with AIDS, and letermovir has been approved in adults for prophylaxis of CMV infection and disease in adult CMV-seropositive recipients of allogeneic HCT (see Non-HIV Antiviral Drugs, p 1044). Foscarnet is more toxic (with high rates of limiting nephrotoxicity) but may be advantageous for some people living with HIV infection, including people with disease caused by ganciclovir-resistant virus or people who are unable to tolerate ganciclovir. Cidofovir can be used for CMV retinitis in adults with AIDS when there is a need to avoid both ganciclovir and foscarnet, but it is associated with significant nephrotoxicity and increased risk of immune recovery uveitis, hypotony, and neutropenia. In November 2021, maribavir was approved as the first drug for treating adults and pediatric patients (12 years and older and weighing at least 35 kg) with post-transplant CMV infection or disease that does not respond (with or without genetic mutations that cause resistance) to available antiviral treatment for CMV (see Non-HIV Antiviral Drugs, p 1044).

CMV establishes lifelong persistent infection, and as such, it is not eliminated from the body with antiviral treatment of CMV disease. Until immune reconstitution is

achieved with antiretroviral therapy, chronic suppressive therapy should be administered to people living with HIV with a history of CMV end-organ disease (eg, retinitis, colitis, pneumonitis) to prevent recurrence. Discontinuing prophylaxis may be considered for pediatric patients 6 years and older with CD4+ T-lymphocyte counts of >100 cells/mm³ for >6 consecutive months and for children younger than 6 years with percentages of total CD4+ T-lymphocytes of $>15\%$ for >6 consecutive months. For immunocompromised children with CMV retinitis, such decisions should be made in close consultation with an ophthalmologist and should account for such factors as magnitude and duration of CD4+ T-lymphocyte cell increases, anatomic location of the retinal lesion, vision in the contralateral eye, and the feasibility of regular ophthalmologic monitoring. All patients who have had anti-CMV maintenance therapy discontinued should continue to undergo regular ophthalmologic monitoring at 3- to 6-month intervals for early detection of CMV relapse as well as immune reconstitution uveitis.¹

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES:

Care of Exposed People. When caring for children, hand hygiene, particularly after changing diapers, is advised to decrease transmission of CMV. Because asymptomatic excretion of CMV is common in people of all ages, a child with congenital CMV infection should not be treated differently from other children.

Although unrecognized exposure to people who are shedding CMV likely is common, concern may arise when immunocompromised patients or pregnant people, including health care professionals, are exposed to patients with clinically recognizable CMV infection. Standard precautions should be sufficient to interrupt transmission of CMV (see Infection Prevention and Control for Hospitalized Children, p 163).

Child Care. Workers in child care centers capable of becoming pregnant should be aware of CMV and its potential risks and should have access to appropriate hand hygiene measures to minimize occupationally acquired infection (www.cdc.gov/cmiv/index.html).

Immunoprophylaxis. CMV-IGIV is generally not recommended for prophylaxis of CMV disease in solid organ transplant recipients. CMV-IGIV may be useful for prevention of CMV in high-risk heart, lung, and small bowel transplant recipients when used in combination with antiviral agents.^{2,3} The use of CMV-IGIV in pregnant people to prevent CMV transmission to the fetus is not recommended because of lack of effectiveness in randomized controlled clinical trials. Evaluation of investigational vaccines

² Kotton CN, Kumar D, Caliendo AM, Huprikar S, Chou S, Danziger-Isakov L, Humar A; The Transplantation Society International CMV Consensus Group. The Third International Consensus Guidelines on the Management of Cytomegalovirus in Solid-organ Transplantation. *Transplantation*. 2018;102(6):900-931

³ Razonable RR, Humar A. Cytomegalovirus in solid organ transplant recipients. Guidelines of the American Society of Transplantation Infectious Diseases Community of Practice. *Clin Transplant*. 2019;33(9):e13512

in healthy volunteers and renal transplant recipients is in progress, but to date, only inconsistent evidence of efficacy has been reported.

Prevention of Transmission by Blood Transfusion. Transmission of CMV by blood transfusion to newborn infants or other immune-compromised hosts has been virtually eliminated by use of CMV antibody-negative donors and the use of leukoreduced blood products.

Prevention of Transmission by Human Milk. Pasteurization of donated human milk can decrease the likelihood of CMV transmission. Holder pasteurization (62.5°C [144.5°F] for 30 minutes) and short-term pasteurization (72°C [161.6°F] for 15 seconds) of human milk appear to inactivate CMV; short-term pasteurization may be less harmful to the beneficial constituents of human milk. Freezing human milk at -20°C (-4°F) for the sole purpose of reducing CMV infectivity is not advised because, although it may reduce the viral load of CMV, it does not change the risk of CMV sepsis-like syndrome and freezing reduces the bioactivity of human milk. If fresh donated human milk is needed for infants born to CMV antibody-negative birthing parents, providing these infants with milk from only CMV antibody-negative donors should be considered. For infants already infected with CMV, either congenitally or postnatally, the benefits of human milk from their birthing parents outweigh any risk of additional CMV exposure. For further information on human milk banks, see Human Milk Banks (p 143).

Prevention of Transmission in Transplant Recipients. CMV-seronegative recipients of tissue from CMV-seropositive donors are at high risk of CMV disease. If such circumstances cannot be avoided, prophylactic administration of antiviral therapy or monitoring for viremia and administering preemptive antiviral therapy are options to decrease the incidence of CMV disease. Monitoring and preemptive therapy result in lower risk for drug associated toxicity. For solid organ transplant patients receiving antiviral prophylaxis, the risk of delayed-onset CMV disease is highest during the first 3 months after cessation of antiviral prophylaxis. Among CMV-negative recipients of a liver transplant from a CMV-positive donor, preemptive therapy recently has been shown to significantly reduce CMV disease compared with prophylaxis.

Dengue

CLINICAL MANIFESTATIONS: Dengue infection may be asymptomatic or, if symptomatic, may have a wide range of clinical presentations. The 2009 World Health Organization classification for dengue severity (https://apps.who.int/iris/bitstream/handle/10665/44188/9789241547871_eng.pdf?sequence=1&isAllowed=y) is divided into: (1) **Dengue without warning signs:** fever plus 2 of the following: nausea/vomiting, rash, aches and pains, leukopenia, or positive tourniquet test; (2) **Dengue with warning signs:** dengue as defined above plus any of the following: abdominal pain or tenderness, persistent vomiting, clinical fluid accumulation (ascites, pleural effusion), mucosal bleeding, lethargy, restlessness, liver enlargement >2 cm, or increase in hematocrit concurrent with rapid decrease in platelet count; and (3) **Severe dengue:** dengue with at least 1 of the following criteria: severe plasma leakage leading to shock or fluid accumulation with respiratory distress, severe bleeding as evaluated by a clinician, or severe organ involvement (eg, aspartate aminotransferase [AST] or alanine aminotransferase [ALT]

≥ 1000 IU/L, impaired consciousness, failure of heart and other organs). Less common clinical syndromes include myocarditis, pancreatitis, hepatitis, hemophagocytic lymphohistiocytosis, and neurologic disease, including acute meningoencephalitis and post-dengue acute disseminated encephalomyelitis (ADEM).

Dengue begins abruptly with a nonspecific, acute febrile illness lasting 2 to 7 days (**febrile phase**), often accompanied by muscle, joint, or bone pain, headache, retro-orbital pain, facial erythema, injected oropharynx, macular or maculopapular rash, leukopenia, and petechiae or other minor bleeding manifestations. During defervescence, usually on days 3 through 7 of illness, an increase in vascular permeability in parallel with increasing hematocrit (hemoconcentration) may occur. The increased vascular permeability may result in plasma leakage. The period of clinically significant plasma leakage usually lasts 24 to 48 hours (**critical phase**), followed by a **convalescent phase** with gradual improvement and stabilization of the hemodynamic status. Warning signs of progression to severe dengue occur in the late febrile phase and include persistent vomiting, severe abdominal pain, mucosal bleeding, difficulty breathing, early signs of shock, and a rapid decline in platelet count with an increase in hematocrit. Patients with nonsevere disease begin to improve during the critical phase, but people with clinically significant plasma leakage develop severe disease that may include pleural effusions, ascites, hypovolemic shock, and hemorrhage.

ETIOLOGY: Four related RNA viruses of the genus *Flavivirus* (see Arboviruses, p 237), dengue viruses 1, 2, 3, and 4, cause symptomatic (approximately 25%) and asymptomatic (approximately 75%) infections. Infection with one dengue virus serotype most often produces lifelong immunity against that serotype, and a period of cross-protection (often lasting 1 to 2 years) against infection with the other 3 serotypes can be observed. After this, infection with a different serotype may predispose to more severe disease. Because there are 4 serotypes, a person has a lifetime risk of up to 4 dengue virus infections.

EPIDEMIOLOGY: Dengue virus is transmitted to humans primarily through the bite of infected *Aedes aegypti* (and less commonly, *Aedes albopictus* or *Aedes polynesiensis*) mosquitoes. Humans are the main amplifying host of dengue virus and the main source of virus for *Aedes* mosquitoes. A sylvatic nonhuman primate dengue virus transmission cycle exists in parts of Africa and Southeast Asia but rarely crosses to humans. Other forms of transmission are relatively rare and include vertical transmission; transmission via breastfeeding, blood, or organ donation; and health care-associated transmission via needlestick or mucocutaneous exposure. The rate of vertical transmission is around 20% and is even higher when dengue occurs late in pregnancy near delivery. Sexual transmission is also possible but is considered a very rare route of infection.

Dengue is a major public health problem in the tropics and subtropics; about half the world's population is thought to be at risk of infection with dengue viruses and approximately 100 to 400 million dengue infections occur annually worldwide (www.who.int/news-room/fact-sheets/detail/dengue-and-severe-dengue). Dengue is endemic in the United States territories and freely associated states of Puerto Rico, the US Virgin Islands, American Samoa, the Federated States of Micronesia, the Republic of Marshall Islands, and the Republic of Palau.

Approximately 90% of the population in these areas at risk for dengue live in Puerto Rico, and 95% of locally acquired dengue cases reported in the United States from 2010 to 2020 occurred in Puerto Rico.¹ Incidence rates vary significantly by geographic locale, affected by factors such as population density, elevation, and mosquito breeding and water supply patterns. Outbreaks with local dengue virus transmission have occurred in Texas, Hawaii, and Florida and in Mexican cities bordering Yuma, Arizona (San Luis Rio Colorado, Sonora), and Calexico, California (Mexicali, Baja California). Although up to 28 states now have *Ae aegypti* and 40 states have *Ae albopictus* mosquitoes, local dengue virus transmission is uncommon because of housing characteristics including air conditioning and screens that reduce contact between people and infected mosquitoes. Millions of US travelers are at risk; dengue is the leading cause of febrile illness among travelers returning from the Caribbean, Latin America, and Southeast Asia. Dengue occurs in people of all ages but occurs at higher rates in healthy adolescents and young adults and is most likely to cause severe disease in infants, pregnant people, and patients with chronic diseases (eg, asthma, sickle cell anemia, and diabetes mellitus). Severe dengue disease is most likely to occur with second, heterologous dengue serotype infections, although it can occur with a first dengue infection or postsecondary heterologous dengue serotype infections.

The **incubation period** for dengue virus replication in mosquitoes is 8 to 12 days (extrinsic incubation); mosquitoes remain infectious for the remainder of their life cycle. In humans, the **incubation period** is 3 to 14 days before symptom onset (intrinsic incubation). Infected people, both symptomatic and asymptomatic, can transmit dengue virus to mosquitoes 1 to 2 days before symptoms develop and throughout the approximately 7-day viremic period.

DIAGNOSTIC TESTS: Laboratory confirmation of dengue can be made on a single serum, plasma, or whole blood specimen obtained within the first 7 days after the onset of symptoms by nucleic acid amplification tests (NAATs) or detection of dengue virus nonstructural protein 1 (NS-1) antigen by immunoassay.

For patients with a negative NAAT or NS1 test or patients presenting more than 7 days after symptom onset, a positive anti-dengue virus (DENV) immunoglobulin (Ig) M suggests recent infection, although with less certainty than NAAT or NS1 testing because of cross-reactivity with other flaviviruses.

Anti-DENV IgM antibodies are detectable beginning 3 to 5 days after illness onset; 99% of patients have IgM antibodies by day 10. IgM concentrations peak after 2 weeks and then often decline to undetectable levels over 2 to 3 months; they can cross-react with IgM antibodies against Zika virus and other closely related flaviviruses. In patients from areas with ongoing transmission of another flavivirus (eg, Zika virus) and whose only evidence of dengue is a positive anti-DENV IgM test, plaque reduction neutralization tests (PRNT) quantifying virus-specific neutralizing antibody titers can distinguish DENV from other flaviviruses in some but not all cases. PRNT, however, is rarely available in clinical laboratories and results typically are not available within a timeframe that is meaningful for clinicians managing acute disease. PRNT may be valuable in circumstances where confirming the diagnosis may have important clinical implications, such as distinguishing dengue from a Zika virus infection in a pregnant

¹ Paz-Bailey G, Adams L, Wong JM, et al. Dengue vaccine: recommendations of the Advisory Committee on Immunization Practices, United States, 2021. *MMWR Recomm Rep*. 2021;70(RR-6):1–16

individual.^{1,2} Anti-DENV IgG antibody remains elevated for life after dengue virus infection. Anti-DENV IgG antibody may be falsely positive in people with previous infection with or immunization against other flaviviruses (eg, West Nile, Japanese encephalitis, yellow fever, or Zika viruses). See Fig 3.23, p 966, for dengue and Zika virus testing recommendations for nonpregnant persons with a clinically compatible illness and risk for infection with both viruses. A fourfold or greater increase in anti-DENV IgG antibody titers between the acute (≤ 5 days after onset of symptoms) and convalescent (> 15 days after onset of symptoms) samples is indicative of recent infection. Conventional serologic tests may be less reliable for diagnosis of acute dengue virus infection in individuals who have been vaccinated with a dengue vaccine within the previous several months. Dengue diagnostic testing is available through commercial reference laboratories and some state public health laboratories; reference testing is available from the Dengue Branch of the Centers for Disease Control and Prevention (www.cdc.gov/dengue/).

TREATMENT: No specific antiviral therapy exists for dengue. During the febrile phase, patients should stay well hydrated and avoid use of aspirin (acetylsalicylic acid), salicylate-containing drugs, and other nonsteroidal anti-inflammatory drugs (eg, ibuprofen) to minimize potential for bleeding. Additional supportive care is required if the patient becomes dehydrated or develops warning signs of severe disease at or around the time of defervescence.

Early recognition of shock and intensive supportive therapy can reduce risk of death from severe dengue from approximately 5% to 10% to less than 1%. During the critical phase, maintenance of fluid volume and hemodynamic status is crucial to management of severe cases. Patients should be monitored for early signs of shock, occult bleeding, and plasma leakage to avoid prolonged shock, end organ damage, and fluid overload. Patients with refractory shock may require intravenous colloids and/or blood or blood products after an initial trial of intravenous crystalloids. Reabsorption of extravascular fluid occurs during the convalescent phase with stabilization of hemodynamic status and diuresis. It is important to watch for signs of fluid overload, which may manifest as a decrease in the patient's hematocrit as a result of the dilutional effect of reabsorbed fluid.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended, with attention to the potential for bloodborne transmission. When indicated, attention should be given to control of *Aedes* mosquitoes to prevent secondary transmission of dengue virus from infected patients to others.

CONTROL MEASURES: Vector control can reduce dengue transiently, when applied rigorously, but is limited by widespread insecticide resistance in areas where the virus is endemic. A recombinant live attenuated tetravalent dengue vaccine, CYD-TDV (chimeric yellow fever dengue-tetravalent dengue vaccine) (Dengvaxia) with a 3-dose schedule administered at 0, 6, and 12 months has been approved by the US Food and Drug Administration for use in individuals 6 through 16 years of age with laboratory-confirmed previous dengue infection and living in areas with endemic infection.

¹ Sharp TM, Fischer M, Muñoz-Jordán JL, et al. Dengue and Zika virus diagnostic testing for patients with a clinically compatible illness and risk for infection with both viruses. *MMWR Recomm Rep*. 2019;68(1):1–10

² Wong JM, Adams LE, Durbin AP, et al. Dengue: a growing problem with new interventions. *Pediatrics*. 2022;149(6):e2021055522

The Centers for Disease Control and Prevention (CDC) Advisory Committee on Immunization Practices (ACIP) currently recommends vaccination with the Dengvaxia vaccine for children aged 9 through 16 years of age who live in an area where dengue is endemic and have evidence of a previous dengue infection; as of December 2023, the ACIP had not yet voted on recommending its lower age range align with the FDA's approved range. Evidence of previous dengue infection, such as laboratory confirmation of a previous dengue infection or detection of anti-dengue virus IgG using a highly specific serodiagnostic test, is required for eligible children before vaccination. Dengvaxia is contraindicated in children with severe immunodeficiency or immunosuppression attributable to underlying disease or therapy, including children with symptomatic HIV infection or CD4+ T-lymphocyte count of $<200/\text{mm}^3$.

Analyses of data from clinical trials revealed an increased risk for severe dengue in seronegative vaccine recipients compared with seropositive vaccine recipients, while confirming efficacy in preventing dengue cases, severe dengue, and hospitalizations attributable to any serotype in seropositive individuals. For this reason, CYD-TDV is not approved for use in individuals not infected previously by any dengue virus serotype or for whom this information is unknown, because those not infected previously are at increased risk for severe dengue when vaccinated and subsequently infected with dengue virus. Previous dengue infection can be documented by providing history of a laboratory-confirmed dengue infection or a positive result of a highly accurate serodiagnostic screening test. Immunogenicity and safety of recombinant live attenuated dengue vaccine after administration of immune globulin intravenous (IGIV) and other immunoglobulin-containing products has not been studied. Clinicians considering dengue vaccine for people who recently received blood products (including IGIV) or other immunoglobulin-containing products should delay prevaccination testing and administration of vaccine doses by 12 months. Safety and effectiveness of CYD-TDV have not been established in individuals living in areas where dengue is not endemic but who travel to areas with endemic infection, and this vaccine is not recommended for travelers.

Another live attenuated tetravalent dengue vaccine (QDenga), administered subcutaneously as a 0.5-mL dose in a 2-dose schedule (0 and 3 months), is approved for use in several countries outside of the United States in individuals 4 years or older regardless of previous dengue exposure. However, on July 11, 2023, Takeda voluntarily withdrew the QDenga biologic license application from US FDA review, so no approval in the United States is anticipated.

People traveling to areas where dengue is endemic (www.healthmap.org/dengue/) are at risk of dengue and should take precautions to protect themselves from mosquito bites. Travelers should select accommodations that are air conditioned and/or have screened windows and doors and use a bed net to sleep, although this may have limited effect because the vector mosquitoes bite primarily during the day. Travelers should wear clothing that covers arms and legs completely whenever possible, especially during early morning and late afternoon, and use mosquito repellents registered by the US Environmental Protection Agency (see Prevention of Mosquito-borne and Tick-borne Infections, p 207).

Public Health Reporting. Dengue is a nationally notifiable disease, whether obtained locally in the United States or during travel. Suspected cases should be reported to the state or local health department.

Diphtheria

CLINICAL MANIFESTATIONS: Respiratory tract diphtheria usually presents as membranous nasopharyngitis, obstructive laryngotracheitis, or bloody nasal discharge. Local infections are associated with low-grade fever and gradual onset of manifestations over 1 to 2 days. Less commonly, diphtheria presents as cutaneous, vaginal, conjunctival, or otic infection. Cutaneous diphtheria is more common in tropical areas and among people in urban areas lacking housing; the disease is typically mild and associated with shallow, indistinct ulcers. With upper respiratory infection, extensive neck swelling with cervical lymphadenitis (bull neck) is a sign of severe disease. Life-threatening complications of respiratory diphtheria include upper airway obstruction caused by membrane formation; myocarditis with heart block; and cranial and peripheral neuropathies. Palatal palsy, noted by nasal speech, frequently occurs in pharyngeal diphtheria. Case fatality rates attributable to respiratory disease are 5% to 10% and up to 50% in untreated people.

ETIOLOGY: Diphtheria is caused by toxigenic strains of *Corynebacterium diphtheriae*. Toxigenic strains of 2 zoonotic strains, *Corynebacterium ulcerans* and *Corynebacterium pseudotuberculosis*, also have emerged as important causes of diphtheria-like illness. *C. diphtheriae* is an irregularly staining, gram-positive, non-spore-forming, nonmotile, pleomorphic bacillus with 4 biotypes (*mitis*, *intermedius*, *gravis*, and *belfanti*). All biotypes of *C. diphtheriae* may be toxigenic or nontoxigenic. Bacteria remain confined to superficial layers of skin or mucosal surfaces, inducing a local inflammatory reaction. Within several days of respiratory tract infection, a dense pseudomembrane forms, becoming adherent to tissue. Toxigenic strains produce an exotoxin that consists of an enzymatically active A domain and a binding B domain, which promotes the entry of the A toxin into the cell. The toxin, an ADP-ribosylase, inhibits protein synthesis in all cells, including myocardial, renal, and peripheral nerve cells, resulting in myocarditis, acute tubular necrosis, and delayed peripheral nerve conduction. Nontoxigenic strains of *C. diphtheriae* can cause an exudative pharyngitis and also have been associated with invasive infections including endocarditis and osteomyelitis.

EPIDEMIOLOGY: Humans are believed to be the sole reservoir of *C. diphtheriae*. Infection is spread by respiratory tract droplets and by contact with discharges from skin lesions. In untreated people, organisms can be present in discharges from the nose and throat and from eye and skin lesions for 2 to 6 weeks after infection. Patients treated with an appropriate antimicrobial agent usually are not infectious beginning 48 hours after treatment is initiated. Transmission results from close contact with patients or carriers. People traveling to areas with endemic diphtheria or people who come into contact with infected travelers from such areas are at increased risk of infection; rarely, fomites or milk products can serve as vehicles of transmission. Severe disease occurs more often in people who are unimmunized or inadequately immunized. Fully immunized people may be asymptomatic carriers or have mild sore throat.

Prior to 2019, respiratory disease caused by *C. diphtheriae*, regardless of toxigenicity status, was nationally notifiable. From 2000 through 2018, 8 cases of respiratory diphtheria were reported in the United States; however, the last bacteriologically confirmed case caused by toxigenic *C. diphtheriae* occurred in 1997. There has been increasing recognition of cutaneous diphtheria, with 4 toxigenic cases identified from 2015 to 2018 among travelers to areas with endemic diphtheria. Therefore, beginning in 2019,

national notification requirements were changed to capture disease caused by toxigenic *C diphtheriae* originating from any anatomic (respiratory or nonrespiratory) site. In the years 2019–2020, there were 3 cases of nonrespiratory diphtheria (2 cutaneous infections and 1 bloodstream infection) reported in the United States.

The incidence of respiratory diphtheria is greatest during fall and winter, but summer epidemics may occur in warm climates where skin infections are prevalent. Globally, endemic diphtheria occurs in parts of Africa, Latin American, Asia, the Middle East, and Europe, where immunization coverage with diphtheria toxoid-containing vaccines is suboptimal. Since 2011, large outbreaks have been reported in Indonesia, Laos, Haiti, Venezuela, Yemen, and Bangladesh. In 2020, the World Health Organization reported 10 107 global cases of diphtheria; although this was a decline in the number of reported cases compared with previous years, reporting was likely impacted by the COVID-19 pandemic.

The **incubation period** usually is 2 to 5 days (range, 1–10 days).

DIAGNOSTIC TESTS: Laboratory personnel should be notified if *C diphtheriae* is suspected. Specimens for culture should be obtained from the nares and throat and from any mucosal or cutaneous lesion. Obtaining multiple samples from respiratory sites increases yield of culture. Material should be obtained for culture from beneath the membrane (if present) or a portion of the membrane. Specimens collected for culture can be placed in any transport medium or in a sterile container and transported at 4°C. All isolates of *C diphtheriae* should be sent through the state health department to the Centers for Disease Control and Prevention (CDC) to verify toxigenicity status.

TREATMENT:

Antitoxin. Because patients with respiratory diphtheria can deteriorate rapidly, a single dose of diphtheria (equine) antitoxin (DAT) should be administered on the basis of clinical presentation, history of travel, and vaccination status before culture results are available. DAT, its indications for use, suggested dosage, and instructions for administration are available through the CDC Emergency Operations Center (telephone: 770-488-7100 or www.cdc.gov/diphtheria/dat.html). DAT is not available from any commercial source. To neutralize toxin as rapidly as possible, intravenous administration of antitoxin is preferred. Before intravenous administration of antitoxin, tests for sensitivity to horse serum should be performed according to instructions provided with the material. Allergic reactions to horse serum varying from anaphylaxis to rash can be expected in 5% to 20% of patients. The dose of antitoxin depends on the site and size of the membrane, duration of illness, and degree of toxic effects, and specific recommendations are available from the CDC. DAT is generally not recommended in cases of nonrespiratory diphtheria.

Antimicrobial Therapy. 14 days of erythromycin administered orally or parenterally or penicillin administered orally, intravenously, or intramuscularly constitute acceptable therapy for respiratory and nonrespiratory *C diphtheriae* infections (regardless of toxigenicity status) (see Table 4.3, p 993). Parenteral therapy should be given if the patient has severe disease or is unable to swallow. In areas of the world where there is increasing resistance of *C diphtheriae* isolates to penicillin, erythromycin is preferred empiric treatment. Fluoroquinolones (see Fluoroquinolones, p 973), rifampin, clarithromycin, and azithromycin have demonstrated in vitro activity against *C diphtheriae*. Antimicrobial therapy is required to eradicate *C diphtheriae* organisms, stop toxin production, and prevent transmission but is not a substitute for antitoxin. Elimination of

the toxigenic *C diphtheriae* should be documented 24 hours after completion of treatment by 2 consecutive negative cultures from specimens taken 24 hours apart for both respiratory and nonrespiratory infections. Follow-up testing to confirm elimination is not required for nontoxigenic *C diphtheriae* infections.

Immunization. Active immunization against diphtheria should be undertaken during convalescence from diphtheria, because disease does not necessarily confer immunity.

Cutaneous Diphtheria. Thorough cleansing of the lesion with soap and water and administration of an appropriate antimicrobial agent for 10 days are recommended.

Carriers. If not immunized, *C diphtheriae* carriers should receive active immunization promptly and measures should be taken to ensure completion of the immunization schedule. If a carrier has been immunized previously but has not received a booster of diphtheria toxoid within 5 years, a booster dose of age-appropriate vaccine containing diphtheria toxoid (DTaP, Tdap, or Td) should be administered. Note that as of 2023, DT is no longer available in the United States (www.cdc.gov/vaccines/vpd/dtap-tdap-td/hcp/recommendations.html and www.cdc.gov/vaccines/vpd/dtap-tdap-td/hcp/td-offlabel.html). Carriers should receive antibiotic treatment with any of the following regimens: oral erythromycin for 10 to 14 days, oral azithromycin for 5 days, or a single dose of intramuscularly administered penicillin G benzathine.¹ Data are limited on the use of oral penicillin to eradicate carriage. If a person is carrying a toxigenic *C diphtheriae* strain, 2 follow-up cultures should be performed after completing antimicrobial treatment to detect persistence of carriage, which occurs following erythromycin treatment in some cases. The first culture should be performed 24 hours after completing treatment. If results of either culture is positive, an additional 10-day course of oral erythromycin should be administered and follow-up cultures should be performed again. Erythromycin-resistant strains have been identified, but their epidemiologic significance is undetermined. Follow-up cultures are not required for nontoxigenic *C diphtheriae* carriers.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, droplet precautions are recommended for patients and carriers with respiratory diphtheria until 2 cultures from both the nose and throat collected 24 hours or more after completing antimicrobial treatment are negative for *C diphtheriae*. Contact precautions are recommended for patients with cutaneous diphtheria until 2 cultures of skin lesions taken at least 24 hours apart and 24 hours after cessation of antimicrobial therapy are negative.

CONTROL MEASURES:

Care of Exposed People. Whenever respiratory diphtheria is suspected or proven, local public health officials should be notified promptly. Toxigenic *C diphtheriae* isolated from any anatomical site (respiratory or nonrespiratory) requires contact investigation and prophylaxis of close contacts. Cutaneous or respiratory disease caused by nontoxigenic strains of *C diphtheriae* do not require routine investigation or prophylaxis of contacts. Management of exposed people is based on individual circumstances, including immunization status and likelihood of adherence to follow-up and prophylaxis. Close

¹ UK Health Security Agency. Public health control and management of diphtheria in England. 2022 guidelines. Available at: https://assets.publishing.service.gov.uk/government/uploads/system/uploads/attachment_data/file/1106302/diphtheria-guidelines-2022-v16.1-corrected.pdf

contacts of a person with infection caused by toxigenic diphtheria should be identified, and the following are recommended:

- Contact tracing usually can be limited to household members and people with direct, habitual close contact with the index patient or health care personnel exposed to nasopharyngeal secretions, people sharing kitchen facilities, or people caring for infected children.
- For close contacts, *regardless of their immunization status*, the following measures should be taken: (1) surveillance for evidence of disease for 7 days from last exposure to an untreated patient; (2) culture for *C diphtheriae*; and (3) antimicrobial prophylaxis with oral erythromycin (40–50 mg/kg per day for 7 to 10 days, maximum 1 g/day) or a single intramuscular injection of penicillin G benzathine (600 000 U for children weighing <30 kg, and 1.2 million U for children weighing ≥30 kg and for adults). Follow-up cultures of nasal or oropharyngeal specimens should be performed after completion of therapy for contacts proven to be carriers. If cultures are positive, an additional 10-day course of erythromycin should be administered, and follow-up cultures of pharyngeal specimens should be repeated after completion of therapy.
- Asymptomatic, previously immunized close contacts should receive a booster dose of an age-appropriate diphtheria toxoid-containing vaccine (DTaP, Tdap, or Td) if they have not received a booster dose of a diphtheria toxoid-containing vaccine within 5 years.
- Asymptomatic close contacts who have had fewer than 3 doses of a diphtheria toxoid-containing vaccine, children younger than 7 years in need of their fourth dose of DTaP, or people whose immunization status is not known should be immunized with an age-appropriate diphtheria toxoid-containing vaccine (DTaP, Tdap, or Td), as indicated.
- Contacts who cannot be kept under surveillance should receive penicillin G benzathine rather than erythromycin, and if not fully immunized or if immunization status is not known, they should be immunized with DTaP, Tdap, or Td vaccine, as appropriate for age.
- Use of equine diphtheria antitoxin in unimmunized close contacts is not recommended, because there is no evidence that antitoxin provides additional benefit.

Immunization. Universal immunization with a diphtheria toxoid-containing vaccine is the only effective control measure. The schedules for immunization against diphtheria are presented in the childhood and adolescent (<https://publications.aap.org/redbook/pages/Immunization-Schedules>) and adult (www.cdc.gov/vaccines) immunization schedules.

Immunization of children from 2 months of age through 6 years of age (to the seventh birthday) routinely consists of 5 doses of diphtheria and tetanus toxoid-containing and acellular pertussis vaccines (DTaP). Regular booster injections of diphtheria toxoid as Td or Tdap are required every 10 years after completion of the initial immunization series. Immunization against diphtheria and tetanus for children younger than 7 years in whom pertussis immunization is contraindicated (see Pertussis, p 656) is complicated by the fact that DT is no longer available in the United States (www.cdc.gov/vaccines/vpd/dtap-tdap-td/hcp/recommendations.html and www.cdc.gov/vaccines/vpd/dtap-tdap-td/hcp/td-offlabel.html). For young children with a contraindication to pertussis-containing vaccines (see Contraindications and Precautions to DTaP Immunization in the Pertussis chapter, p 664), vaccine providers may administer Td for all recommended remaining doses in place of DTaP.

Td contains a lower dose (approximately 1/12th the amount) of diphtheria toxoid compared with DT. The impact of this lower dose on the protection provided against diphtheria in young children is uncertain. Available evidence suggests young children who receive Td in place of DTaP may have suboptimal protection against diphtheria. Other recommendations for diphtheria immunization, including recommendations for older children (7 through 18 years of age) and adults, can be found in Tetanus (p 848) as well as the childhood and adolescent and adult immunization schedules.

Travelers to countries with endemic or epidemic diphtheria should have their diphtheria immunization status reviewed and updated when necessary.

Pneumococcal and meningococcal conjugate vaccines containing non-live diphtheria toxoid or CRM₁₉₇ protein, a nontoxic variant of diphtheria toxin, are not substitutes for diphtheria toxoid immunization.

***Ehrlichia*, *Anaplasma*, and Related Infections**

(Human Ehrlichiosis, Anaplasmosis, and Related Infections Attributable to Bacteria in the Family *Anaplasmataceae*)

CLINICAL MANIFESTATIONS: Early signs and symptoms of infections by members of the bacterial family *Anaplasmataceae* can be nonspecific. All are acute febrile illnesses with common systemic manifestations including fever, headache, chills, rigors, malaise, myalgia, and nausea. More variable symptoms include rash, arthralgia, vomiting, diarrhea, anorexia, cough, and confusion. Severe manifestations of these diseases can include acute respiratory distress syndrome, encephalopathy, meningitis, disseminated intravascular coagulation, toxic shock-like or septic shock-like syndromes, spontaneous hemorrhage, hepatic failure, and renal failure. Symptoms typically last 1 to 2 weeks when untreated, but prompt treatment with doxycycline shortens duration of illness and reduces the risk of serious manifestations and sequelae. Fatigue can last several weeks, and neurologic sequelae have been reported in some children after severe disease, more commonly with *Ehrlichia* infections.

A maculopapular rash is seen in up to 60% of *Ehrlichia chaffeensis* infections in children but in less than 30% of adults. The rash typically begins 5 days after symptom onset (notably fever). In adults, skin rash is reported more often for *Ehrlichia* infections than for *Anaplasma* infections. Rash occurs in less than 10% of cases of anaplasmosis and may suggest coinfection with another pathogen. Severe disease and fatal outcome are more common in *E. chaffeensis* infections (approximately 1%–3% case fatality) than in *Anaplasma phagocytophilum* infections.

Coinfections of *Anaplasma* with other tick-borne diseases, including babesiosis, Powassan virus, Lyme disease, and other *Borrelia* infections, can cause illness that is more severe or of longer duration than a single infection. Case fatality is uncommon (<1%).

Significant laboratory findings in **both *Anaplasma* and *Ehrlichia* infections** may include leukopenia with neutropenia (anaplasmosis) or lymphopenia (ehrlichiosis), thrombocytopenia, hyponatremia, and elevated serum hepatic aminotransferase concentrations. Cerebrospinal fluid abnormalities (eg, pleocytosis with a predominance of lymphocytes and increased total protein concentration) are common. Hemophagocytic lymphohistiocytosis (HLH) occurs in 10% to 15% of children hospitalized with ehrlichiosis. People with underlying immunosuppressive conditions are at greater risk of severe disease. Severe disease has been reported in people who initially received trimethoprim-sulfamethoxazole before a correct diagnosis was made.

Table 3.5. Taxonomy of *Rickettsiales* predominant in the United States

Order		<i>Rickettsiales</i>		
Family	<i>Rickettsiaceae</i>		<i>Anaplasmataceae</i>	
Genera	<i>Rickettsiae</i>		<i>Anaplasma</i>	<i>Ehrlichia</i>
Species	Spotted fever group (SFG): Rocky Mountain spotted fever, Mediterranean spotted fever, Japanese spotted fever, etc	Typhus group: endemic, epidemic	<i>Anaplasma phagocytophilum</i>	<i>Ehrlichia chaffeensis</i> , <i>Ehrlichia ewingii</i> , <i>Ehrlichia muris eauclairensis</i>

Because of the nonspecific presenting symptoms, Rocky Mountain spotted fever should be considered in the differential diagnosis in the United States. Heartland and Bourbon virus infections also manifest with similar clinical features and should be considered in patients without a more likely explanation who have tested negative for *Ehrlichia* and *Anaplasma* infection or have not responded to doxycycline therapy.

ETIOLOGY: *Ehrlichia* and *Anaplasma* species are obligate intracellular bacteria, which appear as gram-negative cocci that measure 0.5 to 1.5 μm in diameter. Although genetically distinct, *Anaplasma* and *Ehrlichia* infections often are grouped with rickettsia because of overlapping clinical presentation and their vector-borne spread (Table 3.5). Ehrlichiosis is the manifestation of (predominantly) *E chaffeensis*, although *Ehrlichia ewingii* and *Ehrlichia muris eauclairensis* also are found in the United States (Table 3.6). Anaplasmosis is predominantly caused by *A phagocytophilum* in the United States.

EPIDEMIOLOGY: Reported and suspected cases of ehrlichiosis and anaplasmosis are confined to geographic regions where their vectors are prevalent, although climate change is impacting the geographic range of these vectors. Increased incidence is observed with heightened tick activity (mostly warm summer months) as well as with human activities involving exposure to ticks. Infections can occur year-round in endemic areas. As in other tick-borne diseases, patients with *Ehrlichia* or *Anaplasma* infection often have no recollection of being bitten by a tick.

The reported incidence of ***E chaffeensis* infection** in the United States in 2019 was 6.4 cases per million population. Reported incidence of *E ewingii* infection in 2017 was 0.1 cases per million population, but the incidence is believed to be underreported because of nonspecific illness similar to *E chaffeensis* infections. Ehrlichiosis caused by *E chaffeensis* and *E ewingii* is reported most commonly from the south-central and south-eastern United States, from the East Coast extending westward to Texas. *E chaffeensis* and *E ewingii* are transmitted by the bite of the Lone Star tick (*Amblyomma americanum*) and are reported from states within its geographic range. Cases attributable to *E muris eauclairensis* have been reported only from Minnesota and Wisconsin and are transmitted by the blacklegged tick (*Ixodes scapularis*). Cases of ehrlichiosis have occurred after blood transfusion or solid organ donation from asymptomatic donors.

There were 6617 provisional cases of ***Anaplasma* infections** reported in the United States in 2021. Cases of human anaplasmosis are reported most frequently from the northeastern and upper midwestern United States. Cases of anaplasmosis

Table 3.6. Human Ehrlichiosis, Anaplasmosis, and Related Infections in the United States

Disease	Causal Agent	Major Target Cell	Tick Vector	Geographic Distribution
Ehrlichiosis caused by <i>Ehrlichia chaffeensis</i>	<i>E chaffeensis</i>	Usually monocytes	Lone star tick (US) (<i>Amblyomma americanum</i>)	Predominantly southeast, south-central, from the East Coast extending westward to Texas; has been reported outside USA
Anaplasmosis	<i>Anaplasma phagocytophilum</i>	Usually granulocytes	Blacklegged tick (<i>Ixodes scapularis</i>) or western blacklegged tick (<i>Ixodes pacificus</i>) (US)	Northeastern and upper Midwestern states and northern California; Europe and Asia
Ehrlichiosis caused by <i>Ehrlichia ewingii</i>	<i>E ewingii</i>	Usually granulocytes	Lone star tick (US) (<i>A americanum</i>)	Southeastern, south-central, and Midwestern states; Africa, Asia
Ehrlichiosis caused by <i>Ehrlichia muris eauclairensis</i>	<i>E muris eauclairensis</i>	Unknown, suspected in monocytes	Blacklegged tick (<i>Ixodes scapularis</i>)	Minnesota, Wisconsin

also have been reported in northern California. In most of the United States, *A phagocytophilum* is transmitted by *Ixodes scapularis*, which also is the vector for ehrlichiosis caused by *E muris eauclairensis*, Lyme disease (*Borrelia burgdorferi* and *Borrelia mayoni*), tick-borne relapsing fever (*Borrelia miyamotoi*), Powassan virus, and babesiosis (*Babesia microti*). In the western United States, the western blacklegged tick (*Ixodes pacificus*) is the main vector for *A phagocytophilum*. Cases of *Anaplasma* infection have occurred after blood transfusion or solid organ donation from asymptomatic donors. Possible perinatal transmission of *A phagocytophilum* has been reported.

The **incubation period** is 5 to 14 days for both *E chaffeensis* and *A phagocytophilum*. **DIAGNOSTIC TESTS:** Treatment of suspected ehrlichiosis or anaplasmosis with doxycycline should not be delayed while awaiting confirmation of the diagnosis. Nucleic acid amplification tests (NAATs) of whole blood for the organism are most sensitive for anaplasmosis and ehrlichiosis in the first week of illness. A negative result does not rule out the diagnosis. Sensitivity of NAATs decreases rapidly following administration of doxycycline.

Tissue biopsies may be analyzed by NAAT or immunohistochemistry. Because of the hazardous nature of these organisms, tissues should be fixed in paraffin or formalin before testing. Tissue analysis is available at specialized laboratories.

Serologic testing may be used to demonstrate a fourfold change in specific immunoglobulin (Ig) G antibody titer by indirect immunofluorescent antibody (IFA) assay between paired acute and convalescent specimens taken 2 to 4 weeks apart. A single mildly elevated IgG titer may not be diagnostic, particularly in regions with higher prevalence. IgM serologic assays are prone to false-positive reactions, and specific IgM can remain elevated for lengthy periods of time, reducing its diagnostic utility. Serologic tests for *E. chaffeensis* and *A. phagocytophilum* infections are available, but cross-reactivity between species can make interpretation of results difficult in areas where geographic distributions overlap.

Occasionally, *Anaplasma* and *Ehrlichia* bacteria can be identified in Giemsa or Wright-stained peripheral blood smears or buffy coat leukocyte preparations in the first week of illness. Bacteria enter the host cell via phagocytosis, and these compartments provide a protective environment for bacterial replication. These bacterial collections appear as morulae observed within granulocytes (targeted by *Anaplasma*) or monocytes (targeted by *Ehrlichia*). Culture for isolation of these pathogens is not performed routinely given requirement for biosafety level 3 facilities to prevent accidental inoculation or aerosolization.

TREATMENT: Doxycycline is the treatment of choice for all tick-borne rickettsial diseases, including ehrlichiosis and anaplasmosis (see Table 4.3, p 993). Early initiation of therapy can minimize complications and should not be delayed awaiting laboratory confirmation. Treatment with doxycycline is recommended in patients of all ages when rickettsial diseases are being considered (see Tetracyclines, p 975). After doxycycline is initiated, fever generally subsides within 24 to 48 hours.

Patients with suspected **ehrlichiosis** should be treated with doxycycline until at least 3 days after defervescence and until evidence of clinical improvement, typically 5 to 7 days. Patients with suspected **anaplasmosis** should be treated with doxycycline for 10 to 14 days to provide appropriate length of therapy for possible concurrent *Borrelia burgdorferi* infection (Lyme disease).

Rifampin may provide an alternative to doxycycline in patients with anaplasmosis who demonstrate hypersensitivity to doxycycline. Rifampin has been used successfully in several pregnant people with anaplasmosis, and studies suggest that this drug appears effective against *A. phagocytophilum*. Small numbers of young children have also been treated successfully for anaplasmosis with rifampin for 7 to 10 days. Rifampin is not an effective treatment when coinfection with Lyme disease is present, nor is it effective treatment for Rocky Mountain spotted fever, a disease with similar clinical manifestations. Rifampin has been shown to be effective against *E. chaffeensis* in a laboratory setting but has not been evaluated as an alternative therapy in a clinical setting.

Administration of trimethoprim-sulfamethoxazole has been linked to more severe outcomes in ehrlichiosis and is contraindicated.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended. Human-to-human transmission via direct contact has not been documented.

CONTROL MEASURES: Limiting exposures to ticks and tick bites is the primary means of prevention (see Prevention of Mosquito-borne and Tick-borne Infections, p 207).

Risk of transmission through blood transfusion or organ transplantation should be considered in areas with endemic infection. Prophylactic administration of doxycycline after a tick bite is not indicated because of the low risk of infection and lack of proven effectiveness. Instead, persons bitten by ticks should be counseled to watch for symptoms, including fever and rash, within 2 weeks of a tick bite. Additional information is available on the Centers for Disease Control and Prevention (CDC) website (www.cdc.gov/ehrlichiosis, www.cdc.gov/anaplasmosis and www.cdc.gov/ticks), including a collaborative report providing recommendations for the diagnosis and management of tick-borne rickettsial diseases.¹

Public Health Reporting. Ehrlichiosis and anaplasmosis are nationally notifiable diseases in the United States and should be reported to the state or local health department.

Serious Neonatal Bacterial Infections Caused by *Enterobacteriales* (Including Septicemia and Meningitis)

CLINICAL MANIFESTATIONS: Neonatal septicemia or meningitis caused by *Escherichia coli* and other gram-negative bacilli cannot be differentiated clinically from septicemia or meningitis caused by other organisms. The early signs of sepsis can be subtle and similar to signs observed in noninfectious processes. Signs of septicemia include fever, temperature instability, heart rate abnormalities, grunting respirations, apnea, cyanosis, lethargy, irritability, anorexia, vomiting, jaundice, abdominal distention, cellulitis, and diarrhea. Meningitis, especially early in the course, can occur without overt signs suggesting central nervous system involvement. Some gram-negative bacilli, such as *Citrobacter koseri*, *Cronobacter* (formerly *Enterobacter*) *sakazakii*, *Serratia marcescens*, and *Salmonella* species, are associated with increased risk for brain abscesses in infants with meningitis caused by these organisms.

ETIOLOGY: *Enterobacteriales* are a large family of gram-negative, facultatively anaerobic, rod-shaped bacteria that include *Escherichia* species, *Klebsiella* species, *Enterobacter* species, *Proteus* species, *Providencia* species, and *Serratia* species, among many others. *E. coli* strains, often those with the K1 capsular polysaccharide antigen, are the most common cause of neonatal septicemia and meningitis by *Enterobacteriales* species. Other important *Enterobacteriales* species causing neonatal septicemia include *Klebsiella* species, *Enterobacter* species, *Proteus* species, *Citrobacter* species, *Salmonella* species, and *Serratia* species. *Elizabethkinga meningoseptica*, although not an *Enterobacteriales* species, is another multidrug-resistant gram-negative organism that causes a similar spectrum of disease in neonates.

EPIDEMIOLOGY: The source of *E. coli* and other *Enterobacteriales* organisms in neonatal infections during the first days of life typically is the vaginal tract of the birthing parent. Reservoirs for gram-negative bacilli can also be present within the health care environment. Acquisition of gram-negative organisms can occur through person-to-person transmission from hospital nursery personnel as well as from

¹ Biggs HM, Behraves CB, Bradley KK, et al. Diagnosis and management of tickborne rickettsial diseases: Rocky Mountain spotted fever and other spotted fever group rickettsioses, ehrlichioses, and anaplasmosis—United States. *MMWR Recomm Rep*. 2016;65(RR-2):1–44. Available at: www.cdc.gov/mmwr/volumes/65/rr/rr6502a1.htm

nursery environmental sites such as sinks, countertops, powdered infant formula, and respiratory therapy equipment, especially among very preterm infants who require prolonged neonatal intensive care management. Predisposing factors for neonatal gram-negative bacterial infections include intrapartum infection in the birthing parent, gestation less than 37 weeks, low birth weight, and prolonged rupture of membranes. Metabolic abnormalities (eg, galactosemia), fetal hypoxia, and acidosis have been implicated as predisposing factors. Neonates with defects in the integrity of skin or mucosa (eg, myelomeningocele) or abnormalities of gastrointestinal or genitourinary tracts are at increased risk of gram-negative bacterial infections. In neonatal intensive care units, systems for respiratory and metabolic support, invasive or surgical procedures, and indwelling vascular catheters are risk factors for infection. Frequent use of broad-spectrum antimicrobial agents enables selection and proliferation of strains of gram-negative bacilli that may be resistant to multiple antimicrobial agents.

Multiple mechanisms of resistance in gram-negative bacilli can be present simultaneously. Resistance resulting from production of plasmid-derived extended-spectrum beta-lactamases (ESBLs) and AmpC beta-lactamases occurs primarily in *E coli* and *Klebsiella* species and from production of chromosomally-encoded AmpC beta-lactamases in *Enterobacter* species, but these mechanisms have been reported in many other gram-negative species. Resistant gram-negative infections have been associated with nursery outbreaks, especially in very low birth weight infants. Risk factors for neonatal infection with ESBL-producing organisms include prolonged mechanical ventilation, extended hospital stay, use of invasive devices, and prior use of antimicrobial agents. Infants whose birthing parent is colonized with ESBL-producing *E coli* are themselves at an increased risk of becoming colonized with ESBL-producing *E coli* compared with infants whose birthing parent is noncolonized. Organisms that produce ESBLs typically are resistant to penicillins, cephalosporins, and monobactams and can be resistant to aminoglycosides. Carbapenem-resistant *Enterobacterales* (CRE) that produce carbapenemases have also emerged, especially among *Klebsiella pneumoniae*, *E coli*, and *Enterobacter cloacae*. ESBL- and carbapenemase-producing strains often carry additional plasmid-borne genes that encode for high-level resistance to aminoglycosides, fluoroquinolones, and trimethoprim-sulfamethoxazole.

The **incubation period** is variable; time of onset of infection ranges from birth to several weeks after birth or longer in very low birth weight, preterm infants with prolonged hospitalizations.

DIAGNOSTIC TESTS: Diagnosis is established by growth of *E coli* or other gram-negative bacilli from blood, cerebrospinal fluid (CSF), or other usually sterile sites. Isolates may be identified by traditional biochemical tests, commercially available biochemical test systems, mass spectrometry of bacterial cell components, or molecular methods. Multiplexed molecular tests capable of rapidly identifying a variety of gram-negative rods including *E coli* directly in positive blood culture bottles have been cleared by the US Food and Drug Administration. Special screening and confirmatory laboratory procedures are required to detect some multidrug-resistant gram-negative organisms. Molecular diagnostics can rapidly identify pathogens and some resistance genes from positive blood cultures but do not detect all phenotypic resistance; therefore, antimicrobial resistance testing should be performed on isolates.

TREATMENT^{1,2}:

- Initial empiric treatment for suspected early-onset gram-negative sepsis in neonates should be based on local and regional antimicrobial susceptibility data. The proportion of *E coli* bloodstream infections with onset within 72 hours of life that are resistant to ampicillin is high (approximately two-thirds) among very low birth weight infants. These *E coli* infections almost invariably are susceptible to gentamicin, although monotherapy with an aminoglycoside is not recommended.
- Ampicillin and an aminoglycoside may be first-line therapy for neonatal sepsis in areas with low ampicillin resistance among *E coli*. An alternative regimen of ampicillin and an extended-spectrum cephalosporin (eg, cefotaxime, ceftazidime, cefepime) can be used, but rapid emergence of cephalosporin-resistant organisms and increased risk of colonization or infection with ESBL-producing *Enterobacterales* can occur when cephalosporin use is routine in a neonatal unit. The empiric addition of broader-spectrum antibiotic therapy may be considered until culture results are available if the patient is a severely ill infant at high risk for gram-negative sepsis (such as infants with very low birth weight born after prolonged premature rupture of membranes, infants exposed to prolonged courses of antepartum antibiotic therapy, or infants with prolonged neonatal intensive care unit [NICU] hospitalization and exposure to multiple medical devices and antimicrobials).
- When there is a concern for gram-negative meningitis, an extended-spectrum cephalosporin (eg, cefotaxime, ceftazidime, cefepime) should be used unless prior patient isolates or local resistance profiles increase the likelihood of a multidrug-resistant gram-negative organism, in which case a carbapenem is the preferred choice for empiric therapy.
- Once the causative agent and its in vitro antimicrobial susceptibility pattern are known, nonmeningeal infections should be treated with the narrowest-spectrum antibiotic to which the organism is susceptible.
- For meningitis caused by an ampicillin-susceptible *E coli*, meningitic dosing of ampicillin is the preferred treatment because it is effective and narrow-spectrum. Meningitis caused by an ampicillin-resistant isolate can be treated with an extended spectrum cephalosporin to which it is susceptible. Combination therapy of a beta-lactam with an aminoglycoside can be used until CSF is sterile in complicated meningitis associated with empyema, brain abscess, or other scenarios that may delay CSF sterility. Expert advice from a pediatric infectious diseases specialist is helpful for management of meningitis.
- For ESBL-producing *Enterobacterales* infections, a carbapenem is the drug of choice. Of the aminoglycosides, amikacin retains the most activity against ESBL-producing strains.
- For *Enterobacterales* isolates that contain AmpC beta-lactamase but not ESBLs, cefepime can be used if susceptible, because cefepime does not induce AmpC expression and it resists hydrolysis by AmpC β -lactamases.

² Puopolo KM, Benitz WE, Zaoutis TE; American Academy of Pediatrics, Committee on Fetus and Newborn; Committee on Infectious Diseases. Management of neonates born at ≥ 35 0/7 weeks' gestation with suspected or proven early-onset bacterial sepsis. *Pediatrics*. 2018;142(6):e20182894

- For CRE, treatment should be tailored to the susceptibility profile of the isolate and the type of carbapenemase. Combination antibiotic therapy is often used. Antibiotics that may have activity against CRE include amikacin, trimethoprim-sulfamethoxazole, fluoroquinolones, tigecycline, colistin, and polymyxin B.¹ Tigecycline has a black box warning for an increase in all-cause mortality and should be reserved for situations in which alternative agents are not suitable. In neonates, there is limited experience using newer antibiotic agents with activity against CRE, like ceftazidime-avibactam, ceftolozane-tazobactam, imipenem-relebactam, or cefiderocol. Expert advice from a pediatric infectious disease specialist is recommended for management of infections caused by carbapenem-resistant organisms.
- All neonates with gram-negative meningitis should undergo repeat lumbar puncture to ensure sterility of the CSF after 48 to 72 hours of therapy. If CSF remains culture-positive, the choice and dose of antimicrobial agents should be reevaluated, and another lumbar puncture should be performed after an additional 48 to 72 hours.
- Duration of therapy is based on clinical and bacteriologic response of the patient and the site(s) of infection. The usual duration of therapy for uncomplicated gram-negative bacteremia in an infant who has had clearance of blood cultures and is clinically improving is 10 days. Infants with persistent bacteremia, prolonged clinical course, or other complications may require longer duration of therapy. The minimum treatment duration for gram-negative meningitis is 21 days; this may be extended if there are complications like brain abscess.
- All infants with gram-negative meningitis should undergo careful follow-up examinations, including testing for hearing loss, neurologic abnormalities, and developmental delay.
- Immune globulin intravenous (IGIV) therapy for newborn infants receiving antimicrobial agents for suspected or proven serious infection does not improve outcomes and is not recommended.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended. Exceptions include hospital nursery epidemics, infants with *Salmonella* infection, and infants with infection caused by gram-negative bacilli that are resistant to multiple antimicrobial agents, including ESBL-producing strains and CRE; in these situations, contact precautions also are indicated.²

CONTROL MEASURES: Infection-control personnel should be aware of pathogens causing infections in infants so that clusters of infections are recognized and investigated appropriately. Several cases of infection caused by the same genus and species of bacteria occurring in infants in physical proximity or caused by an unusual pathogen indicate the need for an epidemiologic investigation and related infection prevention and control measures (see Infection Prevention and Control for Hospitalized Children, p 163). Periodic review of in vitro antimicrobial susceptibility patterns of clinically important bacterial isolates from newborn infants, especially infants in the neonatal intensive care unit, can provide useful epidemiologic and therapeutic information.

Enterovirus (Nonpoliovirus)

(Group A and B Coxsackieviruses, Echoviruses, Numbered Enteroviruses)

CLINICAL MANIFESTATIONS: Nonpolio enteroviruses are responsible for significant and frequent illnesses in infants and children and result in a variety of clinical manifestations. The most common manifestation is nonspecific febrile illness, which in young infants may lead to evaluation for bacterial sepsis. Other manifestations can include: (1) respiratory: coryza, pharyngitis, herpangina, stomatitis, parotitis, croup, bronchiolitis, pneumonia, pleurodynia, and bronchospasm; (2) skin: hand-foot-and-mouth disease (HFMD), onychomadesis (shedding of nails), and nonspecific exanthems (particularly associated with echoviruses); (3) neurologic: aseptic meningitis (with or without pleocytosis), encephalitis, and acute flaccid myelitis (AFM); (4) gastrointestinal/genitourinary: vomiting, diarrhea, abdominal pain, hepatitis, pancreatitis, and orchitis; (5) eye: acute hemorrhagic conjunctivitis and uveitis; (6) heart: myopericarditis; and (7) muscle: pleurodynia and other skeletal myositis. Neonates, especially those who acquire infection in the absence of type-specific transplacentally acquired antibody, are at risk of severe and life-threatening disease, including viral sepsis, meningoencephalitis, myocarditis, hepatitis, coagulopathy, and pneumonitis. AFM is an uncommon but serious neurologic illness caused by some enteroviruses that presents with acute onset of flaccid limb weakness and/or cranial nerve dysfunction, most often accompanied by cerebrospinal fluid pleocytosis and nonenhancing lesions predominantly affecting the gray matter of the spinal cord and/or brainstem on magnetic resonance imaging.

Infection with enterovirus A71 (EV-A71) is associated with HFMD, herpangina, and in a small proportion of cases, severe neurologic disease, including AFM and brainstem encephalitis associated with myoclonus, ataxia, and autonomic instability. Noncardiogenic pulmonary edema secondary to brainstem encephalitis can result in fatal cardiopulmonary collapse and sequelae among survivors.

Enterovirus D68 (EV-D68) is associated with mild to severe respiratory illness in infants, children, and teenagers and has been responsible for localized and large multinational outbreaks of respiratory disease. Disease is often characterized by exacerbation of preexisting asthma or new-onset wheezing in children without history of asthma, often requiring hospitalization and, in some patients, intensive supportive care. EV-D68 is also associated with AFM and is believed to have been a major contributor to the biennial AFM outbreaks in the United States between 2014 and 2018.

Other noteworthy but not exclusive clinical associations include coxsackieviruses (CV) A6, A10, and A16 with HFMD (including severe HFMD, “eczema coxsackium,” and atypical cutaneous involvement with CVA6); coxsackievirus A24 variant and enterovirus D70 (EV-D70) with acute hemorrhagic conjunctivitis; and coxsackieviruses B1 through B5 with pleurodynia and myopericarditis.

Patients with humoral and combined immune deficiencies can develop persistent central nervous system infections, a dermatomyositis-like syndrome, arthritis, hepatitis, and/or disseminated infection. Severe and/or chronic neurologic or multisystem disease is reported in hematopoietic cell and solid organ transplant recipients, children with malignancies, and patients treated with anti-CD20 monoclonal antibody (eg, rituximab).

ETIOLOGY: The enteroviruses, along with the rhinoviruses, comprise a genus of small, nonenveloped, single-stranded, positive-sense RNA viruses in the *Picornaviridae* family.

The nonpolio enteroviruses include more than 110 distinct types formerly subclassified as group A coxsackieviruses, group B coxsackieviruses, echoviruses, and newer numbered enteroviruses. A more recent classification system groups the human enteroviruses into 4 species (enterovirus [EV] A, B, C, and D) on the basis of genetic similarity in the viral protein 1, which corresponds well with serotype.

EPIDEMIOLOGY: Humans are the principal reservoir for enteroviruses, although some primates can become infected. Enterovirus infections are common and are distributed worldwide; the majority of infections are asymptomatic. Enteroviruses are spread by fecal-oral and respiratory routes and from mother to infant prenatally, in the peripartum period, and rarely via breastfeeding. EV-D68 is believed to be spread primarily by respiratory transmission; EV-D70 and CVA24 are shed in tears and spread via fingers and fomites. Enteroviruses may survive on environmental surfaces for periods long enough to allow transmission from fomites, and transmission via contaminated water, including swimming pools, and food can occur. Hospital nursery and other institutional outbreaks may occur. Infection incidence, clinical attack rates, and disease severity typically are greatest in infants and young children, and infections occur more frequently in tropical areas and where poor sanitation, poor hygiene, and high population density are present.

Although circulation can occur year-round, most enterovirus infections in temperate climates occur in the summer and fall (approximately June through October in the northern hemisphere); seasonal patterns are less evident in the tropics. Fecal shedding of most enteroviruses can persist for several weeks or months (generally 2–8 weeks) after onset of infection, but respiratory tract shedding usually is limited to 1 to 3 weeks or less. Enterovirus transmission can occur in the absence of signs of clinical illness.

The usual **incubation period** for enterovirus infections is 3 to 6 days, except for acute hemorrhagic conjunctivitis, in which the **incubation period** is 24 to 72 hours. Onset of neurologic disease, such as AFM, can lag several days or even weeks after illness onset, following improvement or resolution of prodromal symptoms.

DIAGNOSTIC TESTS: Enteroviruses generally can be detected by nucleic acid amplification tests (NAATs) and culture from a variety of specimens, including stool, rectal swab, throat swab, nasopharyngeal aspirates, conjunctival swab, tracheal aspirates, vesicle fluid, blood, urine, tissue biopsy specimens, and cerebrospinal fluid (CSF). Prolonged viral shedding after illness occurs, particularly from the pharynx and gastrointestinal tract, so a positive test result may not indicate an etiologic role in an illness. NAATs are rapid and more sensitive than isolation of enteroviruses in cell culture and can detect all enteroviruses, including types that are difficult or impossible to cultivate in cell cultures. Commercial enterovirus NAATs will not detect parechoviruses (and vice versa), and many cannot reliably distinguish enteroviruses from rhinoviruses. Multiplex NAATs designed to detect a number of bacterial and viral agents of meningitis and encephalitis, including enteroviruses, in CSF are available.

Enterovirus type is determined through partial genomic sequencing. Typing may be indicated in cases of special clinical interest or for epidemiologic purposes (eg, for investigation of disease clusters or outbreaks) and is available at some local or state public health laboratories and at the Centers for Disease Control and Prevention Picornavirus Laboratory.

Patients with EV-A71 and EV-D68 neurologic disease often have negative results of a NAAT and culture of CSF (even in the presence of CSF pleocytosis) and blood.

For EV-A71, NAAT and culture of throat or stool/rectal swab and/or vesicle fluid specimens (in cases of HFMD) are more frequently positive. EV-D68 is demonstrated primarily in respiratory tract specimens obtained early in the course of disease. Most commercial multiplex respiratory NAATs can detect enteroviruses, including EV-D68, but do not distinguish enteroviruses from rhinoviruses. Definitive identification of EV-D68 requires partial genomic sequencing or amplification with an EV-D68-specific NAAT.

TREATMENT: No specific therapy is available for enteroviruses infections. Immune globulin intravenous (IGIV), administered intravenously or via intraventricular administration, may be beneficial for chronic enterovirus meningoencephalitis in immunodeficient patients. IGIV is not approved for intraventricular administration. IGIV also has been used for life-threatening neonatal enterovirus infections (convalescent plasma from the birthing parent also has been used), severe enterovirus infections in transplant recipients and people with malignancies, suspected viral myocarditis, EV-A71 neurologic disease, and AFM, but without proven clinical efficacy. The CDC has provided interim guidance on the clinical management of children with AFM (www.cdc.gov/acute-flaccid-myelitis/hcp/clinical-management.html). Interferons occasionally have been used for treatment of enterovirus-associated myocarditis and chronic enterovirus meningoencephalitis, without definitive proof of efficacy.

The antiviral drug pleconaril has in vitro activity against many enteroviruses but is not available commercially. Pocopavir, an antiviral drug that is being developed for the treatment of chronic poliovirus infection in immunodeficient patients, also has activity in vitro against some nonpolio enteroviruses. It is not commercially available but may be accessible under a compassionate use mechanism. Fluoxetine has in vitro activity against enterovirus species B and D (including EV-D68), but studies have not demonstrated clinical benefit.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, contact precautions are indicated for infants and young children for the duration of enterovirus illness. Droplet precautions also are indicated if the patient has respiratory symptoms. Cohorting of infected neonates has been effective in controlling hospital nursery enterovirus outbreaks.

CONTROL MEASURES: Hand hygiene, especially after diaper changing, and respiratory hygiene are important in decreasing spread of enteroviruses within families, child care facilities, and other institutions. Other measures include avoidance of contaminated utensils and fomites, and disinfection of surfaces. Because HFMD is normally mild, children can continue in to go to child care and schools as long as: they have no fever, they have no uncontrolled drooling with mouth sores, and they are able to participate normally in classroom activities. In some cases, the local health department may require children with HFMD to stay home to control an outbreak (see Children in Group Child Care and Schools, p 145). Recommended chlorination treatment of drinking water and swimming pools may help prevent transmission.

Maintenance administration of IGIV in patients with severe deficits of B-lymphocyte function (eg, severe combined immunodeficiency syndrome, X-linked agammaglobulinemia) may prevent chronic enterovirus infection of the central nervous system. Prophylactic use of immune globulin has been used to help abort nursery

epidemics. EV-A71 vaccines have been licensed in China and are being evaluated in other Asian countries where disease is prevalent; vaccines for other enterovirus serotypes associated with more severe disease also are under investigation.

Epstein-Barr Virus Infections

(Infectious Mononucleosis)

CLINICAL MANIFESTATIONS: Infectious mononucleosis is the most common presentation of primary symptomatic Epstein-Barr virus (EBV) infection. It manifests typically as fever, pharyngitis with or without petechiae and often with exudate, lymphadenopathy, and hepatosplenomegaly. Atypical lymphocytosis and elevated hepatic aminotransferase concentrations are frequently found on laboratory evaluation. The spectrum of disease is wide, ranging from asymptomatic to fatal infection. Infections are typically unrecognized or nonspecific in infants and young children. Rash can occur in up to 20% of patients and is more common in patients treated with antibiotics, most commonly ampicillin or amoxicillin as well as with other penicillins. Central nervous system (CNS) manifestations include aseptic meningitis, encephalitis, myelitis, optic neuritis, cranial nerve palsies, transverse myelitis, Alice in Wonderland syndrome, and Guillain-Barré syndrome. Hematologic complications include splenic rupture, thrombocytopenia, agranulocytosis, hemolytic anemia, and hemophagocytic lymphohistiocytosis (HLH, or hemophagocytic syndrome). Pneumonia, clinical hepatitis, tonsil or adenoid enlargement resulting in upper airway obstruction, genital ulcerations, orchitis, and myocarditis are observed infrequently. Early in the course of primary infection, 1% of circulating B lymphocytes are infected with EBV, and EBV-specific cytotoxic/suppressor T lymphocytes account for up to 50% of the CD8⁺ T lymphocytes in the blood. Replication of EBV in B lymphocytes results in T-lymphocyte proliferation and inhibition of B-lymphocyte proliferation by T-lymphocyte cytotoxic responses, natural killer (NK) cell activation, and the production of neutralizing antibodies. Fatal disseminated infection or B-lymphocyte, T-lymphocyte, or NK-cell lymphomas rarely occur in children with no detectable immunologic abnormality as well as in children with congenital or acquired cellular immune deficiencies.

EBV is associated with several other distinct disorders, including X-linked lymphoproliferative syndrome, post-transplantation lymphoproliferative disorders, Burkitt lymphoma, Hodgkin lymphoma, nasopharyngeal carcinoma, undifferentiated B- or T-lymphocyte lymphomas, and leiomyosarcoma. X-linked lymphoproliferative syndrome occurs most often in people with an inherited, maternally derived, recessive genetic defect in the SH2DIA or XIAP/BIRC4 genes, which are important in several lymphocyte signaling pathways. The syndrome is characterized by several phenotypes, including occurrence of fatal infectious mononucleosis early in life among boys; HLH; nodular B-lymphocyte lymphomas, often with CNS involvement; and profound pancytopenia. Similarly, X-linked immunodeficiency with magnesium defect, EBV infection, and neoplasia (XMEN) disease is characterized by loss-of-function mutations in the gene encoding magnesium transporter 1 (MAGT1), chronic high-level EBV DNAemia with increased EBV-infected B cells, and heightened susceptibility to EBV-associated lymphomas. Several other genetic mutations associated with the failure to control EBV infection because of changes in T-lymphocyte and NK cell function have also been described.

EBV-associated lymphoproliferative disorders can also occur in patients who are immunocompromised, such as transplant recipients or people infected with human immunodeficiency virus (HIV). EBV seronegative recipients of organs from EBV-seropositive donors are at highest risk for EBV-associated post-transplant lymphoproliferative disease (PTLD), with the highest incidence occurring in small intestine transplant recipients, followed by lung and heart transplant recipients, and lowest among liver and kidney transplant recipients. Proliferative states range from benign lymph node hypertrophy to monoclonal lymphomas. Other EBV-associated lymphoproliferative syndromes are of greater importance outside the United States, such as Burkitt lymphoma, which can be endemic or sporadic. EBV is present in virtually 100% of cases of endemic Burkitt lymphoma (a B-lymphocyte tumor predominantly found in the jaw or facial bones primarily in Central Africa) versus 20% of sporadic Burkitt lymphoma (a B-lymphocyte tumor of abdominal lymphoid tissue predominantly in North America and Europe). EBV is found in nearly 100% of nasopharyngeal carcinomas in Southeast Asia and the Inuit populations. EBV also has been associated with Hodgkin disease (a B-lymphocyte tumor), non-Hodgkin lymphomas (both B and T lymphocyte types), gastric carcinoma “lymphoepitheliomas,” and a variety of other epithelial malignancies.

Chronic fatigue syndrome is not directly caused by EBV infection; however, fatigue lasting 6 months or more may follow approximately 10% of cases of classic infectious mononucleosis.

ETIOLOGY: EBV (also known as human herpesvirus 4) is a gamma herpesvirus of the *Lymphocryptovirus* genus and is the most common cause of infectious mononucleosis (>90% of cases).

EPIDEMIOLOGY: Humans are the only known reservoir of EBV, and approximately 90% of US adults have been infected. Close personal contact usually is required for transmission. The virus is viable in saliva for several hours outside the body; the role of fomites in transmission is unknown. EBV may be transmitted by blood transfusion or transplantation. Infection commonly is contracted early in life, particularly among members of lower socioeconomic groups, where crowding and intrafamilial spread is common. Endemic infectious mononucleosis is common in group settings of adolescents, such as in educational or military institutions. No seasonal pattern has been clearly documented. Intermittent excretion of EBV in saliva is lifelong after infection and likely explains viral spread and persistence in the population.

The **incubation period** of infectious mononucleosis is estimated to be 30 to 50 days.

DIAGNOSTIC TESTS: Infectious mononucleosis is primarily a clinical diagnosis. An absolute increase in atypical lymphocytes and mild elevations in hepatic aminotransferase concentrations during the second week of illness with infectious mononucleosis are additional characteristic but nonspecific findings. Confirmation of primary EBV infection depends on results of serologic testing. Nonspecific tests for heterophile antibody, including the Paul-Bunnell test and slide agglutination reaction test, are available but have several limitations, including false-positive and false-negative results. The heterophile antibody response primarily is immunoglobulin (Ig) M, which appears during the first 2 weeks of illness and usually disappears over 6 months but may persist for 1 year and may also be positive with other conditions, both infectious (eg, CMV,

adenovirus, HIV) and noninfectious (eg, leukemia, lymphoma, systemic lupus erythematosus). In addition, the results of heterophile antibody tests often are negative during early EBV infection and in children younger than 4 years of age.

Multiple specific serologic antibody tests for EBV infection are available (see Table 3.7 and Fig 3.1). The most commonly performed test is for antibody against the viral capsid antigen (VCA) of EBV. Because IgG antibodies against VCA occur in high titer early in infection and persist for life at modest levels, testing of acute and convalescent serum specimens for IgG anti-VCA alone is not useful for establishing the presence of active infection. In contrast, testing for the presence of IgM anti-VCA antibody and the absence or very low titers of antibodies to Epstein-Barr nuclear antigen (EBNA) is useful for identifying active and recent infections. Because serum antibody against EBNA is not present until several weeks to months after onset of infection and rises with convalescence, a very elevated anti-EBNA antibody concentration typically excludes active primary infection. Testing for antibodies against early antigen (EA) is not usually required to assess EBV-associated mononucleosis. Typical patterns of antibody responses to EBV infection are illustrated in Table 3.7 and Fig 3.1.

Serologic testing for EBV is useful, particularly for evaluating patients younger than 4 years or in whom the infectious mononucleosis syndrome is not classic. Testing for other agents, especially cytomegalovirus, *Toxoplasma*, human herpesvirus 6, adenovirus, and HIV (in those with HIV risk factors), may be indicated for some patients. Diagnosis of the entire range of EBV-associated illness requires use of additional molecular and antibody techniques, particularly for patients with immune deficiencies and transplant recipients.

Nucleic acid amplification tests (NAATs) for detection of EBV DNA in serum, plasma, whole blood, and tissue, and NAATs or in situ hybridization for detection of EBV RNA in lymphoid cells, tissue, and/or body fluids, are available and can be useful in evaluation of immunocompromised patients and in complex clinical situations.

TREATMENT: There is no antiviral treatment approved for EBV infection. Patients suspected of having infectious mononucleosis should not receive ampicillin or amoxicillin, which may cause nonallergic morbilliform rashes in a proportion of patients with active EBV infection. Although therapy with short-course corticosteroids may have a beneficial effect on some acute symptoms, because of potential adverse effects their use is usually considered only for patients with marked tonsillar inflammation with impending airway obstruction, massive splenomegaly, myocarditis, hemolytic anemia, HLH, or severe thrombocytopenia. In those situations, the dosage of prednisone usually is 1 mg/kg per day, orally (maximum 60 mg/day), for 5 to 7 days, usually with tapering over 1 to 2 weeks. Life-threatening HLH has been treated with cytotoxic agents and immunomodulators, including etoposide, corticosteroids, and/or cyclosporine; emapalumab is approved for the treatment of progressive or refractory HLH. Although acyclovir and valacyclovir have in vitro antiviral activity against EBV and reduce viral replication, they produce no clinical benefit in infectious mononucleosis or in the prevention or treatment of EBV-associated PTLT. Decreasing immunosuppressive therapy often is beneficial as part of a preemptive strategy during EBV viral surveillance in response to increasing EBV DNAemia in transplant patients and for patients with EBV-induced PTLT. Rituximab, a monoclonal antibody directed against CD20+ B lymphocytes, is used both preemptively and for treatment of CD20+ PTLT in hematopoietic cell and solid organ transplant patients. Adoptive immunotherapy

Table 3.7. Serum Epstein-Barr Virus (EBV) Antibodies in EBV Infection

Infection	VCA IgG	VCA IgM	EA (D)	EBNA
No previous infection	–	–	–	–
Acute infection	+	+	+/-	–
Recent infection	+	+/-	+/-	+/-
Past infection	+	–	+/-	+

VCA IgG indicates immunoglobulin (Ig) G class antibody to viral capsid antigen; VCA IgM, IgM class antibody to VCA; EA (D), early antigen diffuse staining; and EBNA, EBV nuclear antigen.

with EBV-specific cytotoxic T-lymphocytes may be a treatment option in hematopoietic cell transplant recipients.

Strenuous activity and contact sports should be avoided for at least 21 days after onset of symptoms of infectious mononucleosis because of concern for splenic rupture. After 21 days, limited noncontact aerobic activity can be allowed if there are no symptoms and there is no overt splenomegaly. Clearance to participate in contact sports is appropriate after 4 to 7 weeks following the onset of symptoms if the athlete

FIG 3.1. SCHEMATIC REPRESENTATION OF THE EVOLUTION OF ANTIBODIES TO VARIOUS EPSTEIN-BARR VIRUS ANTIGENS IN PATIENTS WITH INFECTIOUS MONONUCLEOSIS

No further reproduction or distribution is permitted without the prior written permission of American Society for Microbiology.

is asymptomatic and has no overt splenomegaly. Imaging modalities rarely are helpful in decisions about clearance to return to contact sports. Repeat EBV serologic testing is not useful in most clinical situations. It may take 3 to 6 months or longer following mononucleosis for an athlete to return to preillness fitness.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: None in the hospital or clinic. Avoid salivary exchange or sharing food or drink with someone who recently had infectious mononucleosis.

***Escherichia coli* Diarrhea**
(Including Hemolytic-Uremic Syndrome)

CLINICAL MANIFESTATIONS: *Escherichia coli* is a common bacterial cause of diarrheal illness. At least 5 pathotypes of diarrhea-producing *E coli* strains have been identified. Clinical features of disease caused by each pathotype are summarized as follows (Table 3.8):

Table 3.8. Classification of *Escherichia coli* Associated With Diarrhea

Pathotype	Epidemiology	Type of Diarrhea	Mechanism of Pathogenesis
Shiga toxin-producing <i>E coli</i> (STEC)	Nonbloody and bloody diarrhea and hemolytic-uremic syndrome in all ages	Bloody or nonbloody	Shiga toxin production, large bowel adherence, coagulopathy
Enteropathogenic <i>E coli</i> (EPEC)	Acute and chronic endemic and epidemic diarrhea in infants in resource-limited countries; certain atypical strains in industrialized countries may cause disease	Watery	Small bowel adherence and effacement
Enterotoxigenic <i>E coli</i> (ETEC)	Infant diarrhea in resource-limited countries, travelers' diarrhea in all ages, and some cases in nontravelers	Watery	Heat stable and/or heat-labile enterotoxin production
Enteroinvasive <i>E coli</i> (EIEC)	Diarrhea with fever in all ages	Bloody or nonbloody; dysentery	Mucosal invasion and inflammation of large bowel
Enteraggregative <i>E coli</i> (EAEC)	Acute and chronic diarrhea in all ages	Watery, occasionally bloody	Small and large bowel adherence, enterotoxin and cytotoxin production

- **Shiga toxin-producing *E coli* (STEC)** organisms are associated with diarrhea, hemorrhagic colitis, and hemolytic-uremic syndrome (HUS). STEC O157:H7 is the virulent STEC serotype most often implicated in outbreaks, but other serotypes are increasingly common causes of illness. STEC illness typically begins with nonbloody diarrhea. Stools usually become bloody after 2 or 3 days, representing the onset of hemorrhagic colitis. Severe abdominal pain typically is short lived, and low-grade fever is present in approximately one third of cases. Illness caused by *E coli* O157:H7 and other STEC organisms should be considered in people with presumptive diagnoses of intussusception, appendicitis, inflammatory bowel disease, and ischemic colitis. There are 2 types of Shiga toxin (Stx), Stx1 and Stx2, and several variants of each type. In the clinical setting, there is limited ability to differentiate between Stx variants.
- Diarrhea caused by **enteropathogenic *E coli* (EPEC)** is watery with prominent amounts of mucus but without gross blood. EPEC strains do not produce Shiga toxins and are distinguished from other diarrheagenic *E coli* by the distinctive attaching and effacing lesions they cause to the epithelium of the small intestine. Although usually mild, EPEC diarrhea can result in dehydration and death, particularly in resource-limited countries and immunocompromised patients. The diarrhea can be persistent and can result in wasting or growth restriction. Illness attributable to typical EPEC (caused by strains that harbor a virulence plasmid) occurs almost exclusively in children younger than 2 years and predominantly in resource-limited countries, either sporadically or in epidemics. Atypical EPEC (caused by strains which do not harbor a virulence plasmid) can cause diarrhea in all ages, including prolonged diarrhea.
- Diarrhea caused by **enterotoxigenic *E coli* (ETEC)** is a 1- to 5-day, self-limited illness of moderate severity, typically with watery stools and abdominal cramps. ETEC is common in infants in resource-limited countries and in travelers to those countries. ETEC is the leading cause of travelers' diarrhea. The prevalence of ETEC disease in the United States is unknown. With increasing use of culture-independent tests, ETEC infections may be detected more frequently especially in late summer into fall.
- Diarrhea caused by **enteroinvasive *E coli* (EIEC)** is similar clinically to diarrhea caused by *Shigella* species. Although dysentery can occur, diarrhea usually is watery without blood or mucus. Patients often are febrile, and stools can contain leukocytes. Severe cases of EIEC may require hospitalization.
- **Enteraggregative *E coli* (EAEC)** organisms cause watery diarrhea and are common in people of all ages in industrialized as well as resource-limited countries. EAEC is a common cause of childhood diarrhea in resource-limited countries, acute travelers' diarrhea, and persistent diarrhea in children or human immunodeficiency virus (HIV)-infected people. EAEC has been associated with prolonged diarrhea (14 days or longer). Asymptomatic infection can be accompanied by subclinical inflammatory enteritis and may stunt a child's growth. With increasing use of culture-independent tests, EAEC is being identified more frequently in the United States, even among those without international travel history.

Sequelae of STEC Infection. HUS, manifested by varying degrees of hemolysis and uremia, is a serious sequela of STEC enteric infection believed to follow Stx-induced

vasculitis and systemic complement cascade activation. STEC O157:H7 organisms are most commonly associated with HUS, which is defined by the triad of microangiopathic hemolytic anemia, thrombocytopenia, and acute renal dysfunction. HUS occurs more frequently in younger children; approximately 15% of children younger than 5 years develop HUS after *E coli* O157 infection as compared with approximately 6% among people of all ages. Non-O157 STEC infections also may cause HUS but at a much lower frequency (approximately 1%) than O157 infections. HUS typically develops 7 days (up to 2 weeks, and rarely 2–3 weeks) after onset of diarrhea. The risk of developing HUS is lower in children who have a longer interval between diarrhea onset and presentation to the emergency department. More than 50% of children with HUS require dialysis, and up to 5% die. Patients with HUS can develop neurologic complications (eg, seizures, coma, or cerebral vessel thrombosis). Children presenting with an increased white blood cell count ($>20 \times 10^9/\text{mL}$), neurologic complications, or need for dialysis are at higher risk of poor outcome, as are, seemingly paradoxically, children with hematocrit close to normal rather than low. There is increasing recognition of long-term risk for hypertension, proteinuria, and chronic kidney disease following HUS in children.

ETIOLOGY: The 5 pathotypes of diarrhea-producing *E coli* have been distinguished by genetic, pathogenic, and clinical characteristics. Each pathotype is defined by the presence of virulence-related genes, and each comprises characteristic serotypes, indicated by somatic (O) and flagellar (H) antigens. Diarrhea is caused by the direct effects of the pathogens in the intestine.

EPIDEMIOLOGY: Transmission of most diarrhea-associated *E coli* strains is through a fecal-oral mechanism.

STEC is shed in feces of cattle and, to a lesser extent, sheep, deer, and other ruminants. Human infection is acquired via contaminated food or water or via contact with an infected person, a fomite, or a carrier animal or its environment. Many foods have caused STEC outbreaks, including raw leafy vegetables, undercooked ground beef, cookie dough, raw flour, and unpasteurized milk and juice (see the *Red Book Online* outbreaks page for information on current outbreaks at <https://publications.aap.org/redbook/resources/17748>). Outbreak investigations have implicated petting zoos, drinking water, and ingestion of recreational water. The infectious dose of STEC is low; thus, person-to-person transmission is common in households and child care centers. The number of infections reported annually to the US laboratory-based enteric disease system of the Centers for Disease Control and Prevention (CDC) has increased in recent years because of the increasing use of culture-independent diagnostic tests.

The non-O157 STEC serogroups most commonly linked to illness in the United States are O26, O103, O111, O121, O145, and O45. Outbreaks from these serogroups are less common than those caused by serogroup O157 and are generally attributable to contaminated food or person-to-person transmission (often in a child care setting). There is a higher incidence of serogroup O157 infections in northern US states compared with other regions.

With the exception of EAEC, non-STEC pathotypes most commonly are associated with disease in resource-limited countries, where food and water supplies are

commonly contaminated and facilities and supplies for hand hygiene are suboptimal. For young children in resource-limited countries, transmission of ETEC, EPEC, and other diarrheal pathogens via contaminated weaning foods (sometimes by use of untreated drinking water in the foods) is common. ETEC diarrhea occurs in people of all ages but is especially frequent and severe in infants in resource-limited countries and travelers from industrialized countries visiting resource-limited countries. Breastfeeding is protective in such settings.

The **incubation period** for most diarrhea-associated *E coli* strains is 10 hours to 6 days; for *E coli* O157:H7, the **incubation period** usually is 3 to 4 days (range, 1–10 days).

DIAGNOSTIC TESTS: Several US Food and Drug Administration (FDA)-approved multiplex nucleic acid amplification tests (NAATs) (usually offered as diagnostic panels) can detect a variety of enteric pathogens, including EAEC, EPEC, ETEC, and STEC. Some culture-independent tests include an *E coli* O157 specific marker to differentiate *E coli* O157 from non-O157 STEC serotypes. Using these newer culture-independent methods, EAEC, EPEC, and ETEC may be detected more frequently than in the past and may represent colonization. Therefore, the pretest probability of the disease and clinical context, including the presence of other potential pathogens, must be considered when interpreting results of these tests.

Several commercially available, rapid immunologic assays for Shiga toxins in stool or broth culture of stool, including enzyme immunoassays (EIA) and immunochromatographic assays, have been approved by the FDA. The Shiga toxin assays performed on broth enriched stool specimens (usually incubated 18–24 hours) generally are more sensitive than those that test stool directly.

Rapid diagnosis facilitates patient management. Hydration is the cornerstone of management for all diarrhea cases and may be particularly protective against the development of nephropathy associated with HUS. Most *E coli* O157 isolates can be identified presumptively when grown on sorbitol-containing selective media because they cannot ferment sorbitol within 24 hours. All presumptive *E coli* O157 isolates and all Shiga toxin-positive stool specimens that did not yield a presumptive *E coli* O157 isolate should be sent to a public health laboratory for further characterization, including identification of non-O157 serotype and determination of whole genome sequence.

Patients with postdiarrheal HUS should be presumed to have STEC infection, and STEC should be sought in stool specimens from all patients diagnosed with postdiarrheal HUS. However, the absence of STEC does not preclude the diagnosis of probable STEC-associated HUS, because HUS typically is diagnosed a week or more after onset of diarrhea, when the organism may not be detectable by conventional bacteriologic methods. In this setting, the selective enrichment of stool samples followed by immunomagnetic separation can markedly enhance the isolation of *E coli* O157 and other STEC for which immunomagnetic reagents are available. The test is available at some state public health laboratories and through requests to state health departments at the CDC. Serologic diagnosis using enzyme immunoassay to detect serum antibodies to *E coli* O157 and O111 lipopolysaccharides is available at the CDC for outbreak investigations and surveillance for patients with HUS; this testing can be arranged through state health departments.

TREATMENT: Treatment is primarily supportive for all diarrhea-producing *E. coli*.¹ Orally administered electrolyte-containing solutions usually are adequate to prevent or treat dehydration and electrolyte abnormalities.² Antimotility agents should not be administered to children with inflammatory or bloody diarrhea. Many experts advocate intravenous volume expansion during the first 4 days of proven STEC infection to maintain renal perfusion and reduce the risk of renal injury. Careful monitoring of patients with hemorrhagic colitis (including complete blood cell count with smear, blood urea nitrogen, and creatinine concentrations) is recommended to detect changes suggestive of HUS. If patients have no laboratory evidence of hemolysis, thrombocytopenia, or nephropathy 3 days after resolution of diarrhea, their risk of developing HUS is low.

In resource-limited countries, nutritional rehabilitation, including supplemental zinc and vitamin A, should be provided as part of case management algorithms for diarrhea where feasible. Feeding, including breastfeeding, should be continued for young children with *E. coli* enteric infection.

Bismuth subsalicylate has been approved by the FDA for use in children 12 years and older and may be used in mild cases of ETEC travelers' diarrhea. It can cause blackening of the tongue and stool, and patients should be advised to rinse their mouths after each dose. It contains salicylate and should not be used if there is concern for coinfection with varicella or influenza because of increased risk of Reye syndrome.

Antimicrobial Therapy. Antimicrobial therapy in patients with known or likely STEC infection remains controversial because of its association with an increased risk of developing HUS in some studies. A meta-analysis did not find that children with hemorrhagic colitis caused by STEC have a greater risk of developing HUS if treated with an antimicrobial agent. However, an association was found in analyses restricted to studies with low risk of bias and using the accepted HUS definition. Moreover, a controlled trial has not been performed, and a beneficial effect of antimicrobial treatment has not been proven. The most recently published observational studies found that treatment of diarrhea with at least some classes of antimicrobial agents was associated with HUS development. A large case-control study of 1308 US residents with *E. coli* O157 infection found that people treated with a beta-lactam antibiotic had a 2.8-fold higher odds of developing HUS than those treated with other antibiotics. Most experts advise not prescribing antimicrobial therapy for children with *E. coli* O157 enteritis or a clinical or epidemiologic presentation that strongly suggests STEC infection.

Antimicrobial therapy can be considered for travelers in resource-limited areas when diarrhea is moderate to severe or is associated with fever or bloody stools; however, the prevalence of antimicrobial resistance among enteric pathogens is increasing.³ Several antimicrobial agents, such as azithromycin, fluoroquinolones (see Fluoroquinolones, p 973), and rifaximin can be effective in treatment of ETEC or

³ wwwnc.cdc.gov/travel/yellowbook/2024/preparing/travelers-diarrhea

EAEC travelers' diarrhea. Treatment for no more than 3 days is advised. The choice of therapy depends on the pathogen and local antibiotic resistance patterns.

Patients with domestically acquired atypical EPEC (ie, as detected by molecular tests), EAEC, or ETEC will generally have self-limited diarrhea that does not require antimicrobial therapy. For patients with moderate or severe illness with persistent (>14 days) diarrhea attributable to diarrhea-producing *E coli* because they have no other pathogen detected, a treatment regimen similar to that used for ETEC or EAEC travelers' diarrhea (azithromycin, a fluoroquinolone, or rifaximin) may be used.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, contact precautions are indicated for diapered and incontinent patients with all types of *E coli* diarrhea for the duration of illness. Prolonged shedding has been noted in children younger than 5 years.

CONTROL MEASURES:

***E coli* O157:H7 and Other STEC Infection.** All meat should be cooked thoroughly. Ground beef should be cooked to an internal temperature of 160°F (71°C) until no pink meat remains and the juices are clear. Raw milk should not be ingested, and the certification of raw milk does not eliminate the risk of transmission of *E coli* organisms.¹ Only pasteurized apple juice and cider products should be consumed. Care should be taken to prevent cross-contamination in areas of food preparation and good handwashing practices should be in place.

Outbreaks in Child Care Centers. If an outbreak of HUS or diarrhea attributable to STEC occurs in a child care center, immediate involvement of public health authorities is critical. Infection caused by STEC is notifiable, and rapid reporting of cases allows intervention to prevent further disease. Ill children with STEC O157 infection or virulent non-O157 STEC infection should not be permitted to reenter the child care center until all of the following: 2 stool cultures (obtained at least 48 hours after any antimicrobial therapy, if administered, has been discontinued) are negative, stools are contained in the diaper or the child is continent, stool frequency is no more than 2 stools above that child's normal frequency, and the health department agrees with the return to child care (see Table 2.3, p 149). Stool cultures should be performed for any symptomatic contacts, and these children should be excluded from child care centers while symptomatic and the evaluation is pending. In outbreak situations involving STEC strains, stool cultures of asymptomatic contacts may aid controlling spread; consultation with public health authorities is advised. Strict attention to hand hygiene is important but can be insufficient to prevent transmission. The child care center should be closed to new admissions during an outbreak, and care should be exercised to prevent transfer of exposed children to other centers.

Nursery and Other Institutional Outbreaks. Similar to child care institutional setting, strict attention to hand hygiene is essential for limiting spread. Ill patients should be separated from unexposed patients and their stool should be cultured as described above. Exposed patients should be observed closely.

¹ American Academy of Pediatrics, Committee on Infectious Diseases, Committee on Nutrition. Consumption of raw or unpasteurized milk and milk products by pregnant women and children. *Pediatrics*. 2014;133(1):175-179 (Reaffirmed November 2019)

Travelers' Diarrhea. Travelers' diarrhea usually is acquired by ingestion of contaminated food or water or contact with fomites and is a significant problem for people traveling in resource-limited countries. Diarrhea commonly is caused by ETEC and EAEC. Diarrhea attributable to non-O157 STEC infection is common among US residents who have traveled internationally in the previous week, but *E coli* O157 is rare. Travelers should be advised to drink only bottled or canned beverages and boiled or bottled water; travelers should avoid ice, raw produce, including salads, and fruit that they themselves have not peeled (only fruits with a thick peel, such as bananas and oranges, should be consumed). Cooked foods that have been left at ambient temperatures for prolonged periods should not be consumed. Hands should be washed carefully before preparing or eating food or feeding another person. Antimicrobial agents are not recommended for prevention of travelers' diarrhea in children. Rehydration is the mainstay of treatment. Packets of oral rehydration salts can be added to boiled or bottled water and ingested to help maintain fluid balance, and breastfeeding should be encouraged and continued for young children.

Recreational Water (eg, Swimming Pools, Water Slides). People should avoid ingesting recreational water. Because STEC has a low infectious dose and can be waterborne, people with proven or suspected STEC infection should not use recreational water venues when ill with diarrhea. As with other causes of diarrhea, children who have diarrhea attributable to STEC and who are incontinent should continue not to use recreational water venues until 1 week after symptoms resolve (or as advised by local or state public health authorities) (see Prevention of Illnesses Associated With Recreational Water Use, p 214). Showering before swimming, taking children to the restroom frequently, changing diapers at designated diapering stations, and then washing hands can limit transmission of diarrheal pathogens through recreational water.

Other Fungal Diseases

Uncommonly encountered fungi can cause infection in infants and children with immunosuppression or other underlying conditions. Fungi can cause invasive mold infections, such as mucormycosis, fusariosis, scedosporiosis, and the phaeohyphomycoses (black molds), as well as invasive yeast infections with organisms such as *Malassezia*, *Trichosporon*, *Rhodotorula*, and many more (more common mycoses, including aspergillosis, blastomycosis, candidiasis, coccidioidomycosis, cryptococcosis, histoplasmosis, paracoccidioidomycosis, and sporotrichosis, are discussed in individual chapters of Section 3 of the *Red Book*). Children can acquire infection from these fungi through inhalation via the respiratory tract or direct inoculation after traumatic disruption of cutaneous barriers. A list of some of these fungi and the pertinent underlying host conditions, reservoirs or routes of entry, clinical manifestations, diagnostic laboratory tests, and treatments can be found in Table 3.9. Taken as a group, few in vitro antifungal susceptibility data are available on which to base treatment recommendations for these uncommon invasive fungal infections, especially in children; thus optimal treatments are not well established and antifungal choice may depend on the particular species (see Antifungal Drugs for Systemic Fungal Infections, p 1017, and Table 4.7, p 1021, which indicates in Footnote b which species are molds). In addition, attempts to achieve source control and improve the net state of immunosuppression, including reversing severity of neutropenia, are critical. Reduction of immunosuppression

Table 3.9. Additional Fungal Diseases

Disease and Agent	Underlying Host Condition(s)	Reservoir(s) or Route(s) of Entry	Common Clinical Manifestations	Diagnostic Laboratory Test(s)	First-Line Antifungal Treatment ^a
Hyalohyphomycosis					
<i>Fusarium</i> species	Granulocytopenia; hematopoietic cell transplantation; severe immunocompromise; severe neutropenia and/or T-lymphocyte immunodeficiency	Environment; respiratory tract; sinuses; skin; traumatic inoculation	Pulmonary infiltrates; cutaneous lesions (eg, ecthyma); sinusitis; keratitis; disseminated infection, onychomycosis	Culture of blood or tissue specimen, histopathologic examination of tissue	Voriconazole, or Voriconazole plus lipid amphotericin formulation ^b

^bThere are no definitive data to routinely recommend the use of antifungal combination therapy, although combination therapy may frequently be used particularly until final species identification is known to tailor therapy.

^cNo US Food and Drug Administration approval for this indication.

^dConsider use of amphotericin B lipid formulations: liposomal amphotericin B is the preferred formulation; when lipid formulations are not available, deoxycholate amphotericin B may be an alternative.

^eItraconazole has been shown to be effective for cutaneous disease in adults, but safety and efficacy have not been established in children younger than 18 years.

^fVoriconazole demonstrates activity in vitro, but no clinical data are available.

and surgical excision and débridement should always be considered in management of invasive fungal infections, if feasible. Physicians should consider consultation with a pediatric infectious disease specialist experienced in the diagnosis and treatment of invasive fungal infections when treating a child infected with one of these mycoses.

***Fusobacterium* Infections**

(Including Lemierre Syndrome)

CLINICAL MANIFESTATIONS: *Fusobacterium* species, including *Fusobacterium necrophorum* and *Fusobacterium nucleatum*, can be isolated from oropharyngeal specimens in healthy people and are frequent components of human dental plaque with the potential to lead to periodontal disease. Invasive disease attributable to *Fusobacterium* species has been associated with otitis media, tonsillitis, gingivitis, and oropharyngeal trauma including dental and oropharyngeal surgery such as tonsillectomy. Ten percent of cases of invasive *Fusobacterium* infections are associated with concomitant Epstein-Barr virus infection.

Preceding oropharyngeal infection is the most frequent primary source for invasive infection. Invasive infections can be characterized by peritonsillar abscess, deep neck space infection, mastoiditis, and sinusitis that can be complicated by meningitis, cerebral abscess, dural sinus venous thrombosis, endocarditis, and pleural empyema. Otogenic and gynecologic sources of infection have also been reported.

Invasive infection following tonsillitis was described early in the 20th century and was referred to as postanginal sepsis or Lemierre syndrome. The classic syndrome starts with fever and sore throat that progresses to severe neck pain (anginal pain) that can be accompanied by unilateral neck swelling, trismus, dysphagia, and rigors associated with development of suppurative jugular venous thrombosis (JVT). Patients with classic Lemierre syndrome have a sepsis syndrome with metastatic complications from septic embolic phenomena associated with JVT. Patients with Lemierre syndrome may develop complications including multiple pulmonary septic emboli, pleural empyema, pyogenic arthritis, osteomyelitis, or disseminated intravascular coagulation. Laboratory abnormalities associated with Lemierre syndrome can include significantly elevated inflammatory markers, thrombocytopenia, elevated aminotransferases, hyperbilirubinemia, and elevated creatinine. Persistent headache or other neurologic signs may indicate the presence of cerebral venous sinus thrombosis (eg, cavernous sinus thrombosis), meningitis, or brain abscess. *Fusobacterium* species (most commonly *F necrophorum*) can be isolated from blood or other normally sterile sites and account for at least 60% to 80% of Lemierre syndrome cases. Lemierre-like syndromes have also been reported following infection with *Arcanobacterium haemolyticum*, *Bacteroides* species, *Klebsiella* species, anaerobic *Streptococcus* species, other anaerobic bacteria, and methicillin-susceptible and -resistant strains of *Staphylococcus aureus*.

With respect to thrombosis, the JVT can be completely vaso-occlusive. Some children with JVT associated with Lemierre syndrome have evidence of thrombophilia at diagnosis. These findings often resolve over several months and can indicate response to the inflammatory, prothrombotic process associated with infection, rather than an underlying hypercoagulable state.

Fusobacterium species have also been associated with intra-abdominal and pelvic infections including acute appendicitis, suppurative portomesenteric vein thrombosis, and suppurative thrombosis of the pelvic vasculature.

ETIOLOGY: *Fusobacterium* species are filamentous, anaerobic, non-spore-forming, gram-negative bacilli. Human infection usually results from *F necrophorum* subspecies *funduliforme*, but infections with other species including *F nucleatum*, *Fusobacterium gonidiaformans*, *Fusobacterium naviforme*, *Fusobacterium mortiferum*, and *Fusobacterium varium* have been reported. Infection with *Fusobacterium* species, alone or in combination with other oral anaerobic bacteria, may result in Lemierre syndrome, but unlike other anaerobic infections, *Fusobacterium* species are frequently the only organisms identified in these infections.

EPIDEMIOLOGY: *Fusobacterium* species are commonly found in soil and in the respiratory tracts of animals, including cattle, dogs, fowl, goats, sheep, and horses, and can be isolated from the oropharynx of healthy people. *Fusobacterium* infections are most common in adolescents and young adults, but infections, including fatal cases of Lemierre syndrome, have been reported in infants and young children.

DIAGNOSTIC TESTS: *Fusobacterium* species can be isolated using conventional liquid anaerobic blood culture media. However, the organism grows best on semisolid media for fastidious anaerobic organisms or blood agar supplemented with vitamin K, hemin, menadione, and a reducing agent. Colonies generally are cream to yellow colored, smooth, and round and may show a narrow zone of alpha- or beta-hemolysis on blood agar, depending on the species of blood used in the medium; *F nucleatum* may appear as bread crumb-like colonies. Many strains fluoresce chartreuse green under ultraviolet light. Most *Fusobacterium* organisms are indole positive. On Gram stain, *F nucleatum* usually exhibits spindle-shaped cells with tapered ends, while *F necrophorum* and other species may be highly pleomorphic with swollen areas. The accurate identification of anaerobes to the species level has become important with the increasing incidence of microorganisms that are resistant to multiple drugs. Conventional and commercial culture-based biochemical test systems are reasonably accurate, at least to the genus level. Sequencing of the 16S rRNA gene and phylogenetic analysis or the use of mass spectrometry of bacterial cell components can accurately identify *Fusobacterium* species to the species level.

Currently, there are no commercially available tests for rapidly diagnosing *Fusobacterium* pharyngitis, although nucleic acid amplification tests (NAATs) have been used in dental settings to monitor bacterial species in saliva, including *Fusobacterium* species, in patients with periodontal disease. Routine throat cultures for beta-hemolytic streptococci do not generally include screening for the presence of *Fusobacterium* species. Researchers have used special media to grow *F necrophorum* from throat swab specimens or have used NAAT techniques to document and describe *F necrophorum* tonsillitis/pharyngitis and the frequency of *Fusobacterium* species colonization in pharyngeal specimens obtained from asymptomatic adolescents and young adults. A number of experimental multiplex NAAT panels and metagenomic sequencing platforms for the identification of pathogens in blood and other sterile sites are under development and may allow rapid identification of *Fusobacterium* infections in the future.

One should consider Lemierre syndrome in ill-appearing febrile children and especially adolescents having a sore throat with exquisite neck pain and swelling over the angle of the jaw, accompanied by rigors. Aerobic and anaerobic blood cultures should be performed to detect invasive *Fusobacterium* species and other possible pathogens. Imaging studies of the internal jugular veins should be obtained, but it is important to note that a significant proportion of patients with a diagnosis of Lemierre syndrome

will not have a thrombus detected by imaging (thromboses may be missed or embolized prior to imaging). Computed tomography and magnetic resonance imaging are more sensitive than ultrasonography to document thrombosis and thrombophlebitis of the internal jugular vein early in the course of illness and to better identify thrombus extension beyond the areas visible by ultrasonography, including under the mandible and clavicle.

TREATMENT: Aggressive and prompt antimicrobial therapy is the mainstay of treatment. *Fusobacterium* species generally are susceptible to metronidazole, clindamycin, chloramphenicol, penicillin with beta-lactamase inhibitor combinations (ampicillin-sulbactam or piperacillin-tazobactam), carbapenems, cefoxitin, and ceftriaxone. Antimicrobial resistance has increased in anaerobic bacteria, and susceptibilities to particular antibiotic classes are less predictable. Therefore, susceptibility testing is indicated for all clinically significant anaerobic isolates, including *Fusobacterium* species. Combination therapy with metronidazole or clindamycin, in addition to a beta-lactam agent active against aerobic oral and respiratory tract pathogens (eg, cefotaxime, ceftriaxone, or cefuroxime), is recommended for patients with invasive infection caused by *Fusobacterium* species. Alternatively, some experts recommend monotherapy with a penicillin-beta-lactamase inhibitor combination (ampicillin-sulbactam or piperacillin-tazobactam) or a carbapenem (meropenem, imipenem, or ertapenem). Up to 50% of *F nucleatum* and 20% of *F necrophorum* isolates produce beta-lactamases, rendering them resistant to penicillin, ampicillin, and some cephalosporins. *Fusobacterium* species intrinsically are resistant to gentamicin, fluoroquinolone agents, and typically, macrolides. Tetracyclines have limited activity.

The duration of antimicrobial therapy depends on the anatomic location and severity of infection but usually is at least 6 weeks. Surgical intervention involving débridement or incision and drainage of abscesses may be necessary. Anticoagulation therapy has been used in both adults and children with JVT or cavernous sinus thrombosis. However, there is limited evidence for the impact of anticoagulation on patient outcomes.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended. Person-to-person transmission of *Fusobacterium* species has not been documented.

CONTROL MEASURES: Proper oral hygiene and routine dental cleanings may reduce density of oral colonization with *Fusobacterium* species, prevent gingivitis and dental caries, and reduce the risk of invasive disease.

***Giardia duodenalis* (Formerly *Giardia lamblia* and *Giardia intestinalis*) Infections**

(Giardiasis)

CLINICAL MANIFESTATIONS: Symptoms of *Giardia* infection are attributable to dysfunction of the small bowel caused by residing trophozoites and range from asymptomatic carriage to fulminant diarrhea and dehydration. Most infections are asymptomatic, but children are more often symptomatic than adults. Symptomatic patients are mildly to moderately ill and complain frequently of intermittent abdominal cramping, bloating, and foul-smelling flatus and stools. Chronic infection, often

with weight loss, is common, similar to irritable bowel syndrome. A more fulminant presentation with acute and chronic diarrhea, malabsorption, failure to thrive, and weight loss may occur, but systemic symptoms other than malaise are uncommon and extraintestinal involvement (eg, arthritis, urticaria, retinal changes, and bile or pancreatic duct involvement) is unusual. Symptoms are also caused by lactose intolerance and malabsorption, which result in voluminous diarrhea often described as “greasy or fatty.” Sometimes atypical upper gastrointestinal symptoms of belching, nausea, and vomiting predominate, causing a delay in diagnosis. Fever, mucus, and blood in stool are atypical and suggest infection with another agent(s). Duration of infection can be prolonged and may last years in immunosuppressed individuals. In children, development of immunity is poor and repeated infections are common. Patients with cystic fibrosis have an increased prevalence of *Giardia duodenalis* infection.

ETIOLOGY: *G duodenalis* (formerly called *Giardia lamblia* or *Giardia intestinalis*) is a flagellate protozoan that exists in trophozoite and cyst forms; the infective form is the cyst. *Giardia* organisms undergo a simple life cycle alternating between orally ingested, infectious, acid-resistant cysts and motile trophozoites that reside and multiply in the small intestine. Encystation occurs in the lower small bowel, and cysts are infectious when excreted. Infection is limited to the small intestine and biliary tract. *Giardia* cysts are infectious immediately after being excreted in feces and remain viable for 3 months in water at 4°C. A single freeze/thaw cycle kills most *Giardia* cysts; complete killing occurs after multiple freeze/thaw cycles. Heating, drying, and seawater are microcidal to cysts, depending on specific conditions.

EPIDEMIOLOGY: Giardiasis has a worldwide distribution and is the most common intestinal parasitic infection of humans identified in the United States and globally. The highest incidence of giardiasis in the United States is reported among children 1 through 9 years of age, adults 25 through 29 years of age, adults 55 through 59 years of age, and residents of northern states. Peak illness onset occurs from early summer through early fall. High infectivity is a result of the combination of enormous numbers of infectious cysts that may be excreted and the low infectious dose (as few as 10 to 100 cysts are able to cause infection). Giardiasis is communicable for as long as the infected person excretes cysts. Duration of cyst excretion is variable but can range from weeks to months. Transmission of *G duodenalis* is most likely to occur in situations in which exposure to feces with cysts is likely, including: (1) child care centers; (2) areas of the world with endemic disease; (3) close contact, including sexual contact, with infected people; (4) swallowing of contaminated drinking or recreational water; and (5) consumption of unfiltered or untreated water such as when camping or backpacking, including water downstream of beaver dams (leading to giardiasis being known as beaver fever). Although less common, outbreaks associated with food or food handlers have been reported. Among 63 outbreaks of giardiasis with an identified mode of transmission reported from 26 states between 2012 and 2017, waterborne outbreaks were the most common (46%), followed by person-to-person contact (44%) and contaminated food (9.5%). Most of the waterborne outbreaks were associated with drinking water, followed by exposure to recreational water. Surveys conducted in the United States have identified overall prevalence rates of *Giardia* organisms in stool specimens that range from 5% to 7%, with variations depending on age, geographic location, and season.

The **incubation period** usually is 1 to 3 weeks.

DIAGNOSTIC TESTS: *Giardia* cysts or trophozoites are not detected consistently in the stools of infected patients. Diagnostic sensitivity can be increased by examining up to 3 stool specimens over several days. New molecular enteric panel assays generally include *Giardia* organisms as a target pathogen. Diagnostic techniques include direct fluorescence antibody (DFA) assay with microscopy, rapid immunochromatographic cartridge assays, enzyme immunoassay (EIA), microscopy with trichrome staining, and molecular assays. If there is a suspicion of false-negative results, repeat testing should be performed, and use of a different methodology should be considered. Otherwise, retesting is only recommended if symptoms persist after treatment. Invasive testing of the duodenal contents or an intestinal biopsy is required only rarely. Molecular testing to identify the genetic assemblages and subtypes of *Giardia* is not helpful clinically. Giardiasis is not associated with eosinophilia.

TREATMENT: Some infections are self-limited, and treatment may not be required. Tinidazole, metronidazole, and nitazoxanide are the drugs of choice (see Table 4.11, p 1068). Although not approved by the US Food and Drug Administration (FDA) for treatment of *Giardia* infection, the use of metronidazole is widely accepted. It is the least expensive of these therapies but generally has poor palatability when compounded into a suspension. A 5- to 7-day course of metronidazole has an efficacy of 80% to 100% in pediatric patients. Tinidazole, approved by the FDA in 2004 for treatment of giardiasis for children 3 years and older, has high efficacy (about 90%), good tolerability, fewer adverse effects than metronidazole, and is provided as a single oral dose. A 3-day course of nitazoxanide oral suspension has similar efficacy as metronidazole and can also treat other intestinal parasites. Nitazoxanide is approved for use in children 1 year and older with *Giardia* infection. Paromomycin, a poorly absorbed aminoglycoside, is 50% to 70% effective and is the recommended treatment for pregnant persons with giardiasis. Metronidazole has been used in pregnancy, but data regarding safety in the first trimester are conflicting. Tinidazole should not be used during pregnancy.

Symptom recurrence after completing antimicrobial treatment can be attributable to reinfection or recurrence, post-*Giardia* irritable bowel, residual lactose intolerance (occurs in 20%–40% of patients), or symptoms attributable to another process or infection. Recurrences are associated with immunosuppression or poor immunity, insufficient treatment, drug resistance, or reexposure. Because new or residual symptoms are nonspecific, repeated testing should be performed. Options for retreatment include use of an alternative drug of a different class, a longer course of the first failed drug, or combination therapy with 2 different drug classes. One such combination is tinidazole plus quinacrine for at least 2 weeks, which is almost always curative.

Patients who are immunocompromised because of hypogammaglobulinemia or lymphoproliferative disease are at higher risk of giardiasis, and a cure is more difficult for these people. Among human immunodeficiency virus (HIV)-infected children and adults without acquired immunodeficiency syndrome (AIDS), effective combination antiretroviral therapy (ART) and antiparasitic therapy are the major initial treatments for these infections. Patients with AIDS often respond to standard therapy but in some cases additional treatment is required. If giardiasis is refractory to standard treatment among HIV-infected patients with AIDS, longer treatment duration or combination antiparasitic therapy (eg, tinidazole, nitazoxanide, or metronidazole plus one of the following: paromomycin, albendazole, or quinacrine) may be appropriate.

Treatment of asymptomatic carriers is controversial but is recommended in the United States and other areas of low prevalence to prevent infection within families or of other children, which is common. Treatment of children likely to be reinfected, such as those residing in areas of high prevalence, is not recommended unless medically indicated.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended for most. Contact precautions for the duration of illness are recommended for diapered and incontinent children.

CONTROL MEASURES: Safe water, appropriate sanitation, and handwashing are the most important measures to avoid giardiasis. Avoid drinking and recreational water that may be contaminated. If the safety of drinking water is in doubt (eg, during travel to a location with poor sanitation or lack of water treatment systems), the following are recommended:

- Drink commercially bottled water from an unopened factory-sealed container.
- Disinfect tap water by heating it to a rolling boil for 1 minute.
- Use a filter that has been certified for cyst and oocyst reduction.

Boiling is the most reliable method to make water safe for drinking with required boiling time dependent on altitude (1 minute at sea level). Chemical disinfection with iodine is an alternative method of water treatment using either tincture of iodine or tetraglycine hydropyridide tablets. Chlorine in various forms also has been used for chemical disinfection, but germicidal activity is dependent on several factors, including pH, temperature, and organic content of the water. Chlorination has low to moderate effectiveness in killing *Giardia*. Additional information about water purification, including a traveler's guide for buying water filters, can be found at www.cdc.gov/healthywater/drinking/travel/index.html.

Swallowing water during recreational activities in pools, hot tubs, interactive fountains, lakes, rivers, springs, ponds, streams, or the ocean, or drinking untreated water from lakes, rivers, springs, ponds, streams, or shallow wells, should be avoided.

Infected people and individuals at risk especially should adhere to strict hand-hygiene techniques after contact with feces. Use of gloves before handling infected feces or contaminated diapers is a more stringent approach. For additional prevention guidance, visit the CDC *Giardia* website (www.cdc.gov/parasites/giardia).

When an outbreak is suspected in a child care center (also see Children in Group Child Care and Schools, p 145), the local health department should be contacted and an epidemiologic investigation should be undertaken to identify and treat all symptomatic children, child care providers, and family members infected with *G duodenalis*. A directory of state and territorial, city and county, and tribal health departments can be found at www.cdc.gov/publichealthgateway/healthdirectories/index.html. Infected children should be excluded from child care until stools are contained in the diaper or the child is continent, stool frequency is no more than 2 stools above that child's normal frequency, and the health department agrees with the return to child care. Testing of asymptomatic individuals and treatment of asymptomatic carriers in a child care center outbreak are controversial.

People with diarrhea caused by *Giardia* species should not use recreational water venues (eg, swimming pools, water slides) while symptomatic. For additional information, see Prevention of Illnesses Associated With Recreational Water Use (p 214).

Public Health Reporting. Giardiasis is a nationally notifiable disease. Please refer to the state or local health department for details on reporting cases.

Gonococcal Infections

CLINICAL MANIFESTATIONS: Gonococcal infections are manifested by a spectrum of clinical presentations ranging from asymptomatic infection, to localized infections (usually mucosal), to disseminated disease, and should be considered in 3 distinct age groups: newborn infants, prepubertal children, and postpubertal sexually active adolescents and young adults. Multiple sites of infection can occur simultaneously in one person.

- **Asymptomatic infection** has been detected in the oropharynx of child sexual abuse survivors and in the urogenital tract of sexually active female (up to 80% are asymptomatic) and male (less than 10% can be asymptomatic) individuals.¹ In all age groups, most pharyngeal infections are asymptomatic. Likewise, most rectal infections are asymptomatic; rectal carriage can accompany 20% to 70% of urogenital infections in female individuals.
- **Localized disease** presents at the site of inoculation and includes (1) scalp abscess, which can be associated with fetal scalp monitoring; (2) ophthalmia neonatorum in newborn infants following exposure during birth, or conjunctivitis in any age group following eye inoculation with infected secretions (eg, through hand transfer from urogenital tract); (3) acute tonsillopharyngitis, accompanied by cervical adenopathy; (4) urethritis (with mucopurulent discharge, dysuria, and/or suprapubic pain) in any age group or sex; (5) genital disease such as vulvitis and/or vaginitis in prepubertal patients (with vaginal discharge and/or dysuria), Bartholinitis and/or cervicitis in postpubertal patients (with mucopurulent discharge, intermenstrual bleeding, and/or dyspareunia), and penile abscess; and (6) proctitis (symptoms range from painless mucopurulent discharge and scant rectal bleeding to overt proctitis with associated rectal pain and tenesmus). Extension to the upper genital tract and beyond (less common in prepubertal children) can result in pelvic inflammatory disease (endometritis and/or salpingitis), perihepatitis (Fitz-Hugh-Curtis syndrome) in female individuals, and epididymitis, prostatitis, and/or seminal vesiculitis in male individuals, with resultant scarring, ectopic pregnancy, impairment of fertility, and chronic pelvic pain (particularly in female individuals; see Sexually Transmitted Infections in Adolescents and Children, p 179).
- **Disseminated gonococcal infection (DGI)** can occur in up to 3% of untreated people with mucosal gonorrhea. DGI can manifest as petechial or pustular skin lesions and as asymmetric polyarthralgia, tenosynovitis, or oligoarticular septic arthritis (arthritis-dermatitis syndrome). In neonates, DGI can present as sepsis, arthritis, or meningitis. Bacteremia can result in a maculopapular rash with necrosis, tenosynovitis, and migratory arthritis. Arthritis may be reactive (sterile) or septic in nature. Meningitis and endocarditis occur rarely.

ETIOLOGY: *Neisseria gonorrhoeae* is a gram-negative, oxidase-positive diplococcus.

EPIDEMIOLOGY: Gonococcal infections occur only in humans. The source of the organism is exudate and secretions from infected mucosal surfaces; *N gonorrhoeae* is communicable as long as a person harbors the organism. Transmission results from intimate contact, such as sexual acts and parturition. Sexual abuse is the most frequent cause of gonococcal infection in prepubertal children beyond the newborn period (see Sexual Assault and Abuse in Children and Adolescents/Young Adults, p 182).

¹ The terms female, male, women, and men refer to sex assigned at birth.

N gonorrhoeae infection is the second most commonly reported sexually transmitted infection (STI) in the United States, following *Chlamydia trachomatis* infection. Reported gonorrhea cases continued to be highest among adolescents and young adults. Rates of reported gonorrhea are highest in the southern United States and have significant racial/ethnic disparities. The rate of reported gonorrhea cases among Black people in the United States is significantly higher than among white people. These higher rates are not caused by ethnicity or genetic predisposition; rather, they are caused by social factors, such as poverty or inequities in education, which are more likely to affect minority groups. Disparities in gonorrhea rates also are identified in certain sexual networks. For example, surveillance networks that monitor trends in STI prevalence among men who have sex with men (MSM) have found very high proportions of positive gonorrhea pharyngeal, urethral, and rectal test results as well as coinfection with other STIs. Populations at greater risk for DGI include asymptomatic carriers; neonates; menstruating, pregnant, and postpartum people; MSM; and individuals with complement deficiency or taking eculizumab.

Gonorrhea can quickly develop resistance to antibiotics used to treat infection, and in 2019 more than half of all infections were estimated to be resistant to at least 1 antibiotic. Since 2010, almost all circulating strains in the United States, based on gonococcal isolates collected through sentinel surveillance in the Gonococcal Isolate Surveillance Project (GISP), remain susceptible to ceftriaxone, the primary treatment for gonorrhea; only 0.1% of isolates displayed elevated ceftriaxone minimum inhibitory concentrations (MICs) in 2020. In 2020, 4.8% of isolates had elevated azithromycin MICs; the proportion was higher among MSM versus men who have sex with women (9.2% vs 4.3%). In 2020, the prevalence of ciprofloxacin resistance was 34.8%.

Diagnosis of genitourinary tract gonorrhea infection should also prompt investigation for other STIs, including chlamydia, trichomoniasis, syphilis, and human immunodeficiency virus (HIV) infection. Concurrent infection with *C trachomatis* is common. People treated for gonococcal infection should also be treated with a regimen that is effective against *C trachomatis* if chlamydia infection has not been excluded.

The **incubation period** usually is 2 to 7 days.

DIAGNOSTIC TESTS¹⁻³: Microscopic examination of Gram-stained smears of exudate from the conjunctivae, penile urethra, skin lesions, synovial fluid, and when clinically warranted, cerebrospinal fluid (CSF) may be useful in the initial evaluation. Identification of gram-negative intracellular diplococci in these smears can be helpful, particularly if the organism is not recovered in culture. However, because of low sensitivity, a negative smear result should not be considered sufficient for ruling out infection. Intracellular gram-negative diplococci identified on Gram stain of conjunctival exudate justify presumptive treatment for gonorrhea after appropriate cultures for *N gonorrhoeae* are performed.

² Centers for Disease Control and Prevention. Recommendations for the laboratory-based detection of *Chlamydia trachomatis* and *Neisseria gonorrhoeae*—2014. *MMWR Recomm Rep*. 2014;63(RR-2):1-19

³ Centers for Disease Control and Prevention. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(4):1-187. Available at www.cdc.gov/std/treatment-guidelines/gonorrhea.htm

N gonorrhoeae can be isolated from normally sterile sites, such as blood, CSF, or synovial fluid, using nonselective chocolate agar with incubation in 5% to 10% carbon dioxide. Selective media that inhibit normal flora and nonpathogenic *Neisseria* organisms are used for cultures from nonsterile sites, such as the cervix, vagina, rectum, urethra, and pharynx. Specimens for *N gonorrhoeae* culture from mucosal sites should be inoculated immediately onto appropriate agar because the organism is extremely sensitive to drying and temperature changes. Culture allows for antimicrobial susceptibility testing to aid in management if infection persists following initial therapy.

A nucleic acid amplification test (NAAT) is far superior in overall performance compared with other *N gonorrhoeae* culture and nonculture diagnostic methods to test genital and extragenital specimens. Many commercially available products now are cleared by the US Food and Drug Administration (FDA) for testing penile urethral meatal swab specimens, endocervical or vaginal swab specimens (provider or patient collected), urine specimens, oropharynx or rectal swab specimens (provider or patient collected), or liquid cytology specimens. Although NAATs are not FDA cleared for *N gonorrhoeae* testing on conjunctival swab specimens, they have been shown to be more sensitive compared with *N gonorrhoeae* culture. Product inserts for each NAAT manufacturer should be reviewed because approved collection methods and specimen types vary. For urogenital infections, the Centers for Disease Control and Prevention (CDC) recommends that optimal specimen types for gonorrhea screening using NAATs include first void urine for male patients and vaginal swab specimens for female patients. Patient-collected samples can be used in place of provider-collected samples in clinical settings when testing by NAAT for urine, penile urethral meatal, vaginal, rectal, and oropharyngeal swab specimens, and if appropriate instructions to patients have been provided. Certain NAAT platforms also permit combined testing of specimens for *N gonorrhoeae* and *C trachomatis*.

Infants and Children. Culture can be used to test urogenital and extragenital sites in infants and children. NAATs can be used to test for *N gonorrhoeae* from urine and vaginal specimens. Although data on NAATs from extragenital sites in children are more limited and performance is test dependent, no evidence suggests that performance of a NAAT for detection of *N gonorrhoeae* in children would differ from that in adults. Because of the implications of a diagnosis of *N gonorrhoeae* in a child, however, only validated, FDA-cleared NAATs should be used for extragenital specimens. Consultation with an expert is necessary before using a NAAT in this context, to minimize the possibility of cross-reaction with nongonococcal *Neisseria* species and other commensals. Gram stains are inadequate for evaluating prepubertal children for gonorrhea and should not be used to diagnose or exclude gonorrhea.

TREATMENT¹: A single dose of intramuscular ceftriaxone is the recommended treatment for uncomplicated gonorrhea infections of the cervix, urethra, and rectum. If chlamydial infection has not been excluded, treatment for *C trachomatis* with either oral doxycycline, azithromycin, levofloxacin, or erythromycin, depending on weight of the child/adolescent. Treatment regimens for most syndromes caused by gonococcal infections, including urethritis, cervicitis, pelvic inflammatory disease, epididymitis, and

¹ Centers for Disease Control and Prevention. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(4):1-187. Available at www.cdc.gov/std/treatment-guidelines/gonorrhea.htm.

proctitis, are provided in the chapter on Sexually Transmitted Infections (Table 4.4, p 1007, and Table 4.5, p 1014). A single 500-mg dose of intramuscular ceftriaxone also is recommended for the treatment of uncomplicated gonococcal infections of the pharynx. Gonococcal infections of the pharynx are more difficult to eradicate than are infections at urogenital and anorectal sites.

Resistance to penicillin and tetracycline is widespread, and as of 2007, the CDC no longer recommends the use of fluoroquinolones for gonorrhea because of the increased prevalence of quinolone-resistant *N gonorrhoeae* in the United States. Over the past decade, the MIC for cefixime against *N gonorrhoeae* strains circulating in the United States and other countries has increased, and treatment failure following the use of cefixime has been described in North America, Europe, and Asia. Therefore, as of 2012, the CDC no longer recommends the use of cefixime as a first-line treatment for gonococcal infection. Only ceftriaxone is recommended currently for treatment of gonorrhea in the United States.

To maximize adherence with recommended therapies and reduce complications and transmission, medication for gonococcal infection should be provided on site and directly observed. If medications are not available when treatment is indicated, linkage to an STI treatment facility should be provided for same-day treatment. To minimize disease transmission, people treated for gonorrhea should be instructed to abstain from sexual activity for 7 days after treatment and until all sex partners are adequately treated (7 days after receiving treatment and resolution of symptoms, if present).

Neonatal Infection. Infants with clinical evidence of ophthalmia neonatorum or scalp abscess attributable to *N gonorrhoeae* should be hospitalized, managed in consultation with a pediatric infectious disease specialist, and evaluated for disseminated infection (sepsis, arthritis, meningitis).

One dose of ceftriaxone (25–50 mg/kg, intravenously [IV] or intramuscularly [IM]) is adequate therapy for gonococcal ophthalmia. For neonates who are unable to receive ceftriaxone because of simultaneous administration of intravenous calcium, 1 dose of cefotaxime (100 mg/kg, IV or IM) may be given. Topical antibiotic therapy alone is inadequate and unnecessary if systemic treatment is administered.

For gonococcal scalp abscesses and disseminated gonococcal infections in neonates, treatment is with ceftriaxone (25–50 mg/kg/day, IV, administered once daily) or cefotaxime (50 mg/kg/day in 2 divided daily doses, IV or IM) for 7 days, with a duration of 10 to 14 days if meningitis is documented.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended, including for newborn infants with ophthalmia.

CONTROL MEASURES: Current control measures consist of counseling on the use of barrier protection during sexual intercourse, close follow-up of infected patients and their contacts, chemoprophylaxis recommended for specific clinical scenarios, routine screening in accordance with guidelines, and case reporting to public health authorities. There is no vaccine to prevent gonococcal infections.

Follow-up. A test-of-cure is not needed for people in whom uncomplicated urogenital or rectal gonorrhea is diagnosed who are treated with a single dose of ceftriaxone. Any person with pharyngeal gonorrhea should return between 7 to 14 days after initial treatment for a test-of cure using culture, NAAT, or both. If the NAAT result is positive, effort should be made to perform a confirmatory culture before retreatment, if a

culture was not already collected. All positive cultures for test-of-cure should undergo antimicrobial susceptibility testing. People who have been treated for gonorrhea should be retested 3 months after treatment for the possibility of reinfection, regardless of whether they believe their sex partners were treated. If retesting at 3 months is not possible, clinicians should retest whenever people next present for medical care within 12 months following initial treatment. All people in whom gonorrhea is diagnosed should be tested for other STIs, including chlamydia, trichomoniasis (vaginal specimens), syphilis, and HIV infection.

Management of Sex Partners. Recent sex partners (ie, people having had sexual contact with the infected patient within the 60 days preceding onset of symptoms or gonorrhea diagnosis) should be referred for evaluation, testing, and presumptive treatment. If the patient's last potential sexual exposure was >60 days before onset of symptoms or diagnosis, the most recent sex partner should be treated. To avoid reinfection, sex partners should be instructed to abstain from condomless sexual intercourse for 7 days after they and their sexual partner(s) have completed treatment and after resolution of symptoms, if present.

For people with gonorrhea for whom health department partner-management strategies are impractical or unavailable and whose providers are concerned about partners' access to prompt clinical evaluation and treatment, expedited partner therapy (EPT) can be delivered to the partner by the patient, a disease investigation specialist, or a collaborating pharmacy, as permitted by law. Details are provided in the CDC STI Guidelines.¹

Prophylaxis.

Neonatal Ophthalmia. If gonorrhea is prevalent in the region and prenatal treatment cannot be ensured, or where required by law, a prophylactic agent should be instilled into the eyes of all newborn infants (including those born by cesarean delivery) to prevent sight-threatening gonococcal ophthalmia (see Neonatal Ophthalmia Prevention, p 1129).

Newborn Infants Whose Birthing Parent Has Gonococcal Infection. A neonate whose birthing parent has untreated gonorrhea is at high risk for infection. These neonates should be tested for gonorrhea at exposed sites (eg, conjunctive, vaginal, rectal, and oropharynx) and treated presumptively for gonorrhea (see Neonatal Ophthalmia Prevention, p 1129).

Children and Adolescents With Sexual Exposure to a Patient Known to Have Gonorrhea. People sexually exposed within the 60 days preceding onset of symptoms or gonorrhea in the index case (or most recent sexual contact, if last potential sexual exposure was >60 days before onset of symptoms or gonorrhea) should undergo examination and culture and should receive the same treatment as do people known to have gonorrhea.

Postexposure Prophylaxis. Doxycycline, 200 mg, administered within 24 to 72 hours of condomless sex (doxy-PEP) has been shown in studies to reduce the incidence of syphilis, chlamydia, and gonorrhea among cisgender men who have sex with men (MSM) and transgender women with a recent history of these infections.

¹ Centers for Disease Control and Prevention. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep.* 2021;70(4):1-187. Available at www.cdc.gov/std/treatment-guidelines/clinical-partner-services.htm

Routine Screening. Annual screening for *N gonorrhoeae* infection is recommended for all sexually active women younger than 25 years.¹ Additional risk factors for gonorrhea include inconsistent condom use among people who are not in mutually monogamous relationships, previous or coexisting STIs, and exchanging sex for money or drugs. Clinicians should consider the communities they serve and might opt to consult local public health authorities for guidance on identifying groups at increased risk. Gonococcal infection is concentrated in specific geographic locations and communities. MSM at high risk for gonorrhea infection (multiple anonymous partners, substance use) or those at risk for HIV acquisition should be screened at all sites of exposure every 3 to 6 months. At least annual screening is recommended for all MSM. A recent travel history with sexual contacts outside of the United States should be part of any gonorrhea evaluation.

All pregnant people younger than 25 years should be screened for gonorrhea at the first prenatal visit. Pregnant people 25 years and older should be screened if they are considered at risk (ie, a new sex partner, more than 1 sex partner, a sex partner with concurrent partners, or a sex partner who has an STI or lives in an area with a high rate of gonorrhea). A repeat screen in the third trimester is recommended for pregnant people at continued risk of gonococcal infection, including all patients younger than 25 years. Pregnant people with a diagnosis of gonorrhea should be treated immediately and rescreened within 3 months.

Public Health Reporting. All cases of gonorrhea must be reported to local public health officials (see Appendix III, Nationally Notifiable Infectious Diseases in the United States, p 1141). Cases in prepubertal children must be investigated to determine the source of infection (see Sexual Assault and Abuse in Children and Adolescents/Young Adults, p 182).

Granuloma Inguinale (Donovanosis)

CLINICAL MANIFESTATIONS: Initial lesions of this sexually transmitted genital ulcerative disease are single or multiple painless subcutaneous nodules that gradually ulcerate. These nontender, granulomatous ulcers have raised, rolled margins, are beefy red and highly vascular, and bleed readily on contact. “Kissing” lesions may occur from auto-inoculation on adjacent skin. Lesions usually involve the genitalia or perineum without regional adenopathy; however, lesions at both the genitalia and inguinal region occur in 5% to 10% of patients. Subcutaneous granulomas extending into the inguinal area can mimic inguinal adenopathy (ie, “pseudobubo”). Extragenital lesions (eg, face, mouth) account for 6% of cases. Dissemination to intra-abdominal organs and bone is rare.

ETIOLOGY: The disease, donovanosis, is caused by *Klebsiella granulomatis* (formerly known as *Calymmatobacterium granulomatis*), an intracellular gram-negative bacillus.

EPIDEMIOLOGY: Indigenous granuloma inguinale occurs very rarely in the United States and most industrialized nations. Sporadic cases have been described in India, South America, and South Africa. The incidence of infection seems to correlate with sustained high temperatures and high relative humidity. Infection usually is acquired

¹ US Preventive Services Task Force. Final Recommendation Statement: Chlamydia and Gonorrhea: Screening. September 14, 2021. Available at: www.uspreventiveservicestaskforce.org/uspstf/recommendation/chlamydia-and-gonorrhea-screening

by sexual contact, most commonly with a person with active infection. Young children and others can, less commonly, acquire infection by contact with infected secretions. The period of communicability extends throughout the duration of active lesions.

The **incubation period** is uncertain; a range of 1 to 360 days has been reported. Experimental production of typical donovanosis lesions was induced in humans 50 days after inoculation.

DIAGNOSTIC TESTS: The causative organism is difficult to culture, and diagnosis requires microscopic demonstration of dark-staining intracytoplasmic Donovan bodies on Wright, Leishman, or Giemsa staining of a crush preparation from subsurface scrapings of a lesion or tissue. The microorganism also can be detected by histologic examination of biopsy specimens. Culture of *K granulomatis* is difficult to perform and is not available routinely. No molecular tests exist that have been cleared by the US Food and Drug Administration for the detection of *K granulomatis*. Diagnosis by nucleic acid amplification test (NAAT) and serologic testing is only available in research laboratories.

TREATMENT¹: The recommended treatment regimen is azithromycin (Table 4.4, p 1007) for at least 3 weeks and until all lesions have completely healed. Alternative treatment regimens include doxycycline, erythromycin, or trimethoprim-sulfamethoxazole. Pregnant and lactating people with granuloma inguinale should be treated with a macrolide regimen (azithromycin or erythromycin). Treatment has been shown to halt progression of lesions. Partial healing usually is noted within 7 days of initiation of therapy and typically proceeds inward from the ulcer margins. Prolonged therapy usually is required to permit granulation and re-epithelialization of the ulcers. Relapse can occur, especially if the antimicrobial agent is stopped before the primary lesion has healed completely. In addition, relapse can occur 6 to 18 months after apparently effective therapy. Complicated or long-standing infection can require surgical intervention.

Patients should be followed clinically until signs and symptoms have resolved. Patients should be evaluated for other sexually transmitted infections, including syphilis, HIV, gonorrhea, and chlamydia.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: People who have had sexual contact with a patient who has granuloma inguinale within the 60 days before onset of the patient's symptoms should be examined and offered therapy. However, the value of empiric therapy in the absence of clinical signs and symptoms has not been established.

***Haemophilus influenzae* Infections**

CLINICAL MANIFESTATIONS: *Haemophilus influenzae* type b causes pneumonia, bacteremia, meningitis, epiglottitis, septic arthritis, cellulitis, otitis media, purulent pericarditis, and less commonly, endocarditis, endophthalmitis, osteomyelitis, peritonitis, and gangrene. Infections caused by encapsulated but non-type b *H influenzae* present in a similar manner to type b infections. Nonencapsulated strains more commonly cause infections of the respiratory tract (eg, otitis media, sinusitis, pneumonia, conjunctivitis),

¹ Centers for Disease Control and Prevention. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(RR-4). Available at: www.cdc.gov/std/treatment-guidelines/donovanosis.htm

but cases of bacteremia, meningitis, chorioamnionitis, and neonatal septicemia are well described.

ETIOLOGY: *H influenzae* is a pleomorphic gram-negative coccobacillus. Encapsulated strains express 1 of 6 antigenically distinct capsular polysaccharides (a through f); non-encapsulated strains lack complete capsule genes and are designated nontypeable.

EPIDEMIOLOGY¹: The mode of transmission is person-to-person by inhalation of respiratory tract droplets or by direct contact with respiratory tract secretions. In neonates, infection is acquired intrapartum by aspiration of amniotic fluid or by contact with genital tract secretions containing the organism. Pharyngeal colonization by *H influenzae* is relatively common, especially with nontypeable strains. In the era before *H influenzae* type b (Hib) vaccines, the major reservoir of *H influenzae* type b was young infants and toddlers, who may asymptotically carry the organism in their upper respiratory tracts.

Before introduction of effective Hib conjugate vaccines, *H influenzae* type b was the most common cause of bacterial meningitis in young children in the United States. The peak incidence of most invasive *H influenzae* type b infections occurred between 6 and 18 months of age, while the peak age for *H influenzae* type b epiglottitis was 2 to 4 years of age.

Unimmunized children younger than 5 years are at increased risk of invasive *H influenzae* type b disease. Other predisposing factors include sickle cell disease, asplenia, human immunodeficiency virus (HIV) infection, certain immunodeficiency syndromes, and chemotherapy for malignant neoplasms. Historically, invasive *H influenzae* type b infection was more common in child care attendees, children living in crowded conditions, and children who were not breastfed.

Since introduction of Hib conjugate vaccines in the United States, the incidence of invasive *H influenzae* type b disease has decreased by more than 99% in young children. In 2019, 18 cases of invasive *H influenzae* type b disease were reported in children younger than 5 years (0.09 cases per 100 000). In the United States, invasive *H influenzae* type b disease occurs primarily in underimmunized children and among infants too young to have completed the primary Hib immunization series; in addition, American Indian/Alaska Native (AI/AN) children continue to experience an elevated burden of disease. *H influenzae* type b remains an important pathogen in many resource-limited countries where Hib vaccine coverage is suboptimal.

The epidemiology of invasive *H influenzae* disease in the United States has shifted in the post-Hib vaccination era. Nontypeable *H influenzae* is now the most common cause of invasive *H influenzae* disease in all age groups. In 2019, the annual incidence of invasive nontypeable *H influenzae* disease was 1.7/100 000 in children younger than 5 years, and the rate was highest in children younger than 1 year (5.1/100 000). Among the cases in children younger than 1 year, approximately half were diagnosed within the first 2 weeks of life; many were in preterm neonates who had a positive culture on the day of birth. In addition to invasive disease, nontypeable *H influenzae* causes about 50% of episodes of acute otitis media and sinusitis in children and is a common cause of recurrent otitis media.

¹ Centers for Disease Control and Prevention. Prevention and control of *Haemophilus influenzae* type b disease: recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR Recomm Rep*. 2014;63(RR-1):1–14

H influenzae type a has emerged as the most common encapsulated serotype causing invasive disease in children <5 years, with a clinical presentation similar to that of *H influenzae* type b. In some North American Indigenous populations (eg, Alaska Native children, northern Canadian Indigenous children), the rate of invasive *H influenzae* type a infection has been increasing and secondary cases have been reported. Although the incidence of invasive *H influenzae* type a is lower among the general population of US children, it has also been increasing in recent years, with a nearly 300% increase over the last 10 years among children younger than 1 year of age. Invasive disease may also be caused by the 4 other encapsulated non-type b strains (ie, c, d, e, and f).

The **incubation period** is unknown.

DIAGNOSTIC TESTS: The diagnosis of invasive disease is established by growth on appropriate media of *H influenzae* from cerebrospinal fluid (CSF), blood, synovial fluid, pleural fluid, or pericardial fluid. Because occult meningitis is known to occur in young children with invasive *H influenzae* type b disease, a lumbar puncture should be strongly considered in the presence of invasive disease, even in the absence of central nervous system signs and symptoms. Gram stain of an infected body fluid specimen can facilitate presumptive diagnosis. Antigen detection methods, which have historically been used on CSF, blood, and urine specimens, are not recommended because they lack sensitivity and specificity. Nucleic acid amplification tests (NAATs) available in multiplexed assays to detect *H influenzae* DNA directly in blood, CSF or pleural fluid, may be particularly useful in patients whose specimens are obtained after the initiation of antibiotics. Most of these assays do not determine the capsular polysaccharide type and, therefore, cannot identify the DNA amplicon as type b, type a, etc, and these tests do not provide antibiotic susceptibilities.

The capsular polysaccharide of *H influenzae* isolates associated with invasive infection should be determined. Molecular methods, such as NAATs of genes in the *cap* locus, are preferred over serotyping by slide agglutination for capsule typing. If typing is not available at the clinical laboratory, isolates should be submitted to the state health department or to a reference laboratory to be typed.

TREATMENT:

- Initial therapy for children with *H influenzae* meningitis is cefotaxime or ceftriaxone at meningitic doses (see Table 4.3, p 993). Intravenous ampicillin at meningitic doses may be substituted if the isolate is found to be susceptible. Beta-lactamase-negative, ampicillin-resistant strains of *H influenzae* have been described, and some experts recommend caution in using ampicillin when minimum inhibitory concentrations (MICs) of 1 to 2 µg/mL are found, especially in the setting of invasive infection or disease in immunocompromised hosts. Treatment of other invasive *H influenzae* infections is similar. Therapy is continued for 7 to 10 days by the intravenous route and longer in complicated infections.
- Dexamethasone is beneficial for treatment of infants and children with *H influenzae* type b meningitis to diminish the risk of hearing loss, if administered before or concurrently with the first dose of antimicrobial agent(s).
- Epiglottitis is a medical emergency. An airway must be established promptly via controlled intubation.
- Infected pleural or pericardial fluid should be drained.
- See the Systems-based Treatment Table (p 1) for discussion of other infections for which *H influenzae* may be a pathogen.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, in patients with invasive *H influenzae* type b disease, droplet precautions are recommended through 24 hours after initiation of effective antimicrobial therapy.

CONTROL MEASURES (FOR INVASIVE *H INFLUENZAE* TYPE B DISEASE):

Care of Exposed People. Secondary cases of *H influenzae* type b disease have occurred in unimmunized or incompletely immunized children exposed to invasive disease in a child care or household setting. Such children should be observed carefully for fever or other signs/symptoms of disease. Exposed young children in whom febrile illness develops should receive prompt medical evaluation.

Chemoprophylaxis.¹ The risk of invasive *H influenzae* type b disease is increased among unimmunized household contacts younger than 4 years. Rifampin eradicates *H influenzae* type b from the pharynx in approximately 95% of carriers and decreases the risk of secondary invasive illness in exposed household contacts. Child care center contacts also may be at increased risk of secondary disease when unimmunized or incompletely immunized children are attending, but secondary disease in child care contacts is rare when all contacts are older than 2 years. Indications and guidelines for chemoprophylaxis in different circumstances are summarized in Table 3.10.

- **Household.** See Table 3.10 for details regarding prophylaxis for household members of a person with invasive *H influenzae* type b disease, when at least 1 household member fits the listed criteria. Given that most secondary cases in households occur during the first week after hospitalization of the index case, prophylaxis should be initiated as soon as possible when it is indicated. Because some secondary cases occur later, initiation of prophylaxis 7 days or more after hospitalization of the index patient still may be of some benefit.
- **Child care and preschool.** When 2 or more cases of invasive *H influenzae* type b disease have occurred within 60 days and unimmunized or incompletely immunized children attend the child care facility or preschool, rifampin prophylaxis for all attendees (irrespective of their age and vaccine status) and child care providers should be considered. In addition to these recommendations for chemoprophylaxis, unimmunized or incompletely immunized children should receive a dose of Hib vaccine and should be scheduled for completion of the recommended age-specific immunization schedule (<https://publications.aap.org/redbook/pages/Immunization-Schedules>). Data are insufficient on the risk of secondary transmission to recommend chemoprophylaxis for child care attendees and providers when a single case of invasive *H influenzae* type b disease occurs; the decision to provide chemoprophylaxis in this situation is at the discretion of the local or state health department.
- **Index case.** See Table 3.10.
- **Dosage.** For prophylaxis, rifampin should be administered orally, once a day for 4 days (20 mg/kg; maximum dose, 600 mg). The dose for infants younger than 1 month is not established; some experts recommend lowering the dose to 10 mg/kg. For adults, each dose is 600 mg. If rifampin is contraindicated, administering a

¹ Centers for Disease Control and Prevention. Prevention and control of *Haemophilus influenzae* type b disease: recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR Recomm Rep*. 2014;63(RR-1):1–14

Table 3.10. Indications and Guidelines for Rifampin Chemoprophylaxis for Contacts of Index Cases of Invasive *Haemophilus influenzae* Type b Disease^a

Chemoprophylaxis Recommended

- For all household contacts^b in the following circumstances:
 - Household with at least 1 child younger than 4 years who is unimmunized or incompletely immunized^c
 - Household with a child younger than 12 months who has not completed the primary *H influenzae* type b (Hib) vaccine series
 - Household with an immunocompromised child, regardless of that child's Hib immunization status or age
- For preschool and child care center contacts when 2 or more cases of *H influenzae* type b invasive disease have occurred within 60 days and unimmunized or incompletely immunized children attend the child care facility or preschool (see text)
- For index patient, if younger than 2 years or member of a household with a susceptible contact and treated with a regimen other than cefotaxime or ceftriaxone, chemoprophylaxis at the end of therapy for invasive infection

Chemoprophylaxis Not Recommended

- For occupants of households with no children younger than 4 years other than the index patient
- For occupants of households when all household contacts are immunocompetent, all household contacts 12 through 48 months of age have completed their Hib immunization series, and when household contacts younger than 12 months have completed their primary series of Hib immunizations
- For preschool and child care contacts of 1 index case
- For index patients over age 2 years or treated with a full course of cefotaxime or ceftriaxone for *H influenzae* type b invasive disease
- For pregnant people

^aSimilar criteria may be used for *H influenzae* type a; however, the criteria for Hib immunization are not applicable.

^bDefined as people residing with the index patient or nonresidents who spent 4 or more hours with the index patient for at least 5 of the 7 days preceding the day of hospital admission of the index case.

^cComplete immunization is defined as having had at least 1 dose of Hib conjugate vaccine at 15 months of age or older; 2 doses between 12 and 14 months of age; or the 2- or 3-dose primary series when younger than 12 months with a booster dose at 12 months of age or older.

single dose of ceftriaxone can be considered, although the durability of eradication using this approach has not been well established.

- **Invasive *H influenzae* type a disease.** Clinicians can consider chemoprophylaxis of household contacts of index cases of invasive *H influenzae* type a disease in those households with a child younger than 4 years or with an immunocompromised child. For these individuals and contacts, chemoprophylaxis recommendations for *H influenzae* type b listed in Table 3.10 may be followed; however, because there is not a licensed vaccine for *H influenzae* type a, the criteria regarding vaccination do not apply. A similar approach as *H influenzae* type b disease also may be considered for

Table 3.11. *Haemophilus influenzae* Type b (Hib) Conjugate Vaccines Licensed and Available for Use in Infants and Children in the United States^a

Vaccine	Trade Name	Components	Manufacturer
PRP-T	ActHIB	PRP conjugated to tetanus toxoid	Sanofi Pasteur
PRP-T	Hiberix	PRP conjugated to tetanus toxoid	GlaxoSmithKline Biologicals
PRP-OMP	PedvaxHIB	PRP conjugated to OMP	Merck & Co, Inc
DTaP-IPV-Hib ^b	Pentacel	DTaP-IPV + PRP-T	Sanofi Pasteur
DTaP-IPV-Hib-HepB	Vaxelis	DTaP-IPV + PRP-OMP + HepB	Sanofi Pasteur and Merck & Co, Inc

PRP-T indicates polyribosylribitol phosphate-tetanus toxoid; OMP, outer membrane protein complex from *Neisseria meningitidis*; DTaP, diphtheria and tetanus toxoids and acellular pertussis; IPV, inactivated (non-live) poliovirus vaccine; HepB, hepatitis B vaccine.

^aHib conjugate vaccines may be administered in combination products or as reconstituted products, provided the combination or reconstituted vaccine is licensed by the US Food and Drug Administration (FDA) for the child's age and administration of the other vaccine component(s) also is justified.

^bThe DTaP-IPV liquid component is used to reconstitute a lyophilized ActHIB vaccine component to form Pentacel.

preschool and child care contacts in consultation with the local or state public health department.

Immunization.¹ Three single-antigen (monovalent) Hib conjugate vaccine products and 2 combination vaccine products that contain Hib conjugate are available in the United States (see Table 3.11). The Hib conjugate vaccine consists of the Hib capsular polysaccharide (polyribosylribitol phosphate [PRP]) covalently linked to a carrier protein. Protective antibodies are directed against PRP.

Depending on the vaccine, the recommended primary series consists of 3 doses administered at 2, 4, and 6 months of age or of 2 doses administered at 2 and 4 months of age (see Recommendations for Immunization, p 407, and Table 3.12). The regimens in Table 3.12 likely are to be equivalent in protection after completion of the recommended primary Hib series. For AI/AN children, administration of PRP-OMP (outer membrane protein complex) monovalent Hib vaccine (PedvaxHIB) is preferred, because this formulation elicits a protective immune response after dose 1 and this population historically experienced invasive *H influenzae* type b disease at a younger age compared with the general US population. Information on immunogenicity after dose 1 of new PRP-OMP-containing Hib vaccines is important for assessing their suitability for use in AI/AN children.

- **Combination Vaccines.** Two combination vaccines that contain Hib are licensed in the United States. DTaP-IPV-Hib (Pentacel) is administered as a 4-dose series at 2, 4, 6, and 15 through 18 months of age. DTaP-IPV-Hib-HepB (Vaxelis)

Table 3.12. Recommended Regimens for Routine *Haemophilus influenzae* Type b (Hib) Conjugate Immunization for Children Immunized at 2 Months Through 4 Years of Age^a

Vaccine Product	Primary Series	Booster Dose	Catch-up Doses ^b
PRP-T (ActHIB, Sanofi Pasteur)	2, 4, 6 mo	12 through 15 mo	16 mo through 4 y
PRP-T (Hiberix, GlaxoSmithKline)	2, 4, 6 mo	12 through 15 mo	16 mo through 4 y
PRP-OMP (PedvaxHIB, Merck) ^{c,d}	2, 4 mo	12 through 15 mo	16 mo through 4 y
Combination vaccine			
DTaP-IPV-Hib (Pentacel, Sanofi Pasteur)	2, 4, 6 mo	12 through 15 mo	16 mo through 4 y
DTaP-IPV-Hib-HepB (Vaxelis, Sanofi Pasteur, Merck & Co, Inc)	2, 4, 6 mo	Use other Hib-containing vaccine for booster, at least 6 months after last priming dose	

PRP-T indicates polyribosylribitol phosphate-tetanus toxoid; OMP, outer membrane protein complex from *Neisseria meningitidis*; DTaP, diphtheria and tetanus toxoids and acellular pertussis; IPV, inactivated (non-live) poliovirus vaccine; Hep B, hepatitis B vaccine.

^aSee text and Table 3.11 (p 405) for further information about specific vaccines and Table 1.10 (p 65) for information about combination vaccines.

^bSee Catch-up Immunization Schedule (<https://publications.aap.org/redbook/pages/Immunization-Schedules>) for additional information.

^cIf a PRP-OMP(PedvaxHIB) vaccine is not administered as both doses in the primary series, a third dose of Hib conjugate vaccine is needed to complete the primary series.

^dPreferred for American Indian/Alaska Native (AI/AN) children.

is administered as a 3-dose primary series at 2, 4, and 6 months of age; a Hib-containing vaccine other than Vaxelis should be administered for the booster dose at 15 to 18 months of age. Until information on the immunogenicity after the first dose of the PRP-OMP-containing combination vaccine (DTaP-IPV-Hib-HepB [Vaxelis]) is available, this vaccine does not have a preferential recommendation for use in AI/AN infants.

- **Vaccine Interchangeability.** Hib conjugate vaccines licensed within the age range for the primary vaccine series are considered interchangeable as long as recommendations for a total of 3 doses in the first year of life are followed (ie, if 2 doses of monovalent PRP-OMP are not administered, 3 doses of a Hib-containing vaccine are required). Data are not available on safety and effectiveness of interchangeability of some vaccines (see package inserts).
- **Dosage and Route of Administration.** The dose of each Hib conjugate vaccine is 0.5 mL, administered intramuscularly.
- **Children With Immunologic Impairment.** Children at increased risk of *H influenzae* type b disease may have impaired anti-PRP antibody responses to

conjugate vaccines. Examples include children with functional or anatomic asplenia, HIV infection, or immunoglobulin deficiency (including an isolated immunoglobulin [Ig] G2 subclass deficiency) or early component complement deficiency; recipients of hematopoietic cell transplants; and children undergoing chemotherapy for a malignant neoplasm. Some children with immunologic impairment may benefit from more doses of conjugate vaccine than usually indicated (see Recommendations for Immunization: Indications and Schedule).

- **Adverse Reactions.** Adverse reactions to Hib conjugate vaccines are uncommon. Pain, redness, and swelling at the injection site occur in approximately 25% of recipients, but these symptoms typically are mild and last fewer than 24 hours. Refer to the manufacturer package inserts for additional information.

Recommendations for Immunization

Indications and Schedule

- All children should be immunized with a Hib conjugate vaccine beginning at approximately 2 months of age (see Table 3.12). Other general recommendations are as follows:
 - ♦ Immunization can be initiated as early as 6 weeks of age.
 - ♦ Vaccine can be administered during visits for other childhood immunizations (see Simultaneous Administration of Multiple Vaccines, p 63).
- For routine immunization of children younger than 7 months, the following guidelines are recommended:
 - ♦ **Primary series.** Table 3.12 lists the options for the primary vaccination series. Doses are administered at approximately 2-month intervals. When sequential doses of different vaccine products are administered or uncertainty exists about which products previously were used, 3 doses of a conjugate vaccine are considered sufficient to complete the primary series, regardless of the regimen used (see package inserts; data are not available for some vaccines on interchangeability).
 - ♦ **Booster immunization at 12 through 15 months of age.** For children who have completed a primary series, an additional dose of conjugate vaccine is recommended at 12 through 15 months of age and at least 2 months after the last dose. Any monovalent or the pentavalent combination (Pentacel) Hib conjugate vaccine is acceptable for this dose. Vaxelis should not be used for the booster dose.
- Children younger than 5 years who did not receive Hib conjugate vaccine during the first 6 months of life should be immunized according to the recommended catch-up immunization schedule (see <https://publications.aap.org/redbook/pages/Immunization-Schedules> and Table 3.12). For accelerated immunization in infants younger than 12 months, a minimum of a 4-week interval between doses can be used.
- Children with invasive *H influenzae* type b infection who are younger than 24 months of age can remain at risk of developing a second episode of disease. These children should be immunized according to the age-appropriate schedule for unimmunized children as if they had received no previous Hib vaccine doses (see Table 3.12, and Table 1.10, p 65). Immunization should be initiated 1 month after onset of disease or as soon as possible thereafter.
- Immunologic evaluation should be performed in children who experience invasive *H influenzae* type b disease despite 2 to 3 doses of vaccine and in children with recurrent invasive disease attributable to type b strains.

- See Table 3.13 for special circumstances such as patients undergoing chemotherapy, radiation therapy, hematopoietic cell transplant, or splenectomy. Additional details are as follows:
 - ♦ **Lapsed immunizations.** Recommendations for children who have had a lapse in the schedule of immunizations are summarized in the annual immunization schedule (<https://publications.aap.org/redbook/pages/Immunization-Schedules>).
 - ♦ **Preterm infants.** For preterm infants who are medically stable, immunization should be based on chronologic age and should be initiated at 2 months following birth according to recommendations in Table 3.12.
 - ♦ **Functional/anatomic asplenia.** Children with decreased or absent splenic function who have received a primary series of Hib immunizations and a booster dose at 12 months or older need not be immunized further against *H influenzae* type b.

Table 3.13. Use of *Haemophilus influenzae* Type b (Hib) Conjugate Immunization in Special Populations

High-Risk Group	Vaccine Recommendations
Patient <12 mo	Follow routine Hib vaccination recommendations
Patients 12 through 59 mo	If unimmunized or received 0 or 1 dose before age 12 months: 2 doses 2 months apart
	If received 2 or more doses before age 12 months: 1 dose
	If completed a primary series and received a booster dose at age 12 months or older: no additional doses
Patients undergoing chemotherapy or radiation therapy, age <60 mo	If routine Hib doses administered 14 or more days before starting therapy: revaccination not required
	If dose administered within 14 days of starting therapy or during therapy: repeat doses starting at least 3 months following therapy completion of therapy
Patients undergoing elective splenectomy, age ≥15 mo	If unimmunized ^a : 1 dose, preferably at least 14 days prior to procedure
Asplenic patients ≥60 mo and adults	If unimmunized ^a : 1 dose ^b
HIV-infected children ≥60 mo	If unimmunized ^a : 1 dose ^b
HIV-infected adults	Hib vaccination is not recommended
Recipients of hematopoietic cell transplant, all ages	Regardless of Hib vaccination history: 3 doses (at least 1 month apart) beginning 6–12 mo after transplant ^b

^aPatients who have not received a primary series and booster dose or at least 1 dose of Hib vaccine after 14 months of age are considered unimmunized.

^bRecommended by the Centers for Disease Control and Prevention Advisory Committee on Immunizations Practices, although Hib vaccines are not licensed for individuals older than 5 years.

- **Other high-risk groups.** Children with HIV infection, IgG2 subclass deficiency, or early component complement deficiency are at increased risk of invasive *H influenzae* type b disease. Whether these children will benefit from additional doses after completion of the primary series of immunizations and the booster dose at 12 months or older is unknown.
- Catch-up immunization for high-risk groups (<https://publications.aap.org/redbook/pages/Immunization-Schedules>) (Table 3.13):
 - For children 12 through 59 months of age with an underlying condition predisposing to *H influenzae* type b disease (functional or anatomic asplenia, HIV infection, immunoglobulin deficiency, early component complement deficiency, or receipt of hematopoietic cell transplant or chemotherapy for a malignant neoplasm) who are not immunized or have received only 1 dose of conjugate vaccine before 12 months of age, 2 doses of any conjugate vaccine, separated by 2 months, are recommended. For children in this age group who received 2 or more doses before 12 months of age, 1 additional dose of conjugate vaccine is recommended.

Public Health Reporting. All cases of *H influenzae* invasive disease, including type b, non-type b, and nontypeable, should be reported to the local or state public health department.

Hantavirus Pulmonary Syndrome

CLINICAL MANIFESTATIONS: Hantaviruses cause 2 distinct clinical syndromes: (1) hantavirus pulmonary syndrome (HPS), also known as hantavirus cardiopulmonary syndrome (HCPS), characterized by noncardiogenic pulmonary edema, which is observed in the Americas; and (2) hemorrhagic fever with renal syndrome (HFRS), which occurs worldwide (see Hemorrhagic Fevers and Related Syndromes Caused by Bunyaviruses, p 420). After an incubation period of 1 to 8 weeks, the prodromal illness of HPS lasts 3 to 7 days and is characterized by fever, chills, headache, myalgia, nausea, vomiting, diarrhea, dizziness, and sometimes cough. Respiratory tract symptoms or signs usually do not occur during the first 3 to 7 days, but then pulmonary edema and severe hypoxemia appear abruptly and present as cough and dyspnea. The disease then progresses over hours. In severe cases, myocardial dysfunction causes hypotension, which is why the syndrome sometimes is called hantavirus cardiopulmonary syndrome.

Extensive bilateral interstitial and alveolar pulmonary edema with pleural effusions are attributable to diffuse pulmonary capillary leak. Intubation and assisted ventilation usually are required for only 2 to 4 days, with resolution heralded by onset of diuresis and rapid clinical improvement.

The severe myocardial depression is different from that of septic shock, with low cardiac indices and stroke volume index, normal pulmonary wedge pressure, and increased systemic vascular resistance. Poor prognostic indicators include persistent hypotension, marked hemoconcentration, a cardiac index of less than 2, and abrupt onset of lactic acidosis with a serum lactate concentration of >4 mmol/L (36 mg/dL).

The mortality rate for patients with HPS is between 30% and 40%; death usually occurs in the first 1 or 2 days of hospitalization. A disproportionate number of cases occurs in American Indian/Alaska Native (AI/AN) populations, and case fatality rates for these populations are higher than for non-Native populations. Milder forms of disease have been reported. Limited information suggests that clinical manifestations

and prognosis are similar in adults and children. Serious sequelae are uncommon. There are typically 20 to 40 cases of HPS reported annually in the United States, with the majority (94%) of cases occurring west of the Mississippi River. Cases in children younger than 10 years are exceedingly rare. Children may be less likely to become infected than adults, because children are less likely to perform tasks that would place them at increased risk.

ETIOLOGY: Hantaviruses are RNA viruses of the *Hantaviridae* family. Sin Nombre virus (SNV) is the major cause of HPS in the western and central regions of the United States. Bayou virus, Black Creek Canal virus, Monongahela virus, and New York virus are responsible for sporadic cases in Louisiana, Texas, Florida, New York, and other areas of the eastern United States. Other hantaviruses, including Andes virus, Oran virus, Laguna Negra virus, and Choclo virus, are responsible for cases in South and Central America.

EPIDEMIOLOGY: Rodents are natural hosts for hantaviruses and acquire lifelong, asymptomatic, chronic infection with prolonged viremia and virus in saliva and feces. Humans acquire infection through direct contact with infected rodents, rodent droppings, or rodent nests or through the inhalation of aerosolized virus particles from rodent urine, droppings, or saliva. Rarely, infection may be acquired from rodent bites or contamination of broken skin with excreta. At-risk activities include handling or trapping rodents, cleaning or entering closed or rarely used rodent-infested structures, cleaning feed storage or animal shelter areas, hand plowing, and living in a home with an increased density of mice. For backpackers or campers, sleeping in a structure inhabited by rodents has been associated with HPS. Exceptionally heavy rainfall improves rodent food supplies, resulting in an increase in the rodent population with more frequent contact between humans and infected rodents, resulting in more human disease. Most cases occur during the spring and summer, with the geographic location determined by the habitat of the rodent carrier.

SNV is transmitted by the deer mouse, *Peromyscus maniculatus*; Black Creek Canal virus is transmitted by the cotton rat, *Sigmodon hispidus*; Bayou virus is transmitted by the rice rat, *Oryzomys palustris*; and the New York and Monongahela viruses are transmitted by the white-footed mouse, *Peromyscus leucopus* and *Peromyscus maniculatus*. Andes virus is transmitted by the long-tailed rice rat (*Oligoryzomys longicaudatus*), endemic in most of Argentina and Chile. Unlike all other hantaviruses, Andes virus can also be transmitted person to person.

DIAGNOSTIC TESTS: HPS should be considered when thrombocytopenia occurs with severe pneumonia clinically resembling acute respiratory distress syndrome in the proper epidemiologic setting. Other characteristic laboratory findings include neutrophilic leukocytosis with immature granulocytes, including more than 10% immunoblasts (basophilic cytoplasm, prominent nucleoli, and an increased nuclear:cytoplasmic ratio), increased hematocrit, and elevated lactate dehydrogenase. Increases in hepatic aminotransferases occur late. In areas where HPS is known to occur, use of a 5-point peripheral blood screen has aided in the early detection of patients with HPS. Elements of the screen are: (1) hemoglobin elevated for gender/age; (2) left shift of granulocytic series; (3) absence of toxic changes on the blood smear; (4) thrombocytopenia; and (5) immunoblasts and plasma cells >10% of lymphocytes. For cases fulfilling 4 of 5 criteria, the positive predictive value of the 5-point screen is >90%.

Hantavirus-specific immunoglobulin (Ig) M and IgG antibodies often are present at the onset of clinical disease, and serologic testing remains the method of choice for diagnosis. IgG may be negative in rapidly fatal cases. Although some commercial labs offer hantavirus serologies, any positive IgM test results are referred to state health departments or the Centers for Disease Control and Prevention (CDC) for confirmation. Molecular detection of virus has been described in peripheral blood mononuclear cells and other clinical specimens from the early phase of the disease but not usually in bronchoalveolar lavage fluids. Viral culture is not useful. Immunohistochemical staining of tissues (capillary endothelial cells of the lungs and almost every organ in the body) can establish the diagnosis at autopsy. Clinicians can contact the CDC Emergency Operations Center 770-488-7100 for assistance with diagnosis and management.

TREATMENT: Patients with suspected HPS should be transferred immediately to a tertiary care facility where supportive management of pulmonary edema, severe hypoxemia, and hypotension can occur during the first critical 24 to 48 hours.

In severe forms, early mechanical ventilation and inotropic and pressor support are necessary. Extracorporeal membrane oxygenation (ECMO) should be considered when pulmonary wedge pressure and cardiac indices have deteriorated and may provide short-term support for the severe capillary leak syndrome in the lungs.

There is no specific antiviral treatment for hantavirus infection. Ribavirin is active in vitro against hantaviruses, including SNV. However, 2 clinical studies of intravenous ribavirin (1 open-label study and 1 randomized, placebo-controlled, double-blind study) failed to show benefit in treatment of HPS in the cardiopulmonary stage.

Cytokine-blocking agents for HPS theoretically may have a role, but these agents have not been evaluated in a systematic fashion. Antibacterial agents do not provide benefit in this viral disease, but broad-spectrum antibiotic therapy often is administered until the diagnosis is established because bacterial shock is far more common than shock attributable to hantavirus.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended. Health care-associated or person-to-person transmission has not been associated with HPS in the United States but has been rarely reported in Chile and Argentina with Andes virus.

CONTROL MEASURES:

Care of Exposed People. Serial clinical examinations should be used to monitor individuals at high risk of infection after exposure (see Epidemiology).

Environmental Control. Hantavirus infections of humans occur primarily in adults and are associated with domestic, occupational, or leisure activities facilitating contact with infected rodents, usually in a building in a rural setting. Eradicating the host reservoir is not feasible. Risk reduction includes practices that discourage rodents from colonizing the home and work environment and that minimize aerosolization and contact with rodent saliva and excreta. Tactics include eliminating food sources for rodents, reducing nesting sites by sealing holes, and using “snap traps” and rodenticides. Before entering areas with potential rodent infestations, doors and windows should be opened to ventilate the enclosure. Regionally and culturally appropriate educational materials should be used to direct prevention messages.

Hantaviruses, because of their lipid envelope, are susceptible to diluted bleach solutions, detergents, and most general household disinfectants. Dusty areas or articles should be moistened with 10% bleach or other disinfectant solution before being cleaned. Brooms and vacuum cleaners should not be used to clean rodent-infested areas. Use of a 10% bleach solution to disinfect dead rodents and wearing rubber gloves before handling trapped or dead rodents is recommended. Gloves and traps should be disinfected after use. The cleanup of areas potentially infested with hantavirus-infected rodents should be conducted by knowledgeable professionals using appropriate personal protective equipment. Potentially infected material should be handled according to local regulations for infectious waste.

Public Health Reporting. Possible hantavirus cases should be reported to local and state public health authorities. For state health department contact information, see www.cdc.gov/hantavirus/surveillance/index.html. HPS and nonpulmonary hantavirus infections are nationally notifiable diseases, reportable through the Nationally Notifiable Disease Surveillance System.

***Helicobacter pylori* Infections**

CLINICAL MANIFESTATIONS: Most *Helicobacter pylori* infections in children are believed to be asymptomatic. *H pylori* may cause chronic active gastritis and may result in duodenal and, to a lesser extent, gastric ulcers. Persistent infection with *H pylori* also increases the risk for the development of gastric cancers including mucosal-associated lymphoid tissue (MALT) lymphoma and adenocarcinoma in adults. However, complications of infection are infrequent in children. In children, acute *H pylori* infection can result in gastroduodenal inflammation that can manifest as epigastric pain, nausea, vomiting, hematemesis, and guaiac-positive stools. If present, these symptoms usually are self-limited. There is no clear association between infection and recurrent abdominal pain in the absence of peptic ulcer disease. The presence of night-time waking is associated with peptic ulcer disease rather than with chronic gastritis attributable to *H pylori* infection (for which night-time waking rarely occurs). Endoscopic findings of *H pylori* infection include nodular gastritis, chronic gastritis, and rarely, the presence of gastric or duodenal erosions or ulcers. Extraintestinal conditions in children that have been associated with *H pylori* infection include treatment-refractory iron-deficiency anemia and chronic immune thrombocytopenia purpura.

ETIOLOGY: The *H pylori* bacterium is a gram-negative, spiral, curved, or U-shaped microaerobic bacillus that has single or multiple flagella at one end. The organism is positive for catalase, oxidase, and urease activity. The 2 main virulence factors associated with more severe disease include the cytotoxin associated gene (CagA) and the vacuolating cytotoxin (VacA).

EPIDEMIOLOGY: *H pylori* organisms have been isolated from humans and other primates. An animal reservoir for human transmission has not been demonstrated. Organisms are believed to be transmitted from infected humans by the fecal-oral, gastro-oral, and oral-oral routes. *H pylori* is estimated to have infected 70% of people living in resource-limited countries and 30% to 40% of people living in industrialized countries. Infection rates in children are low in resource-abundant, industrialized

countries, except in children from lower socioeconomic groups, immigrants from resource-limited countries, and those living in poor hygienic conditions. Most infections are acquired in the first 8 years of life. The organism can persist in the stomach for years or for life.

Although all infected people have gastritis, over a lifetime, approximately 10% to 15% will develop peptic ulcer disease and less than 1% will develop gastric cancer.

The **incubation period** is unknown.

DIAGNOSTIC TESTS: Laboratory analysis of endoscopic specimens is the recommended approach for diagnosis in children. *H pylori* infection can be diagnosed by culture of gastric biopsy tissue on nonselective media (eg, chocolate agar, brucella agar, brain-heart infusion agar) or selective media (eg, Skirrow agar) at 37°C under microaerophilic conditions (decreased oxygen, increased carbon dioxide, and increased hydrogen concentrations) for 3 to 10 days. Colonies are small, smooth, and translucent and are positive for catalase, oxidase, and urease activity. Antimicrobial susceptibility testing of cultured isolates should be performed to guide therapy. Organisms can be visualized on histologic sections with Warthin-Starry silver, Steiner, Giemsa, or Genta staining. Presence of *H pylori* can be confirmed but not excluded on the basis of hematoxylin-eosin stains. Immunohistologic staining with specific *H pylori* antibodies may improve specificity. Because of production of high levels of urease by these organisms, urease testing of a gastric biopsy specimen can be used to detect the presence of *H pylori*. Urease hydrolyzes urea into ammonia and carbonate; the resulting increase in pH from the production of ammonia is detected in the assay.

Unlike in adults, noninvasive tests are not recommended for initial diagnosis of *H pylori* in children. Commercially available noninvasive tests include urea breath tests and stool antigen tests; these tests are designed for detection of active infection and have high sensitivity and specificity. Stool antigen tests by enzyme immunoassay monoclonal antibodies are available commercially and can be used for children of any age. The urea breath test detects labeled carbon dioxide in expired air after oral administration of isotope-labeled urea (^{13}C or ^{14}C). Although urea breath tests are expensive and are not useful in very young children, there is a test approved by the US Food and Drug Administration (FDA) for children 3 to 17 years of age.

H pylori can be detected by nucleic acid amplification tests (NAATs) or fluorescence in situ hybridization (FISH) of gastric biopsy tissue, and NAATs also have been used to detect the organism in stool specimens. However, none of these assays are currently cleared by the FDA for *H pylori* testing.

Serologic testing for *H pylori* infection by detection of immunoglobulin (Ig) G antibodies specific for *H pylori* should not be used in children for diagnosis or for confirming eradication.

Indications for *H pylori* Testing. Indications for testing for *H pylori* in children are not as broad as for adults, for whom there is stronger evidence for disease associations and lower risk of reinfection following treatment. Children with identified peptic ulcer disease may benefit from testing and treatment for *H pylori* infection. Patients with functional abdominal pain (absence of alarm symptoms by Rome criteria¹) should not

¹ Hyams JS, Di Lorenzo C, Saps M, Shulman RJ, Staiano A, van Tilburg M. Functional disorders: children and adolescents. *Gastroenterology*. 2016;150(6):1456-1468

be tested, because there is a lack of evidence that treating *H pylori* infection provides relief. Testing is appropriate to confirm eradication of infection following completion of treatment.

The European Society for Paediatric Gastroenterology, Hepatology and Nutrition and the North American Society for Pediatric Gastroenterology, Hepatology & Nutrition (ESPGHAN/NASPGHAN) joint guideline recommends against a “test and treat” strategy for *H pylori* infection in children. Instead, they recommend the following¹:

- The diagnosis of *H pylori* infection should be based on either (a) histopathology (*H pylori*-positive gastritis) plus at least 1 other positive biopsy-based test (eg, urease test or molecular-based assays including NAAT or fluorescent in situ hybridization) or (b) positive culture.
- When testing for *H pylori*, wait at least 2 weeks after stopping a proton pump inhibitor (PPI) and 4 weeks after stopping antimicrobial agents.
- Testing for *H pylori* should be performed in children with gastric or duodenal ulcers. If *H pylori* infection is identified, then treatment should be advised and eradication should be confirmed.
- Diagnostic testing for *H pylori* infection should not be performed as part of the initial investigation in children with iron-deficiency anemia. In children with refractory iron-deficiency anemia for which other causes have been ruled out, testing for *H pylori* during upper endoscopy may be considered.
- Diagnostic testing for *H pylori* infection should not be performed in children with functional abdominal pain (unless accompanied by alarm symptoms by Rome criteria²).
- Diagnostic testing for *H pylori* infection should not be performed when investigating causes of short stature.

The 2019 guideline from the American Society of Hematology (ASH) recommends against routine testing for *H pylori* in children with chronic immune thrombocytopenia purpura.³

Testing to confirm eradication of infection following completion of treatment is appropriate. Noninvasive tests may be used for this purpose.

TREATMENT¹: Treatment options are detailed in Tables 3.14 and 3.15. Treatment is recommended for infected patients who have peptic ulcer disease, gastric mucosa-associated lymphoid tissue-type lymphoma, or early gastric cancer. Treatment of *H pylori* infection, if documented, may be considered for children who have unexplained and refractory iron-deficiency anemia. Additionally, the ESPGHAN/NASPGHAN

guideline recommends eradication if infection is associated with chronic immune thrombocytopenia purpura. For patients with *H pylori* infection in the absence of clinical or endoscopic evidence of peptic ulcer disease, treatment is not recommended unless the patient is within a risk group or region with high incidence of gastric cancer. Medication adherence is critical to the success of eradication.

The backbone of all recommended therapies includes a PPI and amoxicillin. Additions of metronidazole, clarithromycin, and/or bismuth are based on the patient's previous treatment experience or known susceptibilities to clarithromycin and metronidazole. Reports of increasing prevalence of antibiotic-resistant strains (particularly

Table 3.15. Rescue Therapies in Pediatric Patients Who Fail Therapy for *Helicobacter pylori*^{a,b}

Initial Antibiotic Susceptibilities	Past Treatment Regimen	Suggested Rescue Treatment
Susceptible to clarithromycin, susceptible to metronidazole	PPI + amoxicillin + clarithromycin	PPI + amoxicillin + metronidazole
	PPI + amoxicillin + metronidazole	PPI + amoxicillin + clarithromycin
Susceptible to clarithromycin, susceptible to metronidazole	Sequential therapy ^c	Consider performing a second endoscopy and tissue culture and use cultured-directed treatment for 14 days
		OR Treat like double-resistant in Table 3.14
Resistant to clarithromycin	PPI + amoxicillin + metronidazole	Treat like double-resistant in Table 3.14
Resistant to metronidazole	PPI + amoxicillin + clarithromycin	Consider performing a second endoscopy and use a tailored treatment for 14 days
		OR Treat like double-resistant in Table 3.14
Susceptibilities not known	PPI + amoxicillin + clarithromycin	Consider performing a second endoscopy to assess secondary antimicrobial susceptibility
	OR	
	PPI + amoxicillin + metronidazole	OR Treat like double-resistant in Table 3.14
	OR	
	Sequential therapy ^c	

PPI indicates proton pump inhibitor.

Available at https://naspghan.org/files/Joint_ESPGHAN_NASPGHAN_Guidelines_for_the.33.pdf.

^bRefer to joint ESPGHAN/NASPGHAN guidelines^a for antibiotic dosing.

^cSequential therapy consists of PPI + amoxicillin for 5 days, followed by PPI + clarithromycin + metronidazole for 5 days.

clarithromycin resistance) as well as increasing failures of triple therapies suggest the need for bismuth-based quadruple therapy regimens (meaning 3 antibiotics and bismuth) and longer durations (14 days) for eradication of *H pylori*. A number of treatment regimens have been evaluated and are approved for use in adults; the safety and efficacy of these regimens in pediatric patients have not been firmly established. There is no current evidence to support the use of probiotics to reduce medication adverse effects or improve eradication of *H pylori*. Limited options exist for penicillin-allergic patients.

Initial Therapy

- In a treatment-naïve patient with *H pylori*, selection of therapeutic regimen is best guided by knowledge of the susceptibilities of that patient's organism.
- Treatment options are detailed in Table 3.14.
- A breath or stool test should be performed to document organism clearance 4 to 6 weeks after completion of initial therapy; relief of clinical symptoms is not an indicator of successful eradication.

Rescue Therapy

- Infection within the first 12 months following treatment is likely a relapse of the previous infection. In contrast to adults, reduced options exist for rescue therapy for children.
- Management and treatment options are detailed in Table 3.15.
- A breath or stool test should be performed to document organism eradication 4 to 6 weeks after completion of rescue therapy.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: Disinfection of gastroscopes prevents transmission of the organism between patients.

Hemorrhagic Fevers Caused by Arenaviruses¹

CLINICAL MANIFESTATIONS: Arenaviruses are responsible for several hemorrhagic fever (HF) syndromes. Arenaviruses are divided into 2 groups: New World (Tacaribe complex, including Argentine HF, Bolivian HF, and Venezuelan HF), and Old World (including Lassa virus, lymphocytic choriomeningitis virus [LCMV], and Lujo virus) (see Etiology). LCMV is discussed in a separate chapter (p 559). Disease associated with arenaviruses ranges from asymptomatic or mild, acute, febrile infections to severe illnesses in which vascular leak, shock, and multiorgan dysfunction are prominent features. Fever, weakness, malaise, headache, arthralgia, and myalgia are common early symptoms. Patients may develop conjunctival suffusion, cough, retro-orbital pain, facial flushing, anorexia, vomiting, diarrhea, and abdominal pain after 3 to 4 days. Thrombocytopenia, leukopenia, petechiae, generalized lymphadenopathy, and encephalopathy usually are present in Argentine HF, Bolivian HF, and Venezuelan HF, and exudative pharyngitis often occurs in Lassa fever. Mucosal bleeding generally occurs in severe cases as a consequence of vascular damage, coagulopathy, thrombocytopenia, and platelet dysfunction. In Lassa fever, hemorrhagic manifestations occur in only one third

¹ Does not include lymphocytic choriomeningitis virus, which is reviewed on p 559.

of patients. Proteinuria is common; renal failure, although unusual overall, is seen frequently among hospitalized Lassa fever patients. Increased serum concentrations of aspartate aminotransferase (AST) can portend a severe or possibly fatal outcome of Lassa fever. Shock develops 7 to 9 days after onset of illness in more severely ill patients with these infections. Encephalopathic signs, such as tremor, alterations in consciousness, and seizures, can occur in South American HFs and in severe cases of Lassa fever. Transient or permanent deafness is reported in 30% of survivors of Lassa fever. The overall mortality rate in Lassa fever ranges from 1% to 20%, but is highest among hospitalized patients (15%–60%); for South American HFs, the mortality rate is 10% to 35%, and for Lujo virus HF, the mortality rate is 80% (estimated from a small number of patients). Pregnant people are at substantially higher risk of mortality (~80%) and spontaneous abortion, with 95% mortality in fetuses of infected people. Symptoms resolve 10 to 15 days after disease onset in surviving patients.

ETIOLOGY: Mammalian arenaviruses (mammarenaviruses) are enveloped, bisegmented, single-stranded RNA viruses. Old World arenaviruses include LCMV, which causes lymphocytic choriomeningitis, Lassa virus (Lassa HF), and Lujo virus (Lujo HF) in western and southern Africa. New World arenaviruses include Junín virus (Argentine HF), Machupo virus (Bolivian HF), Sabiá virus (Brazilian HF), Guanarito virus (Venezuelan HF), and Chapare virus (Chapare HF). Whitewater Arroyo virus is a rare cause of human disease in North America. Antibodies to Tamiami virus have been detected in people in North America, but clinical disease has not been confirmed. Several other arenaviruses are known only from their rodent reservoirs in the Old and New World.

EPIDEMIOLOGY: Arenaviruses are maintained in nature by association with specific rodent hosts, in which they produce chronic viremia and viruria. The principal routes of infection in humans are inhalation and direct contact of mucous membranes and skin (eg, through cuts, scratches, or abrasions) with urine and salivary secretions from these persistently infected rodents. Ingestion of food contaminated by rodent excrement also may cause disease transmission. All arenaviruses are infectious as aerosols, and human-to-human transmission may occur in community or hospital settings following unprotected contact or through droplets. Excretion of arenaviruses in urine and semen for several weeks after infection has been documented. Arenaviruses causing HF should be considered highly hazardous to people working with any of these viruses in the laboratory. Laboratory-acquired infections have been documented with Lassa, Machupo, Junín, and Sabiá viruses. The geographic distribution and habitats of the specific rodents that serve as reservoir hosts largely determine areas with endemic infection and populations at risk. Before a vaccine became available in Argentina, several hundred cases of Argentine HF occurred annually in agricultural workers and inhabitants of the Argentine pampas. Epidemics of Bolivian HF occurred in small towns between 1962 and 1964; sporadic disease activity in the countryside has continued since then. Venezuelan HF was first identified in 1989 and occurs in rural north-central Venezuela. Lassa fever is endemic in most of western Africa, where rodent hosts live in proximity to humans, causing thousands of infections annually. Lassa fever has been reported in the United States and Western Europe in people who have traveled to western Africa.

The **incubation periods** for these HF range from 6 to 21 days.

DIAGNOSTIC TESTS: Viral nucleic acid can be detected in acute disease by nucleic acid amplification tests (NAATs). Arenaviruses may be isolated from blood of acutely ill patients as well as from various tissues obtained postmortem, but isolation should be attempted only under biosafety level 4 (BSL-4) conditions. Virus antigen is detectable by enzyme immunoassay (EIA) in acute specimens and postmortem tissues. Virus-specific immunoglobulin (Ig) M antibodies, present in the serum during acute stages of illness, can be identified by immunofluorescent antibody or enzyme-linked immunosorbent assays but may be undetectable in rapidly fatal cases. The IgG antibody response is delayed. Diagnosis can be made retrospectively by immunohistochemical staining of formalin-fixed tissues obtained from autopsy.

If a viral HF is suspected, the state/local health department or Centers for Disease Control and Prevention (CDC; Viral Special Pathogens Branch: 404-639-1115) should be contacted to assist with case investigation, diagnosis, treatment, and control measures.

TREATMENT: Although not approved by the US Food and Drug Administration (FDA) for this purpose, intravenous ribavirin has been used as a therapeutic agent, together with supportive care, for treatment of acute Lassa fever infection for more than a quarter of a century. Use of intravenous ribavirin is based primarily on 1 clinical study, conducted about 40 years ago, which showed that ribavirin substantially decreased the mortality rate in patients with severe Lassa fever, particularly those treated early, during the first week of illness. Results of that study, however, have been questioned recently by other investigators. Early supportive care may improve survival.

Transfusion of immune plasma in defined doses of neutralizing antibodies is the standard specific treatment for Argentine HF and reduces mortality to 1% to 2% when administered during the first 8 days from onset of symptoms. Intravenous ribavirin has been used with success to abort a Sabiá laboratory infection and to treat Bolivian HF patients and the only known Lujo virus infection survivor. Ribavirin did not reduce mortality when initiated 8 days or more after onset of Argentine HF symptoms. Whether ribavirin treatment initiated early in the course of the disease has a role in the treatment of Argentine HF remains to be seen. Intravenous ribavirin is available only from the manufacturer through an emergency investigational new drug (eIND) application. Health care providers who need to obtain intravenous ribavirin should contact the FDA (www.fda.gov/drugs/investigational-new-drug-ind-application/physicians-how-request-single-patient-expanded-access-compassionate-use; 24-hour emergency lines: 866-300-4374 or 301-796-8240). Meticulous fluid and electrolyte balance is an important aspect of supportive care in each of the HFs.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, contact and droplet precautions, including careful prevention of needlestick injuries and careful handling of clinical specimens for the duration of illness, are recommended for all HFs caused by arenaviruses. A negative-pressure ventilation room and airborne precautions are recommended for patients with suspected and confirmed infections who are undergoing aerosol-generating procedures. People entering the room should wear personal protective equipment including

respirators and goggles. The CDC infection prevention recommendations for patients under investigation for Ebola virus disease in US hospitals are applicable.¹

CONTROL MEASURES:

Care of Exposed People. No specific measures are warranted for exposed people unless direct contamination with blood, excretions, or secretions from an infected patient has occurred. If such contamination has occurred, recording body temperature twice daily for 21 days is recommended. Reporting of fever or of symptoms of infection is an indication for intravenous ribavirin treatment for Lassa fever, Bolivian HF, or Sabiá or Lujo virus infections. There is no evidence to support ribavirin for postexposure prophylaxis for Lassa fever.

Immunoprophylaxis. A live attenuated Junín vaccine protects against Argentine HF and probably against Bolivian HF. The vaccine is associated with minimal adverse effects in adults; similar findings have been obtained from limited safety studies in children 4 years and older. The vaccine is not licensed in the United States. Various vaccines for Lassa fever are currently in development and undergoing early phase clinical trials in western Africa.

Environmental. In town-based outbreaks of Bolivian HF, rodent control has proven successful. Area rodent control is not practical for control of Argentine HF or Venezuelan HF. Intensive rodent control efforts have decreased the rate of peridomestic Lassa virus infection, but rodents eventually reinvade human dwellings, and infection still occurs in rural settings.

Public Health Reporting. Because of the risk of health care-associated transmission, state health departments and the CDC should be contacted for specific advice about management and diagnosis of suspected cases. Lassa fever and New World arenavirus HFs are reportable in the United States according to guidelines of the US Council of State and Territorial Epidemiologists.

Hemorrhagic Fevers Caused by Bunyaviruses²

CLINICAL MANIFESTATIONS: Bunyaviruses are arthropod- or rodent-borne infections that often result in severe febrile disease with multisystem involvement and may be associated with high rates of morbidity and mortality.

Hemorrhagic fever with renal syndrome (HFRS) is a complex, multiphasic disease characterized by vascular instability and varying degrees of renal insufficiency. Fever, flushing, conjunctival injection, headache, blurred vision, abdominal pain, and lumbar pain are followed by hypotension, oliguria, and subsequently, polyuria. Petechiae are frequent, but more serious bleeding manifestations are rare. Shock and acute renal insufficiency may occur.

Crimean-Congo hemorrhagic fever (CCHF) is a multisystem disease characterized by hepatitis and hemorrhagic manifestations. Fever, headache, and myalgia are followed by signs of a diffuse capillary leak syndrome with facial suffusion,

¹ Centers for Disease Control and Prevention. Infection Prevention and Control Recommendations for Hospitalized Patients Under Investigation (PUIs) for Ebola Virus Disease (EVD) in U.S. Hospitals. Atlanta, GA: Centers for Disease Control and Prevention; 2018. Available at: www.cdc.gov/vhf/ebola/clinicians/evd/infection-control.html

² Does not include hantavirus pulmonary syndrome, which is reviewed on p 409.

conjunctivitis, icteric hepatitis, proteinuria, and disseminated intravascular coagulation associated with petechiae and purpura on the skin and mucous membranes. A hypotensive crisis often occurs after the appearance of frank hemorrhage from the gastrointestinal tract, nose, mouth, or uterus.

Rift Valley fever (RVF), in most cases, is a self-limited undifferentiated febrile illness. In 8% to 10% of cases, however, hemorrhagic fever with shock and icteric hepatitis, encephalitis, or retinitis develops.

ETIOLOGY: The order *Bunyavirales* includes segmented, single-stranded RNA viruses with different geographic distributions depending on their vector or reservoir. Hemorrhagic fever syndromes are associated with viruses from 3 families: *Hantaviridae* (Old World Hantaviruses), *Nairoviridae* (CCHF virus), and *Phenuiviridae* (RVF virus). Old World hantaviruses (Hantaan, Seoul, Dobrava, and Puumala viruses) cause HFRS, and New World hantaviruses (Sin Nombre and related viruses) cause hantavirus pulmonary syndrome (see Hantavirus Pulmonary Syndrome, p 409).

EPIDEMIOLOGY: The epidemiology of these diseases is a function of the distribution and behavior of their reservoirs and vectors. All families except *Hantaviridae* are associated with arthropod vectors. Hantavirus infections are transmitted via contact with virus shed in rodent urine, saliva, or droppings; inhalation of virus in dust from contaminated nesting materials; or being bitten by an infected rodent.

Classic HFRS occurs throughout much of Asia and Europe, with up to 100 000 cases per year. The most severe form of the disease is caused by the prototype Hantaan and Dobrava viruses in rural Asia and Europe, respectively; Puumala virus is associated with milder disease (nephropathia epidemica) in Western Europe. Seoul virus is distributed worldwide in association with brown Norway rat (*Rattus* species) and causes a disease of variable severity. Cases have been reported in the United States among rat fanciers. Person-to-person transmission has never been reported with HFRS. Fatal outcome is seen in 1% to 15% of cases, depending on the species of virus and the level of care.

CCHF occurs in much of sub-Saharan Africa, the Middle East, northwestern China, part of the Indian subcontinent, Ukraine, Russia, Georgia, Armenia, Central Asia, and Southeast Europe. CCHF virus is transmitted by hard ticks and occasionally by contact with viremic livestock and wild animals at slaughter. Health care-associated transmission of CCHF is a serious hazard. Fatal outcome is seen in 9% to 50% of hospitalized patients.

Large outbreaks of RVF have occurred throughout sub-Saharan Africa, Egypt, Saudi Arabia, and Yemen. The virus is mosquito-borne and also can also be transmitted directly from domestic livestock to humans via contact with infected abortuses or freshly slaughtered animal carcasses. Person-to-person transmission has not been reported, but laboratory-acquired cases are well documented. Overall fatal outcome occurs in 1% to 2% of cases but has been reported to be up to 30% in hospitalized patients.

The **incubation periods** for CCHF and RVF range from 2 to 10 days; for HFRS, the **incubation period** usually is longer, ranging from 7 to 42 days.

DIAGNOSTIC TESTS: Acute-phase quantitative nucleic acid amplification tests (NAATs) and serologic testing are the most common diagnostic tests (Table 3.16). Viral culture of blood and/or tissue is available in specialized laboratories. Immunoglobulin

Table 3.16. Diagnostic Tests for Hemorrhagic Fevers Caused by Bunyaviruses

Diagnostic Testing	HFRS	CCHF	RVF
Acute phase virus NAAT	Yes, but not routinely done	Yes	Yes
IgM and IgG serology	Yes (at time of illness onset or within 48 h)	Yes (detectable in early convalescence, but could be absent in fatal cases)	Yes (detectable in early convalescence)
Virus culture of blood or tissue	No (usually not detected at time of illness)	Yes (in biosafety level 4 [BSL-4] conditions)	Yes (in biosafety level 4 [BSL-4] conditions)

CCHF indicates Crimean-Congo hemorrhagic fever; HFRS, hemorrhagic fever with renal syndrome; IgG, immunoglobulin G; IgM, immunoglobulin M; NAAT, nucleic acid amplification testing; RVF, Rift Valley fever.

(Ig) M antibodies or increasing IgG titers in paired serum specimens, as demonstrated by enzyme immunoassay (EIA), are diagnostic; neutralizing antibody tests provide greater virus-strain specificity but rarely are used. Serum IgM and IgG virus-specific antibodies typically develop early in convalescence in CCHF and RVF but can be absent in rapidly fatal cases of CCHF. In HFRS, IgM and IgG antibodies usually are detectable at the time of onset of illness or within 48 hours, when it is too late for virus isolation and NAAT. Diagnosis can be made retrospectively by immunohistochemical staining of formalin-fixed tissues. Although some commercial labs offer hantavirus serologies, any positive IgM results are referred to the Centers for Disease Control and Prevention (CDC) for confirmation. CCHF and RVF testing are only available at the CDC. Referrals are made through the state health department.

TREATMENT: Currently, there are no drugs approved by the US Food and Drug Administration (FDA) for prophylaxis or treatment of HFRS, CCHF, or RVF. Ribavirin, administered intravenously to patients with HFRS within the first 4 days of illness, may be effective in decreasing renal dysfunction, vascular instability, and mortality. Intravenous ribavirin is not available commercially in the United States and is available only from the manufacturer through an emergency investigational new drug (eIND) application. Health care providers who need to obtain intravenous ribavirin should contact the FDA (www.fda.gov/drugs/investigational-new-drug-ind-application/physicians-how-request-single-patient-expanded-access-compassionate-use; 24-hour emergency lines: 866-300-4374 or 301-796-8240). Supportive therapy for HFRS should include: (1) treatment of shock; (2) monitoring of fluid balance; (3) dialysis for complications of renal failure; (4) control of hypertension during the oliguric phase; and (5) early recognition of possible myocardial failure with appropriate therapy.

Oral and intravenous ribavirin, when administered early in the course of CCHF, have been associated with milder disease, although no controlled studies have been performed. Ribavirin also may be efficacious as postexposure prophylaxis of CCHF.

During the RVF outbreak in Saudi Arabia in 2000, a clinical trial of ribavirin in patients with confirmed disease was halted because of an increased observation

of encephalitis in patients receiving ribavirin (more than expected in RVF patients). Experimental data in hamster, mice, and rats reported the same type of observation when treatment was delayed. Therefore, ribavirin should be avoided in RVE.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, contact and droplet precautions, including careful prevention of needlestick injuries and management of clinical specimens, are indicated for patients with CCHF for the duration of illness. Airborne isolation may be required in certain circumstances when patients undergo procedures that stimulate coughing and promote generation of aerosols. Standard precautions should be followed with RVF and HFRS.

CONTROL MEASURES:

Care of Exposed People. People having direct contact with blood or other secretions from patients with CCHF should be observed closely for 14 days with daily monitoring for fever. Immediate therapy with intravenous ribavirin should be considered at the first sign of disease. Ribavirin also may be efficacious as postexposure prophylaxis of CCHF.

Environmental.

Hemorrhagic Fever With Renal Syndrome. Monitoring of laboratory rat colonies, community pet rat colonies, and urban rodent control may be effective for rat-borne HFRS.

Crimean-Congo Hemorrhagic Fever. In countries with endemic CCHF, arachnicides for tick control generally have limited benefit but should be used in stockyard settings. Personal protective measures (eg, physical tick removal and protective clothing with permethrin sprays) may be effective for people at-risk (farmers, veterinarians, abattoir workers). See Prevention of Mosquito-borne and Tick-borne Infections, p 207.

Rift Valley Fever. Regular immunization of domestic animals should have an effect on limiting or preventing RVF outbreaks and protecting humans. Some livestock vaccines are currently in use in endemic areas. Personal protective clothing (with permethrin sprays) and insect repellants may be effective for people at risk (farmers, veterinarians, abattoir workers). Mosquito control measures are difficult to implement. See Prevention of Mosquito-borne and Tick-borne Infections, p 207.

Immunoprophylaxis. No vaccines currently are approved in Europe or the United States for use in humans against HF caused by Bunyaviruses. Non-live vaccines are in use for HFRS and CCHF in some Asian countries and Eastern Europe, respectively.

Public Health Reporting. State health departments and the CDC should be contacted about any suspected diagnosis of viral hemorrhagic fever because of the risk of health care-associated transmission and diagnostic confusion with other hemorrhagic illnesses.

Hemorrhagic Fevers Caused by Filoviruses: Ebola and Marburg

CLINICAL MANIFESTATIONS: More is known about Ebola virus disease (EVD) than Marburg virus disease, although the same principles generally apply to the 2 filoviruses known to cause human disease. Historically, the overall incidence of EVD infections is lower in children compared with adults, but pediatric mortality is high, with the

youngest children having the highest case fatality rates. Symptomatic disease ranges from mild to severe; case fatality rates for severely affected people range from 25% to 90%. Rarely, household contacts (particularly adolescents) of cases with Ebola virus disease may contract asymptomatic infections. After a mean incubation period of 6 to 10 days (range, 2–21 days), disease in children and adults begins with nonspecific signs and symptoms including fever, severe headache, myalgia, arthralgia, fatigue, abdominal pain, and weakness followed a few days later by nausea, vomiting, dysphagia, and diarrhea. Unexplained bleeding or bruising may occur late in the course of illness in a minority of children, whereas hemorrhage occurs in up to 50% of adults. The most common hemorrhagic manifestations consist of bleeding from the gastrointestinal tract, sometimes with oozing from the mucous membranes or venipuncture sites. Data from the 2014–2016 Ebola outbreak in West Africa, the largest since the virus was identified in 1976, indicate that children may have shorter incubation periods than adults and 20% of infected children have no fever at presentation. Respiratory symptoms are more common and central nervous system manifestations less common in children than in adults. A transient erythematous maculopapular rash may be seen on the torso or face after approximately 4 to 5 days of illness. Hiccups and conjunctival injection or subconjunctival hemorrhage also may occur. Leukopenia, frequently with lymphopenia, is followed later by elevated neutrophils, a left shift, and thrombocytopenia. Hepatic dysfunction and myositis commonly lead to elevations in aspartate aminotransferase (AST) and alanine aminotransferase (ALT). Metabolic derangements, including hypokalemia, hyponatremia, hypocalcemia, and hypomagnesemia, are common. In the most severe cases, disseminated intravascular coagulation, increased vascular permeability, and circulatory instability ensue around the end of the first week of disease.

Central nervous system manifestations and renal failure are frequent in end-stage disease. In fatal cases, death typically occurs 7 to 10 days after symptom onset, usually resulting from viral- or bacterial-induced septic shock and multiorgan failure. Factors associated with pediatric Ebola deaths in the 2014–2016 outbreak were age <5 years, bleeding at any time during hospitalization, and high Ebola viral load.

Approximately 30% of pregnant people with EVD present with spontaneous abortion and vaginal bleeding. Mortality in pregnant people approaches 90% when infection occurs during the third trimester. Ebola virus can cross the placenta, and pregnant people infected with the virus will likely transmit the virus to the fetus. In infants whose birthing parent is infected, Ebola virus RNA has been detected in amniotic fluid, fetal meconium, umbilical cord, and buccal swab specimens. There has been only 1 report of survival of a neonate whose birthing parent had active EVD. The neonate was treated with monoclonal antibodies, a buffy coat transfusion from an Ebola survivor, and the antiviral drug remdesivir shortly after birth. The exact mechanism of neonatal death is unknown, but high viral loads of Ebola virus have been documented in amniotic fluid, placental tissue, and fetal tissues of stillborn neonates.

In September 2022, Sudan ebolavirus caused an outbreak in Uganda with 25% of confirmed cases in children younger than 10 years and a high overall mortality rate.

EVD survivors are at risk for post-Ebola syndrome, which consists of persistent musculoskeletal, neurologic, ocular, and other symptoms, as well as reactivation of disease in immune-privileged sites, such as the eye, testicles, or the central nervous system. Disease reactivation is believed to be a rare event. EVD relapse and long-term

shedding of virus in semen have been implicated in the origin of several clusters of EVD in West Africa.

ETIOLOGY: Filoviruses (from the Latin *filo* meaning thread, referring to their filamentous shape) are single-stranded, negative-sense RNA viruses. There are 6 genera in the family *Filoviridae*, but only 2, *Marburgvirus* and *Ebolavirus*, cause disease in humans, including 4 of the 6 viruses within the genus *Ebolavirus* and both known viruses within the genus *Marburgvirus*. These filoviruses are zoonotic pathogens endemic only in Africa.

EPIDEMIOLOGY: Fruit bats are believed to be the animal reservoir for most filoviruses. Human infection is believed to occur from inadvertent exposure to infected bat excreta or saliva following entry into roosting areas in caves, mines, and forests. Nonhuman primates, especially gorillas and chimpanzees, and other wild animals (eg, rodents, small antelopes) may become infected from bat contact and serve as amplifying hosts that transmit filoviruses to humans through contact with their blood and bodily fluids, usually associated with hunting and butchering (see Control Measures, Environmental).

Molecular epidemiologic evidence shows that most outbreaks result from a single point introduction (or very few) into humans from wild animals, followed by human-to-human transmission, almost invariably fueled by health care-associated transmission in areas with inadequate infection-control equipment and resources. Filoviruses are the most transmissible of all hemorrhagic fever viruses. The secondary attack rate in households is generally between 10% to 20% in African communities. Risk to household contacts is associated with direct physical contact, with little to no transmission observed otherwise. Human-to-human transmission usually occurs through oral, mucous membrane, or nonintact skin exposure to blood or bodily fluids of a symptomatic person with filovirus disease or by exposure to objects contaminated with infected blood or bodily fluids, most often in the context of providing care to a sick family or community member (community transmission) or patient (health care-associated transmission). Funeral rituals that involve the touching of the corpse also have been implicated. Sexual transmission has been documented and implicated in several clusters of disease. Ebola virus has been detected in human milk; genomic analysis of Ebola viruses from infants with fatal Ebola virus disease strongly suggests virus transmission through human milk (see Control Measures, Pregnancy and Breastfeeding). Respiratory spread of virus does not occur. Infection through fomites rarely may occur. Health care-associated transmission is highly unlikely if rigorous infection-control practices are in place in health care facilities (see Infection Prevention and Control Measures in Health Care Settings). Filoviruses are not spread through the air, by water, or in general by food (with the exception of bushmeat; see Control Measures, Environmental).

Children may be less likely to become infected from intrafamilial spread than adults when a primary case occurs in a household, possibly because they are not typically primary caregivers of sick individuals and are less likely to take part in funeral rituals that involve touching and washing of the deceased person's body. Underreporting of Ebola cases in children to health officials also is possible.

The degree of viremia correlates with the clinical state. People are most infectious late in the course of severe disease, especially when copious vomiting, diarrhea,

and/or bleeding are present. Disease transmission does not occur during the incubation period, when the person is asymptomatic. Virus may persist in a few sites for several weeks to months after clinical recovery, including in testicles/semen, where it has been detected years after clinical recovery; vaginal fluid; placenta; amniotic fluid; human milk; saliva; the central nervous system (particularly cerebrospinal fluid); joints; conjunctivae; and the chambers of the eye (resulting in transient uveitis and other ocular problems). Because of the proven risk of transmission attributable to persistent virus in semen, abstinence or use of condoms is recommended for at least 12 months after infection or until the semen has tested negative on 2 separate occasions. Immunocompromising disorders, such as HIV infection, also may result in viral persistence. Guidance for the management of survivors of EVD can be found at www.cdc.gov/vhf/ebola/clinicians/evaluating-patients/guidance-for-management-of-survivors-ebola.html.

Updated information on identification, current management of people traveling from areas of transmission or with contact with a person with Ebola virus infection, and communicating with children about Ebola can be found on the Centers for Disease Control and Prevention (CDC) website (www.cdc.gov/vhf/ebola/ and www.cdc.gov/vhf/ebola/pdf/how-talk-children-about-ebola.pdf) and the American Academy of Pediatrics (AAP) website (www.healthychildren.org/English/health-issues/conditions/infections/Pages/Ebola.aspx).

The **incubation period** for Ebola virus disease is typically 6 to 10 days (range, 2–21 days).

DIAGNOSTIC TESTS: The diagnosis of filovirus infection should be considered in a person who develops a fever within 21 days of travel to an area with endemic infection or a current outbreak. Because initial clinical manifestations are difficult to distinguish from those of more common febrile diseases, prompt laboratory testing is imperative in a suspected case. Malaria, measles, typhoid fever, Lassa fever, dengue, hepatitis A, influenza, and COVID-19 should be included in the differential diagnosis of a symptomatic person returning from Africa within 21 days and are much more likely than a filovirus to be the cause of fever. Filovirus disease can be diagnosed by testing of blood with a nucleic acid amplification test (NAAT), enzyme-linked immunosorbent assay (ELISA) for viral antigens or immunoglobulin (Ig) M, and virus isolation early in the disease course, with the latter being attempted only under biosafety level 4 (BSL-4) conditions. Viral RNA generally is detectable by NAAT 3 days after onset of symptoms. If blood is obtained within 3 days of symptom onset, 2 negative NAAT results at least 48 hours apart are required to rule out disease. IgM and IgG antibodies may be used later in the disease course or after recovery. Postmortem diagnosis can be made via immunohistochemical staining of skin or liver or spleen tissue. Testing generally is not performed routinely in clinical laboratories. Local and state public health department officials must be contacted and can facilitate testing at a regional certified laboratory or at the CDC. Current information on the most appropriate diagnostic testing for EVD is available on the CDC website (www.cdc.gov/vhf/ebola/diagnosis/index.html).

In October 2019, the US Food and Drug Administration (FDA) authorized marketing of the OraQuick Ebola Rapid Antigen Test under the De Novo premarket review pathway. This test is a rapid diagnostic test (RDT) for detecting Ebola virus in both symptomatic patients and recently deceased people and is the first Ebola RDT

available through FDA authorization in the United States. The RDT should be used only in cases in which more sensitive molecular testing is not available. All OraQuick Ebola Rapid Antigen Test results are presumptive; all test results (positive and negative) must be verified through a NAAT at a Laboratory Response Network (LRN) laboratory located in 49 states and at the CDC.

TREATMENT: People suspected of having filovirus infection should be placed in strict isolation immediately, and public health officials should be notified. Early initiation of management in patients with filovirus disease is important for improving outcomes. Patient care is primarily supportive, including oral or intravenous fluids with electrolyte repletion, vasopressors, blood products, oxygen, nutritional support, antiemetics, analgesics, antipyretics, antimalarial and antimicrobial medications when coinfections are suspected or confirmed, and psychological support (www.cdc.gov/vhf/ebola/treatment/index.html). Volume losses can be enormous (10 L/day in adults), and some centers in the United States report better results with repletion using lactated Ringer solution rather than normal saline solution in management of adult patients. When antimicrobial agents are used to treat sepsis, the medications should have coverage for intestinal microbiota based on limited evidence of translocation of gut bacteria into the blood of patients with filovirus disease. Use of needles and aerosol-generating procedures should be limited as much as possible.

On October 14, 2020, the FDA approved the first treatment for Zaire ebolavirus infection in adult and pediatric patients. Under the brand name Inmazeb, it consists of a mixture of 3 monoclonal antibodies: atoltivimab, maftivimab, and odesivimab-cbgn (www.accessdata.fda.gov/drugsatfda_docs/label/2020/761169s0001b1.pdf). On December 21, 2020, a second monoclonal antibody therapy, ansuvimab-zykl, which goes by the brand name Ebanga, received FDA approval, also for use in adult and pediatric patients (www.accessdata.fda.gov/drugsatfda_docs/label/2020/761172s0001b1.pdf). There currently are no specific therapies approved by the FDA for other filovirus infections, including those caused by Sudan ebolavirus and Marburg virus. Because therapeutic options are likely to change following results from numerous ongoing clinical trials, it would be appropriate to consult with the CDC to determine the most current treatment guidelines (www.cdc.gov/vhf/ebola/treatment/index.html).

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard, contact, and droplet precautions are recommended for management of hospitalized patients with known or suspected EVD. Although it is prudent to place the patient in a negative-pressure room as an extra precaution, availability of such a resource should not prevent care, because there is no evidence for natural aerosol transmission between humans. A negative-pressure room should be used when aerosol-generating procedures are conducted, such as intubation or airway suctioning. Access to the patient should be limited to a small number of designated staff and family members with specific instructions and training on filovirus infection control and on the use of personal protective equipment (PPE). Although experience suggests that standard universal and contact precautions usually are protective, viral hemorrhagic fever precautions consisting of at least 2 pairs of gloves, fit-tested N95 (or higher) or particulate respirator, impermeable or fluid-resistant gown, face shield over N95 or higher respirator or powered air purifying respirator (PAPR) with face shield, protective apron, and

shoe covers or rubber boots are recommended when filovirus infection is confirmed or suspected. Health care workers should have no skin exposed, and a buddy system should be used for supervision of donning and doffing PPE. All health care workers should be knowledgeable with and proficient in donning and doffing PPE before participating in management of a patient, as detailed on the CDC website (www.cdc.gov/vhf/ebola/healthcare-us/ppe/guidance.html). Particulate respirators are recommended when aerosol-generating procedures, such as endotracheal intubation, are performed. The duration of precautions should be determined in consultation with state and federal public health authorities.

The AAP has published a clinical report¹ that provides guidance to health care providers and hospitals on options to consider regarding parental presence at the bedside while caring for a child with suspected or proven EVD or other highly consequential infections.

CONTROL MEASURES:

Contact Tracing. Monitoring and movement of people with potential Ebola virus exposure currently is based on the degree of possible risk. At a minimum, asymptomatic people with any level of risk should self-monitor for fever and other symptoms of Ebola for 21 days. The individual should notify the public health authority immediately if fever or other symptoms develop. A full description of recommended management for people with consistent signs or symptoms and risk factors for EVD including neonates who are at risk can be found on the following CDC websites: www.cdc.gov/vhf/ebola/clinicians/evaluating-patients/index.html and www.cdc.gov/vhf/ebola/clinicians/evd/neonatal-care.html. Hospitalization of asymptomatic contacts is not warranted, but contacts who develop fever or other manifestations of filovirus disease should be isolated immediately until the diagnosis can be ruled out.

Ebola Vaccine. On December 19, 2019, the FDA approved the world's first Ebola vaccine, ERVEBO, for the prevention of EVD following conditional marketing approval from the European Medicines Agency (EMA) and prequalification by the World Health Organization. This live attenuated recombinant vesicular stomatitis virus platform-based (rVSV-ZEBOV-GP) vaccine has been used under an expanded access protocol in the 2018–2020 outbreak in the Democratic Republic of Congo in a ring vaccination trial of first responders, health care workers, burial providers, and close contacts of cases. The CDC Advisory Committee on Immunization Practices recommends its use for preexposure vaccination of adults 18 years or older in the United States who are at potential risk of exposure to Ebola virus (species Zaire ebolavirus) as a result of responding to an outbreak of Ebola virus disease, working as health care personnel at federal or state designated Ebola treatment centers in the United States, or working as laboratorians or other staff at biosafety level 4 facilities.² A number of experimental vaccines and passively transferred immunoglobulins have been shown to be efficacious in nonhuman primate models when administered before or after exposure.

¹ American Academy of Pediatrics, Committee on Infectious Diseases. Parental presence during treatment of Ebola or other highly consequential infection. *Pediatrics*. 2016;138(3):e20161891

² Choi MJ, Cossaboom CM, Whitesell AN, et al. Use of Ebola vaccine: recommendations of the Advisory Committee on Immunization Practices, United States, 2020. *MMWR Recomm Rep*. 2021;70(RR-1):1–12. DOI: <https://dx.doi.org/10.15585/mmwr.rr7001a1>

Currently there are no FDA-approved vaccines for Sudan ebolavirus, but several candidate vaccines have been developed and efforts are in place to test them.

Pregnancy and Breastfeeding. Limited human data from clinical trials with Ebola vaccines have not identified vaccine-associated risks during pregnancy. The decision regarding whether to vaccinate a pregnant person should consider the risk for exposure to Ebola virus. Live virus has been cultured from human milk up to 15 days after disease onset, and at least 2 fatal cases associated with breastfeeding have been reported. Given what is known about transmission of Ebola virus, regardless of breastfeeding status, infants whose lactating parent is acutely infected with Ebola virus already are at high risk of acquiring Ebola virus infection through close contact with the parent and are at high risk of death overall. Therefore, lactating parents with probable or confirmed Ebola virus infection should not have close contact with their infants and should substitute breastfeeding with an acceptable and safe alternative unless none is available (see Breastfeeding and Human Milk, p 135). Viral RNA has been detected in human milk for up to 16 months after illness onset but there is not enough evidence to provide guidance on when it is safe to resume breastfeeding after a parent's recovery. If feasible, milk should be tested for Ebola virus before resuming breastfeeding.

Travelers. Nonessential travel to areas where Ebola outbreaks are occurring is not recommended. Travelers to an area affected by an Ebola outbreak should practice careful hygiene (eg, wash hands with soap and water or a 9:1 water to bleach solution, use an alcohol-based hand sanitizer, and avoid contact with blood and body fluids). Travelers should not handle items that may have come in contact with an infected person's blood or body fluids, such as clothes, bedding, needles, and medical equipment. Funeral or burial rituals that require handling the body of someone who has died from Ebola should be avoided. Travelers should avoid hospitals where Ebola patients are being treated in areas of Africa with endemic disease; the US Embassy or consulate often is able to provide advice on facilities that should be avoided. Following return to the United States, travelers should monitor their health closely for 21 days and seek medical care immediately if they develop symptoms of Ebola (see Control Measures, Environmental). State laws mandating confinement or quarantine may apply. Current travel information for countries affected by Ebola can be found on the CDC website (www.cdc.gov/vhf/ebola/travelers/index.html).

Environmental. Avoiding contact with bats, primarily by avoiding entry into caves and mines in areas with endemic disease, is a key preventive measure for filoviruses. People also should avoid exposure to blood, bodily fluids, or meat of wild animals (bushmeat), especially nonhuman primates but also bats, porcupines, duikers (a type of antelope), and other mammals, in areas with endemic filovirus disease. In health care settings, detailed guidance for infection control is available at www.cdc.gov/vhf/ebola/clinicians/cleaning/hospitals.html. Disinfectants with a label claim for a non-enveloped virus should be used.

Public Health Reporting. Because of the risk of health care-associated transmission, state/local health departments and the CDC should be contacted immediately for specific advice about confirmation and management of suspected cases. In the United States, Ebola and Marburg hemorrhagic fevers are reportable by guidelines of the Council of State and Territorial Epidemiologists. If a filoviral hemorrhagic fever is suspected,

the state/local health department or CDC Emergency Operations Center (telephone: 770-488-7100) should be contacted to assist with case investigation, diagnosis, management, and control measures.

Hepatitis A

CLINICAL MANIFESTATIONS: Hepatitis A is an acute, self-limited illness associated with fever, malaise, jaundice, anorexia, and nausea that typically lasts less than 2 months, although 10% to 15% of symptomatic people have prolonged or relapsing disease that lasts as long as 6 months. Symptomatic hepatitis A virus (HAV) infection occurs in approximately 30% of infected children younger than 6 years of age, but few of these children will have jaundice. Among older children and adults, infection usually is symptomatic, with jaundice occurring in 70% or more of cases. Fulminant hepatitis is rare but is more common in people with underlying liver disease. Chronic infection does not occur.

ETIOLOGY: HAV is a small, nonenveloped, positive-sense RNA virus with an icosahedral capsid and classified as a member of the family *Picornaviridae*, genus *Hepatovirus*.

EPIDEMIOLOGY: The most common mode of transmission is person-to-person, from fecal contamination and oral ingestion (ie, the fecal-oral route). In resource-limited countries where infection is endemic, most people are infected during the first decade of life. In the United States, rates of HAV infection decreased by 95% from 1996 to 2011 following implementation of universal infant vaccination in 2006. Since 2016, however, the United States has been in the midst of a widespread surge of person-to-person hepatitis A outbreaks unprecedented since introduction of the hepatitis A vaccine (HepA). Outbreaks, primarily among people who use drugs and people lacking housing, have occurred in 37 states; higher rates have been observed in impoverished counties. An estimated 37 700 infections occurred in 2019, a more than tenfold increase since 2015. The number of estimated cases decreased to 19 900 in 2020, possibly because of underreporting during the COVID-19 pandemic. Most HAV infection cases in the United States now are in adults 20 years and older.

Recognized risk groups for HAV infection include people who have close personal contact with a person infected with HAV, people with chronic liver disease, people with human immunodeficiency virus (HIV) infection, men who have sex with men, people who use injection or noninjection drugs, people who lack housing, people traveling to or working in countries that have highly or intermediately endemic HAV, people who have close contact with an adoptee from a country with high or intermediate HAV endemicity during the first 60 days following arrival, and people who work with HAV-infected primates or with HAV in a research laboratory setting. HAV infections and outbreaks associated with food-service establishments and food handlers, health care institutions, institutions for people with developmental disabilities, schools, and child care facilities typically reflect transmission in the community.

Outbreaks have been associated with consumption of raw produce (eg, green onions), fruits (eg, strawberries), oysters, and mussels. Waterborne outbreaks are rare and typically are associated with sewage-contaminated or inadequately treated water.

People with HAV infection are most infectious during the 1 to 2 weeks before onset of jaundice or elevation of liver enzymes, when concentration of virus in the stool is

highest. Risk of transmission subsequently diminishes and is minimal by 1 week after onset of jaundice. HAV can be detected in stool for longer periods, especially in neonates and young children.

The **incubation period** is 15 to 50 days, with an average of 28 days.

DIAGNOSTIC TESTS: Serologic tests for HAV-specific total antibody (ie, immunoglobulin [Ig] G plus IgM), IgG-only anti-HAV, and IgM-only anti-HAV are available commercially, primarily in enzyme immunoassay format. Presence of serum IgM anti-HAV indicates current or recent infection, although false-positive results may occur, particularly if the pretest probability of infection is low. IgM anti-HAV is included in most acute hepatitis serologic test panels offered by hospital or reference laboratories. IgM anti-HAV is detectable in up to 20% of HepA vaccine recipients when measured 2 weeks after vaccination. In infected people, serum IgM anti-HAV becomes detectable 5 to 10 days before onset of symptoms and usually declines to undetectable concentrations within 6 months after infection, although positive test results for IgM anti-HAV more than 1 year after infection have been reported. IgG anti-HAV is detectable shortly after appearance of IgM. A positive IgG anti-HAV or total anti-HAV (IgM and IgG) test result with a negative IgM anti-HAV test result indicates immunity from past infection or vaccination. Nucleic acid amplification tests (NAATs) for hepatitis A are available but not currently licensed by the US Food and Drug Administration (FDA). NAAT may be considered for detection of very early infections and to assist with interpretation of questionable IgM anti-HAV results.

TREATMENT: Supportive and management of complications.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Contact precautions should be practiced in addition to standard precautions for diapered and incontinent patients for at least 1 week after onset of symptoms.

CONTROL MEASURES¹:

General Measures. The major methods of prevention of HAV infections are improved sanitation (eg, in food preparation and of water sources) and personal hygiene (eg, hand hygiene after toilet use and diaper changes). HepA vaccine or immune globulin (IG) is effective in preventing infection when administered within 14 days of exposure (see Table 3.17).

Schools, Child Care, and Work. Children and adults with acute HAV infection who work as food handlers or attend or work in child care settings should be excluded for 1 week after onset of the illness (see Table 2.3, p 149).

Hepatitis A Vaccine. Two non-live single-antigen HepA vaccines, Havrix and Vaqta, are available in the United States. The vaccines are prepared from cell culture-adapted HAV, which is propagated in human fibroblasts, purified from cell lysates, formalin inactivated, and adsorbed to an aluminum hydroxide adjuvant. Vaqta contains no preservative. The hepatitis A and hepatitis B combination vaccine (HepA-HepB), Twinrix, can also be used for people 18 years and older.

Administration, Dosages, and Schedules (see Table 3.18). Both single-antigen HepA vaccines are licensed for people 12 months and older and have pediatric and adult

¹ Nelson NP, Weng MK, Hofmeister MG, et al. Prevention of hepatitis A virus infection in the United States: recommendations of the Advisory Committee on Immunization Practices, 2020. *MMWR Recomm Rep*. 2020;69(RR-5):1-38

Table 3.17. Recommendations for Postexposure Prophylaxis of Hepatitis A Virus (HAV)

Time Since Exposure	Age	Recommended
≤2 wk	<12 mo	IGIM (0.1mL/kg) ^a
	12 mo–40 y	HepA vaccine ^{b,c,d}
	>40 y	HepA vaccine ^{c,d} ; consider IGIM
>2 wk	<12 mo	No prophylaxis
	≥12 mo	No prophylaxis, but HepA vaccine may be indicated for ongoing exposure

IGIM indicates immune globulin intramuscular; HepA indicates hepatitis A vaccine.
^aMeasles, mumps, and rubella vaccine (MMR) should not be administered for at least 6 months after receipt of IGIM.
^bPeople with immunocompromising conditions or chronic liver disease should also receive IGIM.
^cAlthough 1 dose of HepA vaccine is needed for postexposure prophylaxis, the 2-dose series should be completed according to the recommended schedule.
^dPeople with severe allergy to HepA vaccine or its components should receive IGIM (0.1 mL/kg) but not HepA vaccine.

formulations that are administered in a 2-dose schedule. Pediatric formulations are available for ages 12 months through 18 years, and adult formulations are available for people 19 years and older. HepA-HepB vaccine can be used for people 18 years and older and can be administered in a standard 3-dose schedule or an accelerated 3-dose schedule plus a booster dose 12 months later. HepA and HepA-HepB vaccines are administered intramuscularly. Recommended doses and schedules for these vaccines are listed in Table 3.18.

Immunogenicity. HepA vaccines are highly immunogenic. At least 95% of healthy children, adolescents, and adults have protective antibody concentrations when measured 1 month after receipt of the first dose. One month after a second dose, more than 99% of healthy children, adolescents, and adults have protective antibody concentrations.

Antibody concentrations are lower in infants with transplacentally acquired anti-HAV in comparison with vaccine recipients lacking anti-HAV. Transplacentally acquired anti-HAV antibody is not detectable in most infants by 12 months of age. HepA vaccine is highly immunogenic for children who begin immunization at 12 months or older, regardless of anti-HAV status of the birthing parent.

Efficacy. In double-blind, controlled, randomized trials, the protective efficacy in preventing clinical HAV infection was 94% to 100%.

Duration of Protection. Detectable antibody persists for at least 25 years after completion of a 2-dose series of HepA vaccine. Kinetic models of antibody decline indicate that protective levels of anti-HAV could be present for at least up to 50 years. Booster doses beyond the 2-dose primary immunization series are not recommended.

Vaccine in Immunocompromised People. Because HepA vaccine is non-live, no special precautions need to be taken when vaccinating immunocompromised people. The immune response in immunocompromised people, including people with HIV infection, may be suboptimal based on the level of immunosuppression at the time of vaccine administration.

Table 3.18. Recommended Doses and Schedules for Non-Live Hepatitis A Virus Vaccines

Age	Vaccine	Hepatitis A Antigen Dose	Volume per Dose, mL	No. of Doses	Schedule
6–11 mo, traveling to area with endemic hepatitis A ^a	Havrix or Vaqta	720 ELU/25 U	0.5	1	One dose for infants traveling to areas with endemic hepatitis A; this dose does not count toward completing the immunization requirement; 2 doses needed at the routine schedule after 12 mo of age
12 mo–18 y	Havrix	720 ELU	0.5	2	Initial and 6–12 mo later
12 mo–18 y	Vaqta	25 U	0.5	2	Initial and 6–18 mo later
≥19 y	Havrix	1440 ELU	1.0	2	Initial and 6–12 mo later
≥19 y	Vaqta	50 U	1.0	2	Initial and 6–18 mo later
≥18 y	Twinrix ^b	720 ELU	1.0	3 or 4	3-dose series: Initial, 1 mo, and 6 mo 4-dose series: Initial, 7 days, 21–30 days, and 12 mo

ELU indicates enzyme-linked immunosorbent assay units.

^aNelson NP, Link-Gelles R, Hofmeister MG, et al. Update: Recommendations of the Advisory Committee on Immunization Practices for use of hepatitis A vaccine for postexposure and for preexposure prophylaxis for international travel. *MMWR Morb Mortl Wkly Rep*. 2018;67(43):1216–1220.

^bA combination of hepatitis B (Engerix-B, 20 µg) and hepatitis A (Havrix, 720 ELU) vaccine (Twinrix) is licensed for use in people age ≥18 years in 3-dose and 4-dose schedules. For pre- and postexposure hepatitis A prophylaxis, the use of single-antigen hepatitis A vaccine (ie, Havrix or Vaqta) is recommended.

Vaccine Interchangeability. The 2 single-antigen HepA vaccines have similar effectiveness when administered as recommended. Completion of the immunization regimen with the same product is preferable, although interchangeability of products is acceptable if the same product is not available. Studies among adults have found no difference in the immunogenicity of a vaccine series consisting of both compared with using the same vaccine throughout the licensed schedule.

Administration With Other Vaccines. HepA vaccine may be administered concurrently with other vaccines. Vaccines should be administered in a separate syringe and at a separate injection site (see Simultaneous Administration of Multiple Vaccines, p 63).

Adverse Events. No serious adverse events attributed definitively to HepA vaccine have been reported. Adverse reactions are mild and include local pain and, less commonly, induration at the injection site. The vaccine can be administered either in the thigh or the arm; the site of injection does not affect the incidence of local reactions.

Precautions and Contraindications to Immunization. The vaccine should not be administered to people with hypersensitivity to any of the vaccine components. A retrospective cohort study published in 2019 of Vaccine Safety Datalink (VSD) data from 2004 through 2015 did not identify any concerning pattern of adverse events in pregnant people or their infants following hepatitis A immunizations during pregnancy. Risk to the fetus is considered to be low or nonexistent because the vaccine contains inactivated, purified virus particles. Hepatitis A vaccination is recommended during pregnancy for people at risk for HAV infection.

Preimmunization Serologic Testing. Preimmunization testing for anti-HAV generally is not recommended for children (see Table 1.19, p 122). Testing may be cost-effective for people who have a high likelihood of hepatitis A immunity from previous infection, including people whose childhood was in a country with high endemicity and people with a history of jaundice potentially caused by HAV.

Postimmunization Serologic Testing. Postimmunization testing for anti-HAV generally is not indicated because of the high seroconversion rates in adults and children. Some commercially available anti-HAV tests may not detect low but protective concentrations of antibody among immunized people.

Immune Globulin. Postexposure prophylaxis (PEP) with immune globulin intramuscular (IGIM), when administered within 2 weeks after exposure to HAV, is more than 85% effective in preventing symptomatic infection. When administered as preexposure prophylaxis (PrEP), a dose of 0.1 mL/kg confers protection against hepatitis A for up to 1 month, and a dose of 0.2 mL/kg protects for up to 2 months. Recommended PrEP and PEP IGIM doses and duration of protection are provided in Tables 3.19 and 3.17, respectively.

PREVENTION MEASURES:

PrEP Against HAV Infection (see Tables 3.19, p 435, and 3.18, p 433). HepA vaccine is recommended routinely for children age 12 through 23 months of age and children and adolescents age 2 to 18 years of age who have not received HepA vaccine previously. HepA vaccine is recommended for people 18 years or older who are at increased risk of infection or severe disease and during outbreaks. The routine childhood immunization schedule (<https://publications.aap.org/redbook/pages/Immunization-Schedules>) and Table 3.18 (p 433) include HepA-containing vaccines licensed by the FDA, their doses, and schedules.

People at Increased Risk of HAV Infection or its Consequences Who Should Be Immunized.

- **People with chronic liver disease.** Susceptible people with chronic liver disease (including, but not limited to, those with hepatitis C virus [HCV] and/or hepatitis B virus [HBV] infection, cirrhosis, fatty liver disease, alcoholic liver disease, autoimmune hepatitis, or an alanine aminotransferase [ALT] or aspartate aminotransferase [AST] concentrations greater than twice the upper limit of normal) and people who are unvaccinated and awaiting or have received liver transplants should be immunized.
- **People who use drugs.** The United States has been experiencing widespread person-to-person hepatitis A outbreaks since 2016, primarily affecting people who use drugs and people lacking housing. All people who use injection or noninjection drugs should be immunized against HAV.

Table 3.19. Recommendations for Preexposure Prophylaxis of Hepatitis A Virus (HAV) for Travelers to Countries With High or Intermediate Endemic Rates of Hepatitis A^a

Age	Recommended	Notes
<6 mo	IGIM ^b	For travel lasting up to 1 mo, 0.1 mL/kg; up to 2 mo, 0.2 mL/kg (repeat 0.2 mL/kg every 2 mo thereafter if risk remains). ^c
6–11 mo	HepA vaccine	This dose does not count toward the routine 2-dose series. Start the hepatitis A vaccination series at age 12 mo.
12 mo–40 y	HepA vaccine	Those with immunocompromising conditions, chronic liver disease, or other chronic medical conditions may also receive IGIM. ^{b,d}
>40 y	HepA vaccine, consider IGIM	If departure is within 2 wk, may also receive IGIM ^d ; those with immunocompromising conditions, or chronic liver disease may also receive IGIM.

HepA indicates hepatitis A vaccine; IGIM indicates immune globulin intramuscular.

^aPeople age 12 months or older should receive HepA vaccine routinely; those who have a severe allergy to HepA or its components should receive IGIM.

^bMeasles, mumps, and rubella vaccine (MMR) should not be administered for at least 6 months after receipt of IGIM (see Table 1.11, p 69).

^cNelson NP, Link-Gelles R, Hofmeister MG, et al. Update: Recommendations of the Advisory Committee on Immunization Practices for use of hepatitis A vaccine for postexposure and for preexposure prophylaxis for international travel. *MMWR Morb Mortal Wkly Rep.* 2018;67(43):1216–1220.

^dHepA vaccine and IGIM should be administered at the same time at different limbs.

- **People experiencing homelessness.** People 1 year or older experiencing homelessness should be immunized.
- **People who travel to or work in countries that have high or intermediate endemic hepatitis A** (parts of Africa and Asia, Central and South America, and Eastern Europe) should be protected against HAV infection before departure (see Table 3.19) as follows:
 - ♦ Infants age 6 through 11 months should receive a dose of HepA vaccine. This travel-related dose does not count toward the routine 2-dose series that should begin at age 12 months. HepA vaccine does not interfere with response to measles, mumps, and rubella vaccine (MMR), which is also recommended for international travelers 6 months or older.
 - ♦ Healthy people 12 months through 40 years of age should receive a dose of HepA as soon as travel is considered and complete the 2-dose series according to the routine schedule.
 - ♦ Infants younger than 6 months and travelers for whom vaccine is contraindicated or who choose not to receive vaccine should receive IGIM before travel when protection against HAV is recommended. For travel duration up to 1 month, 1 dose of IGIM at 0.1 mL/kg is recommended; for travel up to 2 months, 1 dose of IGIM at 0.2 mL/kg is recommended, and for travel of ≥ 2 months, a 0.2-mL/kg dose of IG

should be repeated every 2 months for the duration of travel or until HepA vaccine is administered (ie, for infants at age ≥ 6 months) (see Table 3.19).

- ♦ People older than 40 years, people with immunocompromising conditions, and people with chronic liver disease should receive a single dose of HepA vaccine as soon as travel is considered. People traveling in < 2 weeks should receive the initial dose of HepA vaccine and simultaneously may receive IGIM in a different anatomic injection site. The HepA vaccine series should be completed according to the routine schedule.
- **Close contacts of newly arriving international adoptees.**^{1,2} Data from a study conducted at 3 adoption clinics in the United States indicate that 1% to 6% of newly arrived international adoptees have acute HAV infection. Risk of HAV infection among close personal contacts of international adoptees is estimated at 106 (range, 90–819) per 100 000 household contacts of international adoptees within the first 60 days of their arrival in the United States. HepA vaccine should be administered to all unvaccinated people who anticipate close personal contact (eg, household contact or regular babysitting) with a child adopted internationally from a country with high or intermediate endemic rates of hepatitis A during the first 60 days following arrival of the child in the United States. The first dose of the 2-dose HepA vaccine series should be administered as soon as adoption is planned, ideally 2 or more weeks before the arrival of the child.
- **Men who have sex with men.** Cyclic outbreaks of hepatitis A among men who have sex with men have been reported often, including in urban areas in the United States, Canada, and Australia. Therefore, men (adolescents and adults) who have sex with men should be immunized. Preimmunization serologic testing may be cost-effective for older people in this group.
- **People at risk of occupational exposure (eg, handle nonhuman primates infected with HAV or work with HAV in a research laboratory).** Outbreaks of HAV infection have been reported among people who work with nonhuman primates infected with HAV. People working with HAV-infected nonhuman primates or HAV in a research laboratory should receive HepA vaccine.

Postexposure Prophylaxis (PEP) (see Table 3.17, p 432). Use of HepA vaccine for PEP provides several advantages compared with IGIM, including induction of active immunity, much longer duration of protection, ease of administration, and greater acceptability and availability. IGIM (0.1 mL/kg) should be used for people who cannot receive HepA vaccine because they are too young or have a severe allergy to the vaccine or its components. Situations in which HepA vaccine and/or IGIM can be considered include the following:

- In general, **healthy people age 12 months and older** who previously have not received HepA vaccine and have been exposed to HAV should receive a dose of single-antigen HepA vaccine as soon as possible within 14 days of exposure (see Table 3.17, p 432, for prophylaxis guidance and dosages). The 2-dose series should be completed according to the recommended schedule.

¹ Centers for Disease Control and Prevention. Updated recommendations from the Advisory Committee on Immunization Practices (ACIP) for use of hepatitis A vaccine in close contacts of newly arriving international adoptees. *MMWR Morb Mortal Wkly Rep*. 2009;58(36):1006–1007

² American Academy of Pediatrics, Committee on Infectious Diseases. Recommendations for administering hepatitis A vaccine to contacts of international adoptees. *Pediatrics*. 2011;128(4):803–804

- In addition to HepA vaccine, IGIM (0.1 mL/kg) may be administered to **people 40 years or older**, depending on the provider's risk assessment.
- **People who are immunocompromised or have chronic liver disease** should receive a dose of HepA and IGIM (0.1 mL/kg) at different limbs at the same time and complete the 2-dose HepA series according to the recommended schedule. Efficacy of HepA vaccine or IGIM for PEP when administered more than 2 weeks after exposure has not been established.
- **Newborn infants born to HAV-infected people** may receive IGIM (0.1 mL/kg) if the birthing parent's HAV infection symptoms began between 2 weeks before and 1 week after delivery. Efficacy in this circumstance has not been established.
- Hepatitis outbreaks in **child care centers** now are rare following widespread adoption of universal childhood immunization. In facilities with diapered children, if 1 or more cases confirmed in child or staff attendees or 2 or more cases in households of staff or attendees, hepatitis A vaccine (HepA) or immune globulin intramuscular (IGIM), depending on age, should be administered within 14 days of exposure to all unimmunized staff and attendees. In centers without diapered children, HepA or IGIM should be administered only to unimmunized classroom contacts to an index case with hepatitis A (see Table 2.3, p 149).
- In **school and non-health care work settings**, HAV exposure generally does not pose a risk of infection. If multiple cases occur among children at a school, a common source of infection should be investigated. PEP is not indicated when a single case occurs in a school and the source of infection is outside the school or work setting.
- **Hospitals and other health care settings.** Health care-associated transmission of HAV is uncommon when recommended infection control practices are followed. PEP within the health care setting may be considered on a case-by-case basis depending on risk of transmission. Health care workers do not have increased prevalence of HAV infection.
- **Common-source food exposure and food handlers.** Food handlers are not at increased risk for hepatitis A infection based on their occupation. Most food handlers with HAV infection do not transmit HAV to others, but PEP can be considered based on risk of transmission.

Hepatitis B

CLINICAL MANIFESTATIONS: People acutely infected with hepatitis B virus (HBV) may be asymptomatic or symptomatic. The likelihood of developing symptoms increases with age: less than 1% of infants younger than 1 year, 5% to 15% of children 1 through 5 years, and 30% to 50% of people 6 through 30 years of age are symptomatic. Few data are available for adults older than 30 years. Acute HBV infection cannot be distinguished from other forms of acute viral hepatitis on the basis of clinical signs and symptoms or nonspecific laboratory findings. The spectrum of signs and symptoms varies and includes subacute illness with nonspecific symptoms (eg, anorexia, nausea, or malaise), clinical hepatitis with jaundice, or fulminant hepatitis. Extrahepatic manifestations associated with circulating immune complexes that have been reported in HBV-infected children include arthralgias, arthritis, polyarteritis nodosa, thrombocytopenia, and glomerulonephritis. Gianotti-Crosti syndrome

(papular acrodermatitis), urticaria, macular rash, or purpuric lesions may be seen in acute HBV infection.

Chronic HBV infection is defined as persistence in serum for at least 6 months of any one of the following: hepatitis B surface antigen (HBsAg), HBV DNA, or hepatitis B envelope antigen (HBeAg). Chronic HBV infection is likely in the presence of HBsAg, HBV DNA, or HBeAg in serum from a person who tests negative for immunoglobulin (Ig) M antibody to hepatitis B core antigen (IgM anti-HBc).

Age at the time of infection is the primary determinant of risk of progressing to chronic infection. Up to 90% of infants infected perinatally or in the first year of life will develop chronic HBV infection. Between 25% and 50% of children infected between 1 and 5 years of age become chronically infected, whereas 5% to 10% of infected older children and adults develop chronic HBV infection. Patients who become infected with HBV while immunosuppressed or with an underlying chronic illness (eg, end-stage renal disease) have an increased risk of developing chronic infection. Without treatment, up to 25% of infants and children who acquire chronic HBV infection will die prematurely from HBV-related hepatocellular carcinoma (HCC) or cirrhosis.

The clinical course of untreated chronic HBV infection varies according to the population studied, reflecting differences in age at acquisition, rate of loss of HBeAg, and possibly HBV genotype. Most children have asymptomatic infection. For years to decades after initial infection, perinatally infected children are in an “immune tolerant” phase with normal or minimally elevated alanine aminotransferase (ALT) concentrations, minimal or mild liver histologic abnormalities, detectable HBeAg, and high HBV DNA concentrations ($\geq 20\,000$ IU/mL). Some children with chronic HBV infection may exhibit growth impairment. Chronic HBV infection acquired during later childhood or adolescence usually is accompanied by more active liver disease and increased serum aminotransferase concentrations. Patients with detectable HBeAg (*HBeAg-positive chronic hepatitis B*) usually have high concentrations of HBV DNA and HBsAg in serum and are more likely to transmit infection. Over time (years to decades), HBeAg becomes undetectable in many chronically infected people. This transition often is accompanied by development of antibody to HBeAg (anti-HBe) and decreases in serum HBV DNA and serum aminotransferase concentrations and may be preceded by a temporary exacerbation of liver disease. These patients have *inactive chronic infection* but still may experience episodes of reactivation, manifested by increases in serum HBV DNA and aminotransferase concentrations. This may occur spontaneously or when these patients become immunosuppressed, receive anti-tumor necrosis factor agents or disease-modifying anti-rheumatic drugs, or have chronic hepatitis C virus (HCV) infection being treated with direct acting antiviral agents.

Because HBV-associated liver injury is believed to be immune-mediated, in people coinfectd with human immunodeficiency virus (HIV) and HBV, the return of immune competence with antiretroviral treatment of HIV infection may lead to a reactivation of HBV-related liver inflammation and damage.

Some patients who lose HBeAg may continue to have ongoing histologic evidence of liver damage and moderate to high concentrations of HBV DNA (*HBeAg-negative chronic hepatitis B*). Patients with histologic evidence of chronic HBV infection, regardless of HBeAg status, remain at higher risk of death attributable to liver failure compared with HBV-infected people with no histologic evidence of liver inflammation

and fibrosis. Chronically infected adults clear HBsAg without treatment at the rate of approximately 1% annually; for chronically infected children, however, the annual clearance rate is less than 1%.

ETIOLOGY: HBV has a partially double-stranded DNA genome contained within a 42-nm-diameter enveloped virion and belongs in the family *Hepadnaviridae*. Important components of the viral particle include an outer lipoprotein envelope containing HBsAg, an inner nucleocapsid consisting of hepatitis B core antigen (HBcAg), and the viral polymerase attached to the viral genome.

EPIDEMIOLOGY: HBV is transmitted through infected blood or body fluids. Although HBsAg has been detected in multiple body fluids including human milk, saliva, and tears, the most potentially infectious fluids include blood, serum, semen, vaginal secretions, and cerebrospinal, synovial, pleural, pericardial, peritoneal, and amniotic fluids. People with chronic HBV infection are the primary reservoirs for infection. Common modes of transmission include perinatal exposure to an infected birthing parent; percutaneous and permucosal exposure to infectious body fluids; sharing or using non-sterilized needles, syringes, or glucose monitoring equipment or devices; sexual contact with an infected person; and household exposure to a person with chronic HBV infection. Risks of HBV acquisition when a susceptible child bites a child who has chronic HBV infection or when a susceptible child is bitten by a child with chronic HBV infection are unknown (see Bite Wounds, p 202, and Table 2.9, p 203). A theoretical risk exists if HBsAg-positive blood enters the oral cavity of the biter, but transmission by this route has not been reported. Transmission by transfusion of contaminated blood or blood products is rare in the United States because of routine screening of blood donors and viral inactivation of certain blood products before administration.

Perinatal transmission of HBV is highly efficient and usually occurs from blood exposures during labor and delivery. In utero transmission accounts for less than 2% of all vertically transmitted HBV infections in most studies. Without postexposure prophylaxis, the risk of an infant acquiring HBV from an infected mother as a result of perinatal exposure is 70% to 90% for infants whose birthing parent is HBsAg and HBeAg positive; the risk is 5% to 20% for infants whose birthing parent is HBsAg positive but HBeAg negative. Infants whose birthing parent has very high HBV DNA levels ($>200\,000$ IU/mL) are at high risk of breakthrough infection despite receipt of postexposure prophylaxis with antibody and vaccine at birth.

Prevalence of HBV infection and patterns of transmission vary markedly throughout the world (see Fig 3.2). Approximately 80% of people worldwide live in regions of intermediate to high HBV endemicity, defined as prevalence of chronic HBV infection of 2% or greater. Historically, most new HBV infections occurred as a result of perinatal or early childhood infections in regions of high HBV endemicity, defined as prevalence of HBV infection of 8% or greater. Infant immunization programs in some of these countries have reduced seroprevalence of HBsAg greatly, but many countries with endemic HBV have yet to implement widespread routine birth-dose and/or childhood hepatitis B immunization programs. In regions of intermediate HBV prevalence (2% to 7%), multiple modes of transmission occur (eg, perinatal, household, sexual, injection drug use, and health care associated). In countries with low prevalence ($<2\%$) and where routine immunization has been adopted, new infections occur most often in age groups where routine immunization is not conducted.

FIG 3.2. MAP OF HEPATITIS B PREVALENCE GLOBALLY

Reproduced from <https://wwwnc.cdc.gov/travel/yellowbook/2024/infections-diseases/hepatitis-b>. Data source: 2021 estimates of hepatitis B virus disease burden. CDA Foundation Polaris Observatory. Available from: <https://cdafound.org/polaris-countries-distribution/>.

In regions of the world with high prevalence of chronic HBV infection, transmission between children in household settings may account for a substantial amount of transmission. Precise mechanisms of transmission from child-to-child are unknown, but frequent interpersonal contact of nonintact skin or mucous membranes with blood-containing secretions, open skin lesions, or blood-containing saliva are potential means of transmission. Transmission from sharing inanimate objects, such as razors or toothbrushes, also may occur. HBV can survive in the environment for 7 or more days but is inactivated by commonly used disinfectants, including household bleach diluted 1:10 with water. HBV is not transmitted by the fecal-oral route.

The **incubation period** for acute HBV infection is 45 to 160 days, with an average of 90 days.

DIAGNOSTIC TESTS: Serologic protein antigen tests are available commercially to detect HBsAg and HBeAg. Serologic antibody assays also are available for detection of anti-HBs, total anti-HBc, IgM anti-HBc, and anti-HBe (see Table 3.20, Fig 3.3, and Fig 3.4). Most laboratories now use nucleic acid amplification tests (NAATs) for analysis of HBV DNA, with very high sensitivity at low levels and broad dynamic range for quantitation.

HBsAg is detectable during acute and chronic infection. If HBV infection is self-limited, HBsAg disappears in most patients within a few weeks to several months after infection, followed by appearance of anti-HBs. The time between disappearance of HBsAg and appearance of anti-HBs is termed the *window period* of infection. During the window period, the only marker of acute infection is IgM anti-HBc. IgM anti-HBc usually is not present in infants infected perinatally. People with chronic HBV infection have circulating HBsAg and circulating total anti-HBc (Fig 3.4); in a minority of chronically infected individuals, anti-HBs also is present. Both anti-HBs and total

Table 3.20. Diagnostic Tests for Hepatitis B Virus (HBV) Antigens, Antibodies, and DNA

Factors To Be Tested	HBV Antigen or Antibody	Use
HBsAg	Hepatitis B surface antigen	Detection of acutely or chronically infected people; antigen used in hepatitis B vaccine; rarely can be detected for up to 3 weeks after a dose of hepatitis B vaccine
Anti-HBs	Antibody to HBsAg	Identification of people who have resolved infections with HBV; determination of immunity after immunization
HBeAg	Hepatitis B envelope antigen	Identification of infected people with high serum HBV DNA concentrations at increased risk of transmitting HBV
Anti-HBe	Antibody to HBeAg	Identification of infected people with low to moderate serum HBV DNA concentrations at lower risk of transmitting HBV
Anti-HBc (total)	IgM + IgG antibody to HBcAg ^a	Identification of people with acute, resolved, or chronic HBV infection (not present after immunization); transplacentally acquired anti-HBc is detectable for as long as 24 months among infants born to HBsAg-positive birthing parent
IgM anti-HBc	IgM antibody to HBcAg ^a	Identification of people with acute or recent HBV infections (including HBsAg-negative people during the “window” phase of infection; unreliable for detecting perinatal HBV infection)
HBV DNA	N/A	Inform use of antiviral therapy, including in pregnant people (to decrease risk of perinatal transmission)

HBcAg indicates hepatitis B core antigen; IgM, immunoglobulin M.

^aNo test is available commercially to measure HBcAg or isolated IgG antibody to HBcAg (without also measuring IgM antibody to HBcAg, as total anti-HBc does).

anti-HBc are present in people with resolved infection, whereas anti-HBs alone is present in people immunized with hepatitis B (HepB) vaccine. The presence of HBeAg in serum correlates with higher concentrations of HBV DNA and greater infectivity. Tests for HBeAg and HBV DNA are necessary in selection of candidates to receive antiviral therapy and to monitor response to therapy.

Transient presence of HBsAg can occur following receipt of HepB vaccine, with (vaccine-derived) HBsAg being detected as early as 24 hours after and up to 3 weeks following administration of the vaccine.

TREATMENT: No therapy for uncomplicated *acute* HBV infection is recommended. Treatment with a nucleoside or nucleotide analogue is indicated if there is concern for

FIG 3.3. TYPICAL SEROLOGIC COURSE OF ACUTE HEPATITIS B VIRUS INFECTION WITH RECOVERY

anti-HBc indicates antibody to hepatitis B core antigen; anti-HBe, antibody to hepatitis B e antigen; anti-HBs, antibody to hepatitis B surface antigen; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; IgM, immunoglobulin M.

From Connors EE, Panagiotakopoulos L, Hofmeister MG, et al. Screening and testing for hepatitis B virus infection: CDC recommendations – United States, 2023. *MMWR Recomm Rep.* 2023;72(RR-1):1-25. Available at: <https://dx.doi.org/10.15585/mmwr.rr7201a1>

severe infection with acute liver failure. Acute HBV infection may be difficult to distinguish from reactivation of HBV. If reactivation is a possibility, referral to a hepatitis specialist would be warranted. Hepatitis B immune globulin (HBIG) and corticosteroids are not effective treatment for acute or chronic disease.

The goal of treatment in chronic HBV infection is to prevent progression to cirrhosis, hepatic failure, and hepatocellular carcinoma, with antibody to HBeAg (anti-HBe) seroconversion, normalization of serum aminotransferase, and suppression of detectable serum HBV DNA concentrations as surrogate endpoints. Current indications for treatment of chronic HBV infection include evidence of ongoing HBV viral replication, as indicated by the presence for longer than 6 months of either serum HBV DNA greater than 20 000 IU/mL with HBeAg or greater than 2000 IU/mL without HBeAg, AND elevated serum ALT concentrations for longer than 6 months or evidence of chronic hepatitis on liver biopsy. Children without necroinflammatory liver disease and children in the immunotolerant phase (ie, normal ALT concentrations despite presence of HBV DNA) do not warrant antiviral therapy. Treatment response is measured by biochemical, serologic, virologic, and histologic response. The American Association for the Study of Liver Diseases and the Centers for Disease Control and Prevention (CDC) recommend that pregnant people with viral

loads >200 000 IU/mL be offered antiviral therapy to prevent transmission to their newborn.^{1,2}

The US Food and Drug Administration (FDA) has approved 3 nucleoside analogues (entecavir, lamivudine, and telbivudine), 3 nucleotide analogues (tenofovir disoproxil fumarate, tenofovir alafenamide fumarate, and adefovir), and 2 interferon-alfa drugs (interferon alfa-2b and pegylated interferon alfa-2a) for treatment of chronic HBV infection in adults. All are available in the United States except telbivudine, which has been discontinued. An important consideration in choice of treatment is to avoid selection of antiviral resistance mutations. Entecavir, tenofovir disoproxil fumarate, tenofovir alafenamide fumarate, and pegylated interferon alfa-2a are preferred in adults as first-line therapy because of lower likelihood of developing antiviral resistance mutations over long-term therapy. FDA licensure in the pediatric population

¹ Terrault NA, Lok ASF, McMahon BJ, et al. Update on prevention, diagnosis, and treatment of chronic hepatitis B: AASLD 2018 hepatitis B guidance. *Hepatology.* 2018;67(4):1560-1599

² Schillie S, Vellozzi C, Reingold A, et al. Prevention of hepatitis B Virus Infection in the United States: recommendations of the Advisory Committee on Immunization Practices. *MMWR Recomm Rep.* 2018;67(RR-1):1-31

is as follows: interferon alfa-2b, ≥ 1 year of age; entecavir, ≥ 2 years of age; tenofovir disoproxil fumarate, ≥ 2 years of age; and telbivudine, ≥ 16 years of age, although this drug is no longer available in the United States (see Non-HIV Antiviral Drugs, p 1044). Pegylated interferon alfa-2a is not approved for treatment of children with chronic hepatitis B but is approved for children ≥ 5 years of age to treat chronic hepatitis C virus infection. Developments in antiviral therapies of HBV and updated practice guidelines may be found on the American Association for the Study of Liver Diseases website (www.aasld.org/practice-guidelines/chronic-hepatitis-b). Specific therapy guidelines for children coinfectd with HIV and HBV can be accessed online (<https://clinicalinfo.hiv.gov/en/guidelines>).

Consultation with health care professionals with expertise in treating chronic hepatitis B in children is recommended.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are indicated for patients with acute or chronic HBV infection. For infants whose birthing parent is HBsAg positive, no special care in addition to standard precautions, as described under Control Measures, is needed, other than removal of birthing parent's blood by a gloved attendant.

CONTROL MEASURES:

Hepatitis B Immune Globulin.¹ HBIG provides short-term protection (3–6 months) and is indicated in specific postexposure circumstances (see Care of Exposed People [Postexposure Immunoprophylaxis], p 455). HBIG is prepared from the plasma of donors with high concentrations of anti-HBs, with an anti-HBs titer of at least 1:100 000 by radioimmunoassay. Standard immune globulin is not effective for postexposure prophylaxis against HBV infection, because concentrations of anti-HBs are too low.

Hepatitis B Vaccine. HepB vaccine is used for preexposure and postexposure prophylaxis and provides long-term protection. Preexposure immunization with HepB vaccine is the most effective means to prevent HBV infections. Highly effective and safe HepB vaccines produced by recombinant DNA technology are licensed in the United States in non-live single-antigen formulations and as components of combination vaccines. Recombinant vaccines contain 5 to 40 μg of HBsAg protein/mL, and a completed vaccine series results in production of anti-HBs of at least 10 mIU/mL in most people, which provides long-term protection for immunocompetent recipients. Single-dose formulations, including all pediatric formulations, contain no thimerosal as a preservative. Although the concentration of recombinant HBsAg protein differs among vaccine products, rates of seroprotection are equivalent when administered to immunocompetent infants, children, adolescents, or young adults in the doses recommended (see Table 3.21). A 2-dose single-antigen hepatitis B vaccine with a novel adjuvant (HepB-CpG [Heplisav-B]) and a 3-dose, 3-antigen vaccine (S, pre-S2, and pre-S1 [PreHevbrio]) are available for people 18 years and older.

High seroconversion rates and protective concentrations of anti-HBs (10 mIU/mL or greater) are achieved when HepB vaccine is administered in any of

¹ Dosages recommended for postexposure prophylaxis are for products licensed in the United States. Because concentration of anti-HBs in other products may vary, different dosages may be recommended in other countries.

Table 3.21. Recommended Dosages of Hepatitis B Vaccines

Patients	Single-Dose Vaccines ^a			Multiple-Antigen Vaccines ^e	Combination Vaccines		
	RecombivaxHB ^b Dose, µg (mL)	Engerix-B ^c Dose, µg (mL)	Heplisav-B ^d Dose, µg (mL)		Pediarix ^f Dose, µg/mL	Twinrix Dose, µg (mL) ^g	Vaxelis ^h Dose, µg (mL)

HBsAg, hepatitis B surface antigen.

^aRecombivax and Engerix-B vaccines are administered in a 3-dose schedule at 0, 1, and 6 months; 4 doses may be administered if a combination vaccine is used (at 2, 4, and 6 months) to complete the series. Only single-antigen hepatitis B vaccine can be used for the birth dose. Single-antigen or combination vaccine containing hepatitis B vaccine may be used to complete the series. See text for management of infants whose birthing parent is HBsAg positive or HBsAg unknown.

^bAvailable from Merck & Co Inc. A 2-dose schedule, administered at 0 months and then 4 to 6 months later, is licensed for adolescents 11 through 15 years of age using the adult formulation of Recombivax HB (10 µg).

Table 3.21. Recommended Dosages of Hepatitis B Vaccines, continued

- ^cAvailable from GlaxoSmithKline Biologicals. The US Food and Drug Administration also has licensed this vaccine for use in an optional 4-dose (0.5-mL/dose for ages birth through 10 years and 1.0 mL/dose for ages 11-19 years) schedule at 0, 1, 2, and 12 months for all age groups. A 0-, 12-, and 24-month schedule is licensed for children 5 through 10 years of age at a 0.5-mL dose and for children 11 through 16 years of age at a 1.0-mL dose for whom an extended administration schedule is appropriate on the basis of risk of exposure.
- ^dAvailable from Dynavax Technologies Corporation. A 2-dose schedule administered at 0 and 1 month for use in people ≥18 years of age; safety and effectiveness of Heplisav-B have not been established in adults on hemodialysis.
- ^eAvailable from VBI Vaccines Inc. A 3-dose schedule administered at 0, 1, and 6 months for use in people ≥18 years of age; safety and effectiveness of PreHevbrio have not been established in adults on hemodialysis.
- ^fCombination of diphtheria and tetanus toxoids and acellular pertussis (DTaP), inactivated (non-live) poliovirus (IPV), and hepatitis B (Engerix-B 10 µg) is approved for use at 2, 4, and 6 months of age (Pediarix [GlaxoSmithKline]). This vaccine should not be administered at birth, before 6 weeks of age, or at 7 years of age or older. For additional information, see Pertussis (p 656).
- ^gA combination of hepatitis B (Engerix-B, 20 µg) and hepatitis A (Havrix, 720 enzyme-linked immunosorbent assay units [ELU]) vaccine; Twinrix is licensed for use in people 18 years of age and older in a 3-dose schedule at 0, 1, and 6 months. Alternately, a 4-dose schedule at days 0, 7, and 21 to 30, followed by a booster dose at 12 months, may be used.
- ^hCombination of DTaP, IPV, *Haemophilus influenzae* type b conjugate, and hepatitis B recombinant vaccines approved for use at 2, 4, and 6 months of age to be used from 6 weeks of age through age 4. Not to be used for the birth dose or for children 5 years and older.
- ⁱSpecial formulation for adult dialysis patients administered at 0, 1, and 6 months.
- ^jWhen administered to these populations, follow-up serologic testing is recommended 1–2 months after completion of 2-dose series.
- ^kTwo 1-mL doses administered in 1 or 2 injections in a 4-dose schedule at 0, 1, 2, and 6 months of age.

the recommended schedules, including schedules begun soon after birth in term infants (see Table 3.21). Only single-antigen HepB vaccine can be used for doses administered between birth and 6 weeks of age. Single-antigen or combination vaccine may be used to complete the series; 4 doses of vaccine may be administered if a birth dose is administered and a combination vaccine containing a hepatitis B component is used to complete the series. For minimum scheduling times between vaccine doses for infants, see Minimum Ages and Minimum Intervals Between Vaccine Doses (p 61).

Recommended schedules for routine and catch-up hepatitis B immunization are available annually from the CDC and American Academy of Pediatrics (www.cdc.gov/vaccines/schedules/index.html and <https://publications.aap.org/redbook/pages/Immunization-Schedules>). Alternate administration schedules are available and licensed by the FDA (see Table 3.21, p 445). These alternate dosage and administration schedules result in equivalent immunogenicity and can be used when acceptable on the basis of low risk of exposure and to facilitate adherence.

HepB vaccine can be administered concurrently with other vaccines (see Simultaneous Administration of Multiple Vaccines, p 63).

Vaccine Interchangeability. In general, the various brands of age-appropriate HepB vaccines are interchangeable within an immunization series. Vaccination should not be deferred when the manufacturer of the previously administered vaccine is unknown or when the vaccine from the same manufacturer is unavailable. Adolescent patients who start their hepatitis B schedule with the adult formulation of Recombivax HB are not candidates to complete their series with the adult formulation of Engerix-B. Similarly, people 18 years or older who start their hepatitis B series with Heplisav-B should complete it with the same product. Of note, data are limited on safety and immunogenicity when PreHevbrio is interchanged with HepB vaccines from other manufacturers.

Routes of Administration. Vaccine is administered intramuscularly in the anterolateral thigh for infants or deltoid area for children and adults (see Vaccine Administration, p 52). Administration in the buttocks or by the intradermal route is not recommended at any age.

Efficacy and Duration of Protection. HepB vaccines licensed in the United States have a 90% to 95% efficacy for preventing HBV infection and clinical HBV disease among susceptible children and adults. Immunocompetent people who achieve anti-HBs concentration ≥ 10 mIU/mL after preexposure vaccination have virtually complete protection against infection with HBV. Long-term studies of immunocompetent adults and children indicate that immune memory remains intact for at least 3 decades and protects against symptomatic acute and chronic HBV infection, even though anti-HBs concentrations may become low or undetectable over time.

Booster Doses. Routine booster doses of HepB vaccine are not recommended for children and adults with normal immune status. For patients undergoing hemodialysis who are at continued risk of infection, immunity should be assessed by annual anti-HBs testing, and a booster dose should be administered when the anti-HBs concentration is <10 mIU/mL. Annual anti-HBs testing and booster doses when anti-HBs concentrations decrease to <10 mIU/mL should be considered for immunocompromised people (eg, people with HIV, hematopoietic cell transplant recipients, and people receiving chemotherapy) if they have an ongoing risk for HBV exposure. Similar

consideration may be given to children with cystic fibrosis, liver disease, or celiac disease if there is an ongoing risk for HBV exposure. Children with HIV and celiac disease may not respond as well to HepB vaccine.

Adverse Events. Adverse effects reported in adults and children are pain at the injection site, fever, reported more commonly in children than adults, and fatigue, reported more commonly in adults. Anaphylaxis is uncommon, occurring in less than 1 in 1.3 million recipients. Large, controlled epidemiologic studies and review by the National Academy of Medicine¹ (NAM [see Understanding Vaccine Evaluation and Safety as an Approach to Addressing Parental Concerns, p 27]) found no evidence of an association between HepB vaccine and sudden infant death syndrome, type 1 diabetes mellitus, seizures, encephalitis, or autoimmune (eg, vasculitis) or demyelinating disease, including multiple sclerosis.

Immunization During Pregnancy or Lactation. No adverse effect on the developing fetus has been observed after immunization during pregnancy. Pregnancy and lactation are not contraindications to immunization. Data are not available to assess the safety of Heplisav-B or PreHevbrio during pregnancy, during breastfeeding, or on milk production and excretion. Thus, providers should vaccinate pregnant people needing HepB vaccination with Engerix-B, Recombivax HB, or Twinrix.

Serologic Testing.² Susceptibility testing before immunization is not indicated routinely for children or adolescents (Table 1.19, p 122). Screening with a triple panel (HBsAg, anti-HBs, and total anti-HBc) is recommended for all adults 18 years and older at least once in their lifetime. People at increased risk for hepatitis B infection, regardless of age, and anyone who requests HBV testing also should be screened. Testing of pregnant individuals for hepatitis B infection is recommended during each pregnancy (see Serologic Screening of Pregnant People, below). Infants whose birthing parent is HBsAg positive should have postvaccination serologic testing for HBsAg and anti-HBs at 9 to 12 months of age. Anti-HBs testing of health care personnel and others at increased or ongoing risk of hepatitis B exposure (see Booster Doses, p 447, and Postimmunization Testing for Anti-HBs, p 455) may be performed to document presence of protective antibody.

Preexposure Universal Immunization. Immunization with HepB vaccine is recommended for all infants, children, adolescents, and adults through 59 years of age (www.cdc.gov/vaccines/schedules/hcp/imz/catchup.html, <https://publications.aap.org/redbook/pages/Immunization-Schedules>, and www.cdc.gov/mmwr/volumes/71/wr/mm7113a1.htm). Age-specific vaccine dosages are provided in Table 3.21 (p 445).

Newborn Immunization, Including Management Based on HBsAg Status of the Birthing Parent

Serologic Screening of Pregnant People.² Testing of all pregnant individuals is recommended to identify newborn infants who require immediate postexposure prophylaxis. Testing with HBsAg is recommended during each pregnancy, regardless of vaccination status or history of testing; a triple panel (HBsAg, anti-HBs, and total

¹ Institute of Medicine. *Adverse Effects of Vaccines: Evidence and Causality*. Washington, DC: National Academies Press; 2011

² Connors EE, Panagiotakopoulos L, Hofmeister MG, et al. Screening and testing for hepatitis B virus infection: CDC recommendations – United States, 2023. *MMWR Recomm Rep*. 2023;72(RR-1):1-25

anti-HBc) may be offered to those who have not had this performed previously. All pregnant individuals should be tested during an early prenatal visit and testing should be repeated at the time of admission to the hospital for delivery for HBsAg-negative people who are at high risk of HBV infection or who have had clinical hepatitis. Individuals who are HBsAg positive also should be tested for hepatitis B virus deoxyribonucleic acid (HBV DNA) and referred to appropriate specialists to assess need for treatment and to ensure follow-up of their infants and immunization of sexual and household contacts.

Birth Dose of Hepatitis B Vaccine and Use of HBIG.¹ The strategy for preventing hepatitis B in newborn infants, based on birth weight and birthing parent's HBsAg status, involves providing a birth dose of hepatitis B vaccine to all infants and, for some infants, HBIG. Starting vaccination at birth for all infants serves as a safety net in case a birthing parent's HBsAg-positive status was not identified at birth, such as if results were not obtained, were misinterpreted, were falsely negative, were transcribed or reported to the infant care team inaccurately, or were not communicated to the nursery. The strategy acknowledges and accounts for risk factors that may not have been reported and high-risk birthing parents who may not have been retested around the time of delivery.

HepB vaccine should be administered to all infants born to HBsAg-negative birth parents within 24 hours of birth for infants with birth weight ≥ 2000 g, and at hospital discharge or 1 month of age (whichever is first) for infants with birth weight < 2000 g. HepB vaccine plus HBIG should be administered within 12 hours of birth to all newborn infants whose birthing parent is HBsAg positive. Appropriate management at birth of these infants and those whose birthing parent's HBsAg status is unknown is described below and in Fig 3.5.

Subsequent Immunization of Newborns Whose Birthing Parent is HBsAg Negative and Those Whose HBsAg Was Unknown at Birth But is Subsequently Confirmed as Negative (Tables 3.21, p 445, and 3.22, p 451). Infants whose birthing parent is HBsAg negative and those whose birthing parent's initial HBsAg status was unknown but subsequently is confirmed as negative should complete hepatitis B immunization according to routine immunization schedules with either single-antigen (at ages 1–2 months and 6–18 months) or combination hepatitis B-containing (ages 2, 4, and 6 months) vaccine. Minimum intervals of 4 weeks (28 days) should occur between doses 1 and 2, and 8 weeks between doses 2 and 3, with a minimum of 16 weeks between doses 1 and 3; when 4 doses are administered, substitute “dose 4” for “dose 3” in these calculations (www.cdc.gov/vaccines/schedules/hcp/imz/child-adolescent.html and <https://publications.aap.org/redbook/pages/Immunization-Schedules>). Infants whose birthing parent's HBsAg is unknown and remains unknown are managed as infants whose birthing parent is HBsAg positive (see below).

Management of Infants Born to HBsAg-Positive People. All infants born to HBsAg-positive people, including infants weighing less than 2000 g, should receive the initial dose of HepB vaccine within 12 hours of birth (see Table 3.22, p 451, for appropriate dosages), and HBIG (0.5 mL) should be administered concurrently but at different

¹ American Academy of Pediatrics, Committee on Infectious Diseases. Elimination of perinatal hepatitis B: providing the first vaccine dose within 24 hours of birth. *Pediatrics*. 2017;140(3):e20171870

FIG 3.5. ADMINISTRATION OF BIRTH DOSE OF HEPATITIS B VACCINE BY BIRTH WEIGHT AND HBsAg STATUS OF BIRTHING PARENT

Modified from American Academy of Pediatrics, Committee on Infectious Diseases, Committee on Fetus and Newborn. Elimination of perinatal hepatitis b: providing the first vaccine dose within 24 hours of birth. *Pediatrics*. 2017;140(3):e20171870

*For newborn infants with birth weight <2000 g, this dose will not count toward total doses in series.

anatomic sites (eg, different extremities) (Fig 3.5). Infants whose birthing parent has other evidence suggestive of HBV infection (eg, presence of HBV DNA, HBeAg positive, or known to be chronically infected with HBV) should be managed this way as well. Effectiveness of HBIG diminishes the longer after exposure it is initiated. The interval of effectiveness is unlikely to exceed 7 days. Subsequent doses of vaccine should be administered as recommended in Table 3.22 (p 451). For infants who weigh <2000 g at birth, the initial vaccine dose should not be counted in the required 3-dose schedule (a total of 4 doses of HepB vaccine should be administered), and the subsequent 3 doses should be administered at months 1, 2 to 3, and 6 months for single-antigen products and months 2, 4, and 6 for hepatitis B-containing combination vaccines (Table 3.22, p 451). By the chronologic age of 1 month, all medically stable preterm infants, regardless of initial birth weight or gestational age, are as likely to respond to HepB immunization as are term and larger infants.

Breastfeeding of an infant by an HBsAg-positive parent poses no additional risk of acquisition of HBV infection by the infant with appropriate administration of HepB vaccine and HBIG (see Breastfeeding and Human Milk, p 135).

FOLLOW-UP MANAGEMENT OF INFANTS WHOSE BIRTHING PARENT IS HBsAg POSITIVE. Infants whose birthing parent is HBsAg positive should be tested for anti-HBs and HBsAg at 9 to 12 months of age, at least 1 to 2 months after completion of

Table 3.22. Hepatitis B Vaccine Schedules for Infants by Hepatitis B Surface Antigen (HBsAg) Status of Birthing Parent and Birth Weight

HBsAg Status of Birthing Parent	Single-Antigen Vaccine		Single-Antigen + Combination (Pediarix or Vaxelis)	
	Dose	Age	Dose	Age
Positive	1 ^a	Birth (12 h or less)	1 ^a	Birth (12 h or less) (combination vaccine should not be used for birth dose)
	HBIG ^b	Birth (12 h or less)	HBIG ^b	Birth (12 h or less)
	2	1 through 2 mo for BW ≥2000 g; 1 mo for BW <2000 g	2	2 mo
	3 ^c	6 mo for BW ≥2000 g; 2–3 mo for BW <2000 g	3	4 mo
	4 Only if BW <2000 g	6 mo	4 ^d	6 mo
Unknown ^c	1 ^a	Birth (12 h or less) BW <2000 g HBIG at birth (12 h or less)	1 ^a	Birth (12 h or less) (Combination vaccine should not be used for birth dose) BW <2000 g HBIG at birth (12 h or less)
	2	1 through 2 mo for BW ≥2000 g; 1 mo for BW <2000 g if status of birthing parent remains unknown	2	2 mo
	3 ^d	6 mo for BW ≥2000 g; 2–3 mo for BW <2000 g if status of birthing parent remains unknown	3	4 mo
	4 Only if BW <2000 g AND status of birthing parent remains unknown	6 mo	4 ^d	6 mo

Table 3.22. Hepatitis B Vaccine Schedules for Infants by Hepatitis B Surface Antigen (HBsAg) Status of Birthing Parent and Birth Weight, continued

HBsAg Status of Birthing Parent	Single-Antigen Vaccine		Single-Antigen + Combination (Pediarix or Vaxelis)	
	Dose	Age	Dose	Age
Negative	1 ^a	Birth (24 h or less) for BW ≥2000 g; hospital discharge or age 1 mo for BW <2000 g	1 ^a	Birth (24 h or less) for BW ≥2000 g; hospital discharge or age 1 mo for BW <2000 g (combination vaccine should not be used for birth dose)
	2	1 through 2 mo	2	2 mo
	3 ^d	6 through 18 mo	3	4 mo
	4	Not applicable	4 ^d	6 mo

BW indicates birth weight; HBIG, hepatitis B immune globulin.

^aRecombivax HB or Engerix-B should be used for the birth dose. Pediarix and Vaxelis should not be administered at birth or before 6 weeks of age.

^bHBIG (0.5 mL) administered intramuscularly in a separate site from vaccine.

^cBirthing parents should have blood drawn and tested for HBsAg as soon as possible after admission for delivery. Infants with birth weight <2000 g should receive HBIG by 12 hours; for infants with birth weight ≥2000 g if the birthing parent is found to be HBsAg positive, the infant should receive HBIG as soon as possible but no later than 7 days of age.

^dThe final dose in the vaccine series should not be administered before 24 weeks (164 days) of age.

Source: Schillie S, Vellozzi C, Reingold A, et al. Prevention of hepatitis B virus infection in the United States: recommendations of the Advisory Committee on Immunization Practices. *MMWR Recomm Rep*. 2018;67(RR-1):1-31.

the immunization series).^{1,2} Testing should not be performed before 9 months of age to maximize likelihood of detecting late onset of HBV infections. Immunized infants with anti-HBs concentrations ≥10 mIU/mL and who are HBsAg negative are considered not to be infected and to have adequate vaccine-associated immune protection. Infants with anti-HBs concentrations <10 mIU/mL and who are HBsAg negative following a 3-dose hepatitis B vaccine series should receive 1 additional dose of hepatitis B vaccine followed by testing for anti-HBs and HBsAg 1 to 2 months after the fourth dose. Infants with anti-HBs concentrations ≥10 mIU/mL and who are HBsAg negative after the fourth dose are considered not to be infected and to have adequate vaccine-associated immune protection. Infants with anti-HBs concentrations <10 mIU/mL and who are HBsAg negative after the fourth dose should receive 2 additional doses of vaccine, separated by at least 8 weeks, followed by testing for anti-HBs and HBsAg 1 to 2 months after the sixth dose. An alternate approach for children who have completed a 3-dose series of HepB vaccine but did not achieve anti-HBs titers ≥10 mIU/mL is to give 3 additional doses of HepB vaccine at the same dosing intervals as the first series and then retest for anti-HBs titers 1 to 2 months after the third dose of this second

¹ Schillie S, Murphy TV, Fenlon N, et al. Update: shortened interval for postvaccination serologic testing of infants born to hepatitis B-infected mothers. *MMWR Morb Mortal Wkly Rep*. 2015;64(30):1118-1120

series. Subsequent doses of hepatitis B vaccine when anti-HBs concentrations are <10 mIU/mL after the sixth dose are not indicated.

Management of Infants Whose Birthing Parent's HBsAg Status is Unknown or Whose Birthing Parent Was Not Tested for HBsAg During Pregnancy.

TERM INFANTS (WEIGHING ≥ 2000 g AT BIRTH). Pregnant people whose HBsAg status is unknown at delivery should undergo blood testing as soon as possible to determine their HBsAg status. While awaiting results, the infant should receive the first HepB vaccine dose within 12 hours of birth, as recommended for infants whose birthing parent is HBsAg positive (see Table 3.22, p 451, and Fig 3.5, p 450). Routine nursery procedures, such as skin-to-skin care, delayed bathing, and breastfeeding within the first hour, may continue as recommended by the facility. If the birthing parent is found to be HBsAg positive, term infants should receive HBIG (0.5 mL) as soon as possible, but within 7 days of birth, and should complete the HepB immunization series as recommended (see Tables 3.21, p 445, and 3.22, p 451). If the birthing parent is found to be HBsAg negative, HepB immunization in the dose and schedule recommended for term infants whose birthing parent is HBsAg negative should be completed (see Table 3.21, p 445). If the birthing parent's HBsAg status remains unknown, it is appropriate to administer HBIG within 7 days of birth and complete the HepB immunization series as recommended for infants whose birthing parent is HBsAg positive (Table 3.22, p 451, and Fig 3.5, p 450).

INFANTS WEIGHING LESS THAN 2000 g. HBsAg status of the birthing parent should be determined as soon as possible. Infants weighing <2000 g whose birthing parent's HBsAg status is unknown should receive HepB vaccine within the first 12 hours of life (Table 3.22, p 451, and Fig 3.5, p 450). Because of the potentially decreased immunogenicity of the HepB vaccine in infants weighing <2000 g at birth, these infants should also receive HBIG (0.5 mL) within 12 hours of birth if the birthing parent's HBsAg status cannot be determined by that time (Table 3.22, p 451, and Fig 3.5, p 450). The initial vaccine dose should not be counted toward the 3 doses of hepatitis B vaccine required to complete the immunization series, and the subsequent 3 doses (for a total of 4 doses) are administered according to the HBsAg status of the birthing parent. If the birthing parent is HBsAg positive or the parent's status remains unknown, the infant would receive the subsequent 3 doses administered at months 1, 2 to 3, and 6 months for single-antigen HepB products, and months 2, 4, and 6 for HepB-containing combination vaccines (Tables 3.21, p 445, and 3.22, p 451). Serologic testing for both of these groups of infants should be performed as described above for infants whose birthing parent is HBsAg positive and revaccination performed if necessary (p 448).

Routine Immunization of Infants, Children, and Adolescents Who Did Not Begin Immunization at Birth. Serologic testing to identify HBV infection (with a triple panel of HBsAg, anti-HBs, and total anti-HBc) should be performed for people in risk groups with high rates of infection, including people born in countries with intermediate or high HBV endemicity (even if immunized, because the series may have been started after the infection was acquired), children born in the United States who were not vaccinated as infants whose parents were born in a country with high HBV endemicity, current or past users of injection drugs, men who have sex with men, people with HIV or HCV infection, people currently or formerly incarcerated, people with STIs or multiple sexual partners, people on dialysis, household and sexual contacts of HBsAg-positive people, people with elevated ALT or AST levels of unknown origin, and anyone who requests

HBV testing. The first dose of vaccine may be given at the time of testing so that immunization is not delayed. Children identified as HBsAg positive should be referred for management and monitoring of hepatitis B infection. Those who are HBsAg negative and anti-HBs negative should be immunized according to doses and schedules noted in Table 3.21 (p 445). Routine postimmunization testing is not recommended.

Lapsed Immunizations. For infants, children, adolescents, and adults with lapsed immunizations (ie, the interval between doses is longer than that in one of the recommended schedules), the vaccine series should be completed without repeating doses, as long as minimum dosing intervals between the remaining doses necessary to complete the series are heeded (see Lapsed Immunizations, p 66).

Negative Anti-HBs in Previously Immunized Children. Providers may be asked to manage children tested for anti-HBs following receipt of hepatitis B immunization given at age-appropriate doses and intervals and found to have anti-HBs <10 mIU/mL. Serologic testing following routine immunization of children is not recommended routinely. If confirming response to vaccine is desired, such as after a needlestick injury, a single dose of vaccine may be administered, followed by testing for anti-HBs 1 to 2 months later. Children with anti-HBs ≥ 10 mIU/mL can be considered to have adequate vaccine-associated immune protection. Those with anti-HBs <10 mIU/mL may be given 2 more doses of hepatitis B with testing for anti-HBs 1 to 2 months after the last dose. A vaccine nonresponder is defined as a person with anti-HBs <10 mIU/mL after 2 complete series of HepB vaccine.

SPECIAL CONSIDERATIONS:

Considerations for High-Risk Groups:

Patients Undergoing Hemodialysis. Immunization is recommended for susceptible patients undergoing hemodialysis. Immunization early in the course of renal disease is encouraged, because response is better than in advanced disease. Specific dosage recommendations have not been made for children undergoing hemodialysis. Some experts recommend increased doses of HepB vaccine for children receiving hemodialysis to increase immunogenicity.

People Born in Countries Where the Prevalence of Chronic HBV Infection Is 2% or Greater. Foreign-born people (including immigrants, refugees, asylum seekers, and internationally adopted children) from countries where prevalence of chronic HBV infection is 2% or greater (see Fig 3.2) should be screened for HBsAg regardless of immunization status (see Medical Evaluation for Infectious Diseases for Internationally Adopted, Refugee, and Other Immigrant Children, p 189). Previously unimmunized family members and other household contacts should be immunized if a household member is found to be HBsAg positive. Positive HBsAg test results are nationally notifiable (see Nationally Notifiable Infectious Diseases in the United States, p 1141), and people with positive HBsAg test results should be referred for medical management to reduce their risk of complications from chronic HBV infection and to reduce risk of transmission.

Inmates in Juvenile Detention and Other Correctional Facilities. Unimmunized or underimmunized people in juvenile and adult correctional facilities should be immunized. If the length of stay is not sufficient to complete the immunization series, the series should be initiated, and follow-up mechanisms with a health care facility should be established to ensure completion of the series.

International Travelers. People traveling to areas where prevalence of chronic HBV infection is 2% or greater (see Fig 3.2, p 440) should be immunized. Ideally, HepB vaccination should be administered ≥ 6 months before travel so that a 3-dose regimen can be completed (see Preexposure Universal Immunization, p 448). If fewer than 4 months are available before departure, the alternative 4-dose schedule of 0, 1, 2, and 12 months, licensed for one vaccine (see Table 3.21, p 445), might provide opportunity for more rapid development of protection. Individual health care providers may choose to use an accelerated schedule (eg, doses at days 0, 7, and 21–30, with a booster at 12 months) for travelers who will depart before an approved immunization schedule can be completed. People who receive immunization on an accelerated schedule that is not licensed by the FDA also should receive a dose at 12 months after initiation of the series to promote long-term immunity. For people 18 years and older, the 2-dose regimen of Heplisav-B can be completed in 1 month and offers greater flexibility before travel.

Postimmunization Testing for Anti-HBs. Routine postimmunization testing for anti-HBs is not necessary after routine vaccination of healthy people but is recommended 1 to 2 months after the final vaccine dose for the following specific groups: (1) hemodialysis patients (and other people who might require outpatient hemodialysis); (2) people with HIV infection; (3) other immunocompromised patients (eg, hematopoietic cell transplant recipients or people receiving chemotherapy); (4) people at occupational risk of exposure from percutaneous injuries or mucosal or nonintact skin exposures (eg, certain health care and public safety workers); (5) sexual partners of HBsAg-positive people, and (6) infants whose birthing parent is HBsAg positive and infants whose birthing parent's HBsAg status remains unknown (testing should consist of HBsAg and anti-HBs).

Management of Nonresponders. Vaccine recipients who do not develop a serum anti-HBs response (≥ 10 mIU/mL) after a primary vaccine series should be tested for HBsAg to rule out the possibility of a chronic infection as an explanation of failure to respond to the vaccine. If the HBsAg test result is negative, a single dose of HepB vaccine can be administered followed by testing for anti-HBs in 1 to 2 months. If anti-HBs is ≥ 10 mIU/mL, no further testing is required. If anti-HBs is < 10 mIU/mL, additional doses should be administered to complete the second vaccine series, with testing for anti-HBs 1 to 2 months after the last dose. For the 3-dose vaccine series using Engerix-B or Recombivax HB, this would require 2 additional doses of vaccine, and for the 2-dose series using Heplisav-B (licensed only in adults), this would require 1 additional dose. For very recently vaccinated HCP with anti-HBs < 10 mIU/mL, in whom the low antibody concentration is more likely to reflect a failure to respond rather than waning antibody concentration, it may be more practical to revaccinate with an entire second series (3 doses of Engerix-B or Recombivax HB; 2 doses of Heplisav-B or PreHevbrio) followed by anti-HBs testing 1 to 2 months after the last dose. Heplisav-B may be used for revaccination following an initial HepB vaccine series that consisted of doses from a different manufacturer. A vaccine nonresponder is defined as a person with anti-HBs < 10 mIU/mL after 2 complete series of HepB vaccine.

Care of Exposed People (Postexposure Immunoprophylaxis).

Household Contacts and Sexual Partners of HBsAg-Positive People. Household and sexual contacts of HBsAg-positive people (with acute or chronic HBV infection)

identified through prenatal screening, blood donor screening, or diagnostic or other serologic testing should be screened for HBV infection with a triple panel (HBsAg, anti-HBs, and total anti-HBc). Unvaccinated and uninfected people should be immunized. The first dose of vaccine should be administered after the blood for serologic tests is obtained and while waiting for the results. People with chronic HBV should be referred for medical evaluation to prevent complications of the infection.

Prophylaxis with HBIG for other unimmunized household contacts of HBsAg-positive people is not indicated unless they have a discrete, identifiable exposure to the index patient (see next paragraph).

Postexposure Prophylaxis for People with Discrete Identifiable Exposures to Blood or Body Fluids. Management of people with a discrete, identifiable percutaneous (eg, needle stick, laceration, bite that breaks the skin), mucosal (eg, ocular or mucous membrane), or sexual exposure to blood or body fluids includes consideration of whether the HBsAg status of the person who was the source of exposure and the hepatitis B immunization and response status of the exposed person are known (also see Table 3.23). If possible, a blood specimen from the person who was the source of the exposure should be tested for HBsAg, and appropriate prophylaxis should be administered according to the hepatitis B immunization status and anti-HBs response status (if known) of the exposed person (see Table 3.23). Detailed guidelines for management of health care personnel and other people exposed to blood that is or might be HBsAg positive

Table 3.23. Guidelines for Postexposure Prophylaxis^a of People With Nonoccupational Exposures^b to Blood or Body Fluids That Contain Blood, by Exposure Type and Vaccination Status

Exposure	Treatment	
	Unvaccinated Person ^c	Previously Vaccinated Person ^d
HBsAg-positive source		
Household member	Consider testing if significant exposure; if negative administer hepatitis B vaccine series	Ensure completion of vaccine series
Percutaneous (eg, bite or needlestick) or mucosal exposure to HBsAg-positive blood or body fluids	Administer hepatitis B vaccine series and hepatitis B immune globulin (HBIG)	Administer hepatitis B vaccine booster dose
Sexual or needle-sharing contact of an HBsAg-positive person	Administer hepatitis B vaccine series and HBIG	Administer hepatitis B vaccine booster dose
Person who has been sexually assaulted or abused by a perpetrator who is HBsAg positive	Administer hepatitis B vaccine series and HBIG	Administer hepatitis B vaccine booster dose

Table 3.23. Guidelines for Postexposure Prophylaxis^a of People With Nonoccupational Exposures^b to Blood or Body Fluids That Contain Blood, by Exposure Type and Vaccination Status, continued

Exposure	Treatment	
	Unvaccinated Person ^c	Previously Vaccinated Person ^d
Source with unknown HBsAg status		
Person who has been sexually assaulted or abused by a perpetrator with unknown HBsAg status	Administer hepatitis B vaccine series	No treatment
Percutaneous (eg, bite or needlestick) or mucosal exposure to potentially infectious blood or body fluids from a source with unknown HBsAg status	Administer hepatitis B vaccine series	No treatment
Sexual or needle-sharing contact of person with unknown HBsAg status	Administer hepatitis B vaccine series	No treatment

HBsAg indicates hepatitis B surface antigen.

^aWhen indicated, immunoprophylaxis should be initiated as soon as possible, preferably within 24 hours. Studies are limited on the maximum interval after exposure during which postexposure prophylaxis is effective, but the interval is unlikely to exceed 7 days for percutaneous exposures or 14 days for sexual exposures. The hepatitis B vaccine series should be completed.

^bThese guidelines apply to nonoccupational exposures. Guidelines for occupational exposures can be found in Schillie S, Murphy TV, Sawyer M, et al. CDC guidance for evaluating health-care personnel for hepatitis B virus protection and for administering post exposure management. *MMWR Recomm Rep*. 2013;62(RR-10):1–19.

^cA person who is in the process of being vaccinated but who has not completed the vaccine series should complete the series and receive treatment as indicated.

^dA person who has written documentation of a complete hepatitis B vaccine series and who did not receive postvaccination testing.

are provided in the recommendations of the Advisory Committee on Immunization Practices of the CDC.¹

Child Care.

Children who are HBsAg positive and who have no behavioral or medical risk factors, such as unusually aggressive behavior (eg, frequent biting), generalized dermatitis, or a bleeding problem, should be admitted to child care without restrictions. Under these circumstances, the risk of HBV transmission in child care settings is negligible, and routine screening for HBsAg is not warranted. Admission of HBsAg-positive children with behavioral or medical risk factors should be assessed on an individual basis by the child's physician, in consultation with the child care staff. A susceptible child who bites another child or adult who is HBsAg-positive should initiate or complete the hepatitis B vaccine series; HBIG is not recommended in this circumstance (see Bite Wounds, p 202).

Hepatitis C

CLINICAL MANIFESTATIONS: Signs and symptoms of hepatitis C virus (HCV) infection are indistinguishable from those of hepatitis A (HAV) or hepatitis B virus (HBV) infections. Acute disease tends to be mild and insidious in onset, and most infections are asymptomatic. Jaundice occurs in less than 20% of patients with HCV infection, and abnormalities in serum alanine aminotransferase concentrations generally are less pronounced than in patients with HBV infection. Rates of spontaneous viral clearance vary, but roughly 20% or more of children with perinatal infection clear the virus by 2 years of age, with upwards of 65% clearing the virus by 5 years of age. Most children with chronic infection are asymptomatic and may not show biochemical evidence of liver disease initially. Liver failure secondary to HCV infection is one of the leading indications for liver transplantation among adults in the United States. Limited data indicate that cirrhosis and hepatocellular carcinoma occur less commonly in children than in adults, but because fibrosis increases with disease duration, individuals who are perinatally infected are at risk of developing severe disease in adolescence or as young adults.

ETIOLOGY: HCV is a small, single-stranded, positive-sense RNA virus and is a member of the family *Flaviviridae* in the genus *Hepacivirus*. At least 7 HCV genotypes exist and more than 60 subtypes have been described to date. Distribution of genotypes and subtypes varies by geographic location; genotype 1a is the most common genotype in the United States.

EPIDEMIOLOGY: Prevalence of HCV infection in the general population of the United States is estimated at 1.0%, equating to an estimated 2.4 (2.0–2.8) million people in the United States with chronic HCV infection. Incidence of HCV infection decreased markedly in the United States in all age groups from the 1990s to reach its lowest incidence in 2006–2010. Since 2010, however, there has been an increase in reported cases of acute HCV infection in the United States, largely related to injection drug use. The highest incidence of acute hepatitis C infection is in people 20 through 39 years of age, leading to an increase in the number of infants exposed prenatally to HCV (www.cdc.gov/hepatitis/statistics/SurveillanceRpts.htm). Worldwide, the prevalence of chronic HCV infection is highest in eastern Europe, central Asia, northern Africa, and the Middle East.

HCV is transmitted primarily through percutaneous (parenteral) exposures to infectious blood that can result from injection drug use, needlestick injuries, and inadequate infection control in health care settings. The most common risk factors for adults are injection drug use and multiple sexual partners. The most common route of infection for children is from birthing parent to infant transmission. The current risk of HCV infection after blood transfusion in the United States is estimated to be less than 1 per 2 million units transfused because of exclusion of high-risk donors and of HCV-positive units after antibody testing as well as screening of blood units by nucleic acid amplification tests (NAATs). All intravenous and intramuscular immune globulin and plasma products now available commercially in the United States undergo an inactivation procedure for HCV or are documented to have undetectable HCV RNA before release.

Of acute hepatitis C cases reported to public health authorities with available risk factor information, two-thirds are in people who acknowledge they inject drugs. Data from recent multicenter, population-based cohort studies indicate that approximately one third of people who inject drugs 18 to 30 years of age are infected with HCV.

People with sporadic percutaneous exposures, such as health care professionals, may be infected; per exposure risk of HCV transmission from needlestick is estimated at 0.2%. Health care-associated outbreaks have been documented, especially in nonhospital settings with inadequate infection control and injection safety procedures. Prevalence of HCV is higher among people with frequent direct percutaneous exposures, such as patients receiving hemodialysis (7%).

Sexual transmission of HCV between monogamous heterosexual partners is extremely rare. Transmission can occur in men who have sex with men, especially in association with sexual practices that result in mucosal trauma, presence of concurrent anogenital ulcerative disease, human immunodeficiency virus (HIV)-positive serostatus, or sex while using methamphetamines. HCV has been identified in semen and rectal and vaginal fluids, especially in those coinfecting with HIV.

Transmission among family contacts could occur from direct or inapparent percutaneous or mucosal exposure to blood (eg, sharing toothbrushes or razors), but this is extremely uncommon.

Seroprevalence among pregnant people in the United States is estimated at 1% to 2% but is higher in some areas. Risk of perinatal transmission is approximately 6% to 7% among HIV-negative pregnant people with hepatitis C. The exact timing of vertical HCV transmission is not established. Recent guidelines from the Centers for Disease Control and Prevention (CDC) recommend testing of all pregnant people for HCV with each pregnancy. Factors that may increase risk of perinatal transmission include invasive prenatal diagnostic testing (eg, chorionic villus sampling), internal fetal monitoring, vaginal lacerations, and prolonged rupture of membranes (>6 hours). Method of delivery has no effect on perinatal infection risk. Coinfection in the pregnant person with poorly controlled HIV is associated with increased risk of perinatal transmission of HCV (twofold greater). Early and sustained control of HIV viremia with antiretroviral therapy (ART) may reduce risk of HCV transmission to infants.

All people with detectable HCV RNA in their blood are considered infectious.

The **incubation period** for HCV infection averages 6 to 7 weeks, with a range of 2 weeks to 6 months. The time from exposure to development of viremia generally is 1 to 3 weeks.

DIAGNOSTIC TESTS^{1,2}: Diagnostic assays for the detection of anti-HCV antibody are available in various formats, which include enzyme immunoassays (EIA), chemiluminescent immunoassays (CIA), and immunochromatographic or rapid tests. NAATs for detection and quantitation of HCV RNA are used for diagnosis of current HCV infection and for monitoring response to antiviral therapy. Screening for HCV infection usually is accomplished by serologic testing for anti-HCV with reflex testing of reactive samples with NAAT to diagnose current infection. Third-generation anti-HCV assays cleared by the US Food and Drug Administration (FDA) are at least 97% sensitive and more than 99% specific. Anti-HCV antibodies can be detected approximately 8 to 11 weeks after exposure. In clinical settings where exposure to HCV is considered likely, testing for HCV RNA should be performed regardless of the anti-HCV

¹ Centers for Disease Control and Prevention. Testing for HCV Infection: an update of guidance for clinicians and laboratorians. *MMWR Morb Mortal Wkly Rep*. 2013;62(18):362-365

² Panagiotakopoulos L, Sandul AL, Connors EE, Foster MA, Nelson NP, Wester C. CDC recommendations for hepatitis C testing among perinatally exposed infants and children—United States, 2023. *MMWR Recomm Rep*. 2023;72(RR-4):1-19

result. Transplacentally acquired antibody may persist for up to 18 months in infants born to anti-HCV-positive mothers.

FDA-cleared NAATs for detection of HCV RNA are available commercially and are recommended in the 2013 CDC HCV testing algorithm as reflex tests for patients with anti-HCV reactive test results. HCV RNA can be detected in serum or plasma within 1 to 3 weeks after exposure to the virus and weeks before onset of liver enzyme abnormalities or appearance of anti-HCV antibody. Assays for detection of HCV RNA are used commonly in clinical practice to: (1) detect HCV infection after needle-stick or transfusion and before seroconversion; (2) identify current infection in anti-HCV-positive patients; (3) identify infection in infants early in life (ie, from perinatal transmission) when transplacentally acquired antibody interferes with ability to detect antibody produced by the infant; (4) identify HCV infection in severely immunocompromised or hemodialysis patients in whom there may be delayed seroconversion to anti-HCV; (5) detect a recent or acute infection when the HCV antibody is negative; and (6) monitor patients receiving antiviral therapy. False-positive and false-negative results of NAATs can occur from improper handling, storage, and contamination of test specimens. HCV genotyping is still needed for determining which direct-acting antiviral (DAA) agents should be used in individual patients, but as pan-genotypic antiviral drugs become available more widely, genotype testing may become less relevant.

Infants exposed perinatally should be tested by NAAT for HCV RNA at age 2 through 6 months to identify children who might go on to develop chronic HCV infection if not treated. Similarly, infants and children aged 7 through 17 months of age who are perinatally exposed to HCV and have not previously been tested should have a NAAT for HCV RNA performed. Infants with detectable HCV RNA should be managed in consultation with a health care provider with expertise in pediatric hepatitis C management. Infants with an undetectable HCV RNA result do not require further follow-up unless clinically warranted. Children aged ≥ 18 months who are perinatally exposed to HCV and have not previously been tested should be tested serologically for anti-HCV immunoglobulin (Ig) G (Fig 3.6).

TREATMENT: Two interferon-free, pan-genotypic antiviral drug regimens have been approved by the FDA for children as young as 3 years: sofosbuvir/velpatasvir and glecaprevir/pibrentasvir (see Non-HIV Antiviral Drugs, p 1044). Two additional antiviral drug therapies, sofosbuvir and ledipasvir/sofosbuvir, have activity against some but not all HCV genotypes and are approved for use in people 3 years or older. All HCV-infected children 3 years or older should be treated in line with public health goals of viral hepatitis elimination. Children with a diagnosis of current HCV infection should be cared for in consultation with a provider with expertise in pediatric hepatitis C for clinical monitoring and consideration for treatment. The American Association for the Study of Liver Disease (AASLD) and the Infectious Diseases Society of America (IDSA) summarize recommended antiviral drug treatment for adults (www.hcvguidelines.org) and children (www.hcvguidelines.org/unique-populations/children).

Management of Chronic HCV Infection. Because of the very high rate of severe hepatitis in patients with HCV-associated chronic liver disease, all patients with chronic HCV infection should be immunized against HAV and HBV. Risk of liver-related morbidity and mortality, including cirrhosis and primary hepatocellular carcinoma, increases with advancing age in individuals with chronic HCV infection. Among

FIG 3.6. TESTING OF CHILDREN PERINATALLY EXPOSED TO HCV

Modified from Connors EE, Panagiotakopoulos L, Hofmeister MG, et al. Screening and testing for hepatitis B virus infection: CDC Recommendations—United States, 2023. *MMWR Recomm Rep.* 2023;72(RR-1):1-25.

children, progression of liver disease appears to be accelerated when comorbid conditions, including HIV, childhood cancer, iron overload, or thalassemia, are present. Pediatricians should be alert for conditions that may worsen liver disease in patients with HCV infection, such as concomitant infections, and alcohol use. After assessment of risks and benefits, hepatotoxic drugs should be used with caution in children with chronic HCV infection. Notably, corticosteroids, cytotoxic chemotherapy, and therapeutic doses of acetaminophen are not contraindicated in children with chronic HCV infection, and acetaminophen is safe and effective in this population when dosed appropriately. Children with chronic infection should be followed closely, including sequential monitoring of serum alanine aminotransferase concentrations, because of the potential for chronic liver disease. Evidence-based, consensus recommendations from the IDSA, the AASLD, and the International Antiviral Society–USA for screening, treatment, and management of patients with HCV infection, including children and pregnant people, can be found online (www.hcvguidelines.org).

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES:

Care of Exposed People.

Immunoprophylaxis. Use of immune globulin for postexposure prophylaxis against HCV infection is not recommended based on lack of clinical efficacy in humans and data from animal studies. Potential donors of immune globulin are screened for antibody to HCV and excluded from donation if positive, so immune globulin preparations are devoid of anti-HCV antibody.

Pregnancy and Breastfeeding.^{1,2} All pregnant people should be tested for HCV during each pregnancy. Pregnant persons with detectable HCV RNA are considered to have current HCV infection; if no HCV test is available from that pregnancy and the most recent NAAT indicated detectable HCV RNA in the absence of treatment, they also are considered to have current HCV infection. If anti-HCV testing is reactive and HCV RNA results are not available, pregnant persons are considered to have probable HCV infection; similarly, if no HCV test is available from pregnancy and the most recent anti-HCV test is reactive in the absence of an undetectable RNA or treatment, they also are considered to have probable HCV infection.

Transmission of HCV by breastfeeding has not been documented. Antibody to HCV (anti-HCV) and HCV RNA have been detected in colostrum, but risk of HCV transmission is similar in breastfed and formula-fed infants. According to current guidelines of the AASLD and IDSA, HCV infection in the parent is not a contraindication to breastfeeding (www.hcvguidelines.org/unique-populations/pregnancy). Breastfeeding parents who are HCV infected should interrupt breastfeeding temporarily if their nipples are bleeding or cracked and can consider expressing and discarding their milk until the nipples are healed. Once the nipples no longer are cracked or bleeding, breastfeeding may resume.

² Schillie S, Wester C, Osborne M, Wesolowski L, Ryerson AB. CDC recommendations for hepatitis C screening among adults—United States, 2020. *MMWR Recomm Rep.* 2020;69(RR-2):1-17

Child Care. Exclusion of children with HCV infection from out-of-home child care is not indicated.

Serologic Testing for HCV Infection.

Universal Screening Recommendations.

- Individuals 18 years or older should be tested at least once in their lifetime, except in settings where the prevalence of HCV infection is <0.1%.
- Pregnant people of any age (during each pregnancy).

People Who Have Risk Factors for HCV Infection.

In addition to the universal screening recommendations above, HCV testing is recommended for anyone at increased risk for HCV infection and other populations, including¹:

- Children whose birthing parent has HCV infection;
- People who have ever injected drugs, including those who injected only once many years ago;
- Recipients of clotting factor concentrates made before 1987;
- Recipients of blood transfusions or solid organ transplants before July 1992;
- Patients who have ever received long-term hemodialysis treatment;
- People with known exposures to HCV, such as
 - ♦ Health care workers after needlesticks, sharps, or mucosal exposures involving HCV-positive blood;
 - ♦ Recipients of blood from a donor who later tested HCV-positive;
- All people with HIV infection;
- Patients with persistently abnormal liver enzyme test results; and
- Any person who requests hepatitis C testing, regardless of disclosure of risk, because many people might be reluctant to disclose stigmatizing risks.

Professional organizations have additional testing recommendations for specific populations, including those on PrEP, those in correctional or detention facilities, those who have had organ transplant, and those with end-stage renal disease).

Children Whose Birthing Parent Has HCV Infection. Children whose birthing parent has HCV infection should be tested for HCV infection, because 5% to 7% of these children will acquire infection, and the risk of transmission is higher if the parent is coinfected with uncontrolled HIV.

Adoptees. See Medical Evaluation for Infectious Diseases for Internationally Adopted, Refugee, and Other Immigrant Children (p 189) for specific situations when serologic testing is warranted.

Counseling of Patients With HCV Infection. All people with HCV infection should be considered infectious, should be informed of the possibility of transmission to others, and should refrain from donating blood, organs, tissues, or semen and from sharing toothbrushes and razors.

Infected people should be counseled to avoid hepatotoxic agents, including medications, and should be informed of the risks of excessive alcohol ingestion. All patients with chronic HCV infection should be immunized against HAV and HBV.

Changes in sexual practices of infected people with a long-term, monogamous partner are not recommended, although these couples should be informed of possible

¹ Centers for Disease Control and Prevention. Recommendations for Hepatitis C Screening among adults- United States 2020. *MMWR Recomm Rep.* 2020;69(2):1-17. Available at: www.cdc.gov/mmwr/volumes/69/rr/rr6902a1.htm

risks and use of precautions to prevent transmission. People with multiple sexual partners should be advised to decrease number of partners and to use condoms to prevent transmission. No data exist to support counseling a person of childbearing age against pregnancy. Currently, HCV antiviral therapy is not recommended during pregnancy, but early phase clinical studies and anecdotal reports suggest this is safe and effective. People who become pregnant while receiving antiviral therapy should discuss risk and benefits of continuing treatment with their physician. The Coalition for Global Hepatitis Elimination has established a registry to track outcomes for any patient who is or becomes pregnant while receiving antiviral treatment. (www.globalhep.org/evidence-base/treatment-pregnancy-hepatitis-c-tip-hepc-registry).

The CDC Division of Viral Hepatitis maintains a website (www.cdc.gov/hepatitis/HCV) with information on hepatitis for health care professionals and the public. Information also can be obtained from the National Institutes of Health Web site (www.niddk.nih.gov/health-information/liver-disease/viral-hepatitis/hepatitis-c).

Hepatitis D

CLINICAL MANIFESTATIONS: Hepatitis D virus (HDV) causes infection only in people with hepatitis B virus (HBV) infection. HDV requires hepatitis B surface antigen (HBsAg) for virion assembly and secretion. The importance of HDV infection lies in its ability to convert an asymptomatic or mild chronic HBV infection into more severe or rapidly progressive disease. HDV infection can be acquired either simultaneously with HBV infection (coinfection) or subsequent to HBV infection (superinfection). Coinfection is indistinguishable from acute hepatitis B and usually is transient and self-limited, whereas superinfection often results in chronic infection. Acute infection with HDV usually causes an illness indistinguishable from other viral hepatitis infections, except that the likelihood of fulminant hepatitis can be as high as 5%.

ETIOLOGY: HDV is the only species in the *Deltavirus* genus and possesses the smallest genome of any human pathogen. HDV has a circular, negative sense ssRNA genome and approximately 70 copies of hepatitis delta antigen, all of which is coated with HBsAg.

EPIDEMIOLOGY: HDV infection is present worldwide, in all age groups. Over the past 20 years, HDV prevalence has varied geographically, with decreases in some regions attributable to long-standing hepatitis B vaccination programs and increases in others related to changing migration patterns. High-prevalence areas include the Mediterranean basin, parts of Eastern Europe, the Amazon basin of South America, West and Central Africa, West and Central Asia, and the Middle East, although considerable heterogeneity exists within specific countries. Distribution does not necessarily parallel that of hepatitis B. HDV infection is found in the United States most commonly in people who inject drugs and people who have emigrated from areas with endemic HDV infection. At least 8 genotypes of HDV have been described, each with a typical geographic pattern, with genotype 1 being found worldwide. Acquisition of HDV is by parenteral transmission from infected blood or body fluids, such as through injection drug use or sexual contact. Transmission from birthing parent to newborn infant is uncommon. Intrafamilial spread can occur among people with chronic HBV infection.

The **incubation period** for HDV superinfection is approximately 2 to 8 weeks. When HBV and HDV viruses infect simultaneously, the incubation period is similar to that of HBV (45 to 160 days; average 90 days).

DIAGNOSTIC TESTS: Because of the dependence of HDV on HBV, diagnosis of hepatitis D cannot be made in the absence of markers of HBV infection. Testing for HDV should be considered, at a minimum, for patients with unusually severe or protracted hepatitis and for patients with positive HBsAg and specific risk factors, such as emigration from a region with endemic disease, injection drug use, men who have sex with men, coinfection with hepatitis C virus (HCV) or human immunodeficiency virus (HIV), or high-risk sexual practices. Abnormal aminotransferase concentrations with low or undetectable HBV DNA levels in patients with HBV infection is suspicious for HDV infection. Testing for immunoglobulin G antibodies against HDV (IgG anti-HDV) using a commercially available test can be performed as an initial screening test. Tests for IgM anti-HDV are of lesser utility because of low sensitivity and specificity. Anti-HDV becomes detectable several weeks after illness onset. Acute HDV superinfection and chronic HDV infection can be distinguished from acute HBV/HDV coinfection by the absence of immunoglobulin (Ig) M hepatitis B core antibody (IgM anti-HBc). Because IgG anti-HDV is detectable during acute, chronic, and resolved phases of infection, HDV RNA testing is required for diagnosing current HDV infection and for monitoring antiviral therapy. Patients with circulating HDV RNA should be staged for severity of liver disease, have surveillance for development of hepatocellular carcinoma, and be considered for treatment.

TREATMENT: HDV has proven difficult to treat, and there are no therapies approved by the US Food and Drug Administration. Data suggest 48 weeks of pegylated interferon-alfa may result in virologic response in up to 40% of patients but is associated with considerable side effects and late virologic relapse in approximately half of patients. Novel therapies under investigation in adults include viral entry inhibitors, prenylation inhibitors, and nucleic acid polymers. The viral entry inhibitor bulevirtide is available in the European Union for the treatment of adults with chronic HDV infection. The farnesyltransferase inhibitor lonafarnib, which is approved for treatment of progeria, has been found in a phase 3 study to decrease HDV RNA and normalize alanine aminotransferase (ALT) at the end of 48 weeks of treatment compared with placebo. Liver transplantation is used in certain individuals with liver failure attributable to HBV/HDV infection.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: The same control and preventive measures used for HBV infection are indicated. HBV immunization protects against HDV infection. People with chronic HBV infection should take care to avoid exposure to HDV. Harm reduction services, including access to sterile needles and syringes, are an important control measure for people who inject drugs.

Hepatitis E

CLINICAL MANIFESTATIONS: Hepatitis E virus (HEV) infection can be asymptomatic or can cause an acute illness with symptoms including jaundice, malaise, anorexia, fever, abdominal pain, arthralgia, and neurologic complications. Disease is more

common among young adults and is more severe in pregnant people, in whom mortality rates can reach 10% to 25% if infection occurs during the third trimester. Chronic HEV infection is rare and, to date, has been reported only in high-income countries. Some recipients of solid organ transplants who acquire HEV after the transplant appear to be at higher risk of chronic infection.

ETIOLOGY: HEV is a spherical, nonenveloped, positive-sense, single-stranded RNA virus. HEV is classified in the genus *Paslahepevirus* of the family *Hepeviridae*. Members of the species *Paslahepevirus balayani* include 8 genotypes (based on phylogenetic analyses); these may infect humans (HEV-1, -2, -3, -4, and -7), pigs (HEV-3 and -4), rabbits (HEV-3), wild boars (HEV-3, -4, -5, and -6), mongooses (HEV-3), deer (HEV-3), yaks (HEV-4), and camels (HEV-7 and -8). There also are reports of human infection caused by the species *Rocahepevirus rattii* (rat HEV), which is usually found in rats and ferrets. Genotype prevalence varies across geographic regions.

EPIDEMIOLOGY: An estimated 20 million HEV infections occur each year worldwide, resulting in 3.4 million cases of acute hepatitis. A recent World Health Organization estimate suggested that there were 55 000 deaths attributable to hepatitis E in 2016. Most HEV infections occur in resource-limited countries (highest prevalence is in Asia and Africa); ingestion of fecally contaminated water is the most common route of HEV transmission, and large waterborne outbreaks occur frequently. HEV infection has been reported throughout the world, including Europe and North America. Foodborne infection with HEV-3 and, less frequently, HEV-4 has occurred sporadically in higher-income countries following consumption of uncooked or undercooked pork, deer meat, sausage, and shellfish. Person-to-person transmission appears to be much less efficient than with hepatitis A virus but occurs sporadically and in outbreak settings. There is limited information on vertical transmission of HEV; it can occur and can account for substantial fetal loss and perinatal mortality, but its contribution to overall disease burden appears to be small. It is unclear whether breastfeeding is a potential route of HEV transmission (see Control Measures).

HEV also is transmitted through blood and blood products. Transfusion-transmitted hepatitis E occurs primarily in countries with endemic disease and also is reported in areas without endemic infection. Serologic studies demonstrated that during 2009-2010 approximately 6% of the population of the United States had immunoglobulin (Ig) G antibodies against HEV, but symptomatic HEV infection in the United States is uncommon and generally occurs in people who acquire HEV-1 infection while traveling in countries with endemic HEV transmission. A number of people without a travel history have been diagnosed with acute hepatitis E, and evidence for the infection should be sought in patients with acute hepatitis of unknown etiology. Hepatitis E may masquerade as drug-induced liver injury.

The **incubation period** is 2 to 8 weeks, with an average of 6 weeks.

DIAGNOSTIC TESTS: HEV infection should be considered in any person with symptoms of viral hepatitis who has traveled to or from a region with endemic hepatitis E or a region where an outbreak of hepatitis E has been identified and in persons with signs and symptoms of viral hepatitis who test negative for serologic markers of hepatitis A, B, and C and other hepatotropic viruses. Testing for anti-HEV IgM and IgG is available through some commercial laboratories. Because anti-HEV assays are not approved by the US Food and Drug Administration and their performance

characteristics are not well defined, results should be interpreted with caution, particularly in cases lacking a discrete onset of illness associated with jaundice or with no recent history of travel to a country with endemic HEV transmission. Definitive diagnosis can be made by demonstrating viral RNA in serum or stool samples by means of a nucleic acid amplification test (NAAT), which is available at a limited number of commercial laboratories and with prior approval through the Centers for Disease Control and Prevention. Because virus circulates in the body for a relatively short period, the inability to detect HEV in serum or stool does not eliminate the possibility that the person was infected with HEV.

TREATMENT: Management is supportive. Some case reports and case series have indicated that reduction of immunosuppression and/or use of antiviral drugs, such as ribavirin, with or without interferon-alpha, may result in viral clearance in immunocompromised patients with chronic hepatitis E, but no randomized controlled clinical trials have been performed.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, contact precautions are recommended for diapered and incontinent patients for the duration of illness.

CONTROL MEASURES: Provision of safe water and improved hygiene practices are the most effective prevention measures. Travelers to regions where HEV is endemic (eg, Asia, Africa, the Middle East, and Central America) should follow precautions used for the prevention of travelers' diarrhea, avoiding food from street vendors, raw or undercooked seafood, meat or pork products, and raw vegetables. Travelers to Europe also should avoid uncooked or undercooked pork/boar sausage or other wild animal meats (eg, rabbit) that have not been heated properly. Until more data are available, breastfeeding among people with confirmed acute HEV infection is discouraged. A recombinant HEV vaccine is licensed in China but is not approved for use in the United States.

Herpes Simplex

CLINICAL MANIFESTATIONS:

Neonatal. In newborn infants with herpes simplex virus (HSV), infection can manifest as: (1) disseminated disease involving multiple organs, most prominently liver and lungs, and in 60% to 75% of cases also involving the central nervous system (CNS); (2) localized CNS disease, with or without skin, eye, or mouth involvement (CNS disease); or (3) disease localized to the skin, eyes, and/or mouth (SEM disease). Approximately 25% of cases of neonatal HSV manifest as disseminated disease, 30% manifest as CNS disease, and 45% manifest as SEM disease. Both HSV type 1 (HSV-1) and type 2 (HSV-2) can cause any of these manifestations of neonatal HSV disease. In the absence of characteristic skin lesions, the diagnosis of neonatal HSV infection is challenging and requires a high index of suspicion. More than 80% of neonates with SEM disease have skin vesicles; those without vesicles have infection limited to the eyes and/or oral mucosa. Approximately two thirds of neonates with disseminated or CNS disease have skin vesicles, but these lesions may not be present at the time of onset of symptoms. Disseminated infection should be considered in neonates with sepsis syndrome with negative bacteriologic culture results, severe liver dysfunction, consumptive coagulopathy, or suspected viral pneumonia, especially

hemorrhagic pneumonia. HSV should be considered as a causative agent in neonates with fever (especially within the first 3 weeks of life), hypothermia, a vesicular rash, or abnormal cerebrospinal fluid (CSF) findings (especially in the presence of seizures or during a time of year when enteroviruses are not circulating in the community). Although asymptomatic HSV infection is common in older children, it rarely, if ever, occurs in neonates. Recurrent skin lesions are common in surviving infants, occurring in approximately 50% of survivors, often within 1 to 2 weeks of completing the initial treatment course of parenteral acyclovir or the longer-term suppressive course of oral acyclovir.

Initial signs of HSV infection can occur anytime between birth and approximately 6 weeks of age, although almost all infected infants develop clinical disease within the first month of life. Infants with disseminated disease and SEM disease have an earlier age of onset, typically presenting between the first and second weeks of life; infants with CNS disease usually present with illness between the second and third weeks of life.

Children Beyond the Neonatal Period and Adolescents. Most primary HSV childhood infections beyond the neonatal period are asymptomatic. Gingivostomatitis, which is the most common clinical manifestation of HSV during childhood, is almost exclusively caused by HSV-1 and is characterized by fever, irritability, tender submandibular adenopathy, and an ulcerative enanthem involving the gingiva and mucous membranes of the mouth, often with perioral vesicular lesions.

Genital herpes is characterized by vesicular or ulcerative lesions of the male or female genitalia, perineum, or perianal areas.¹ Until the last 2 decades, genital herpes most often was caused by HSV-2, but likely because of oral sexual practices, HSV-1 now accounts for more than half of all genital herpes cases in the United States. Most cases of primary genital herpes infection are asymptomatic, so they are not recognized by the infected person or diagnosed by a health care professional. When present, symptoms and signs of the initial episode may include fever, fatigue, myalgias, and inguinal lymphadenopathy.

In immunocompromised patients, severe local lesions and, less commonly, disseminated HSV infection with generalized vesicular skin lesions and visceral involvement can occur.

After primary infection, HSV persists for life in a latent form. Reactivation of latent virus most commonly is asymptomatic. When symptomatic, recurrent HSV-1 herpes labialis manifests as single or grouped vesicles in the perioral region, usually on the vermilion border of the lips (typically called “cold sores” or “fever blisters”). Symptomatic recurrent genital herpes manifests as vesicular lesions on the penis, scrotum, vulva, cervix, buttocks, perianal areas, thighs, or back. Among immunocompromised patients, genital HSV-2 recurrences are more frequent and of longer duration. Recurrences may be heralded by a prodrome of burning or itching at the site of an incipient recurrence, identification of which can be useful in instituting early antiviral therapy.

Ocular manifestations of HSV include conjunctivitis and keratitis that can result from primary or recurrent HSV infection. In addition, HSV can cause acute retinal necrosis and uveitis.

¹ The terms male and female refer to sex assigned at birth.

Eczema herpeticum can develop in patients with atopic dermatitis who are infected with HSV and can be difficult to distinguish from poorly controlled atopic dermatitis. Examination may reveal skin with punched-out erosions, hemorrhagic crusts, and/or vesicular lesions. Pustular lesions attributable to bacterial superinfection also may occur. Herpetic whitlow consists of single or multiple vesicular lesions on the distal parts of fingers. Wrestlers and other contact sports athletes can develop herpes gladiatorum, a cutaneous skin infection that usually is caused by HSV-1 but occasionally by HSV-2. In wrestling, 70% of herpes outbreaks involve the face. HSV infection can be a precipitating factor of other cutaneous manifestations, such as erythema multiforme. Recurrent erythema multiforme often is caused by symptomatic or asymptomatic HSV recurrences.

HSV encephalitis (HSE) occurs in children beyond the neonatal period, in adolescents, and in adults and can result from primary or recurrent HSV-1 infection. One fifth of HSE cases occur in the pediatric age group. Symptoms and signs usually include fever, alterations in the state of consciousness, personality changes, seizures, and focal neurologic findings. Encephalitis commonly has an acute onset with a fulminant course, leading to coma and death in untreated patients. HSE usually involves the temporal lobe, and magnetic resonance imaging is the most sensitive imaging modality. CSF pleocytosis with a predominance of lymphocytes is typical. Historically, erythrocytes in the CSF were considered suggestive of HSE, but with earlier diagnosis (prior to development of a hemorrhagic encephalitis), this finding is rare today.

HSV infection also can manifest as mild, self-limited aseptic meningitis, usually associated with primary genital HSV-2 infection. Unusual CNS manifestations of HSV include Bell's palsy, atypical pain syndromes, trigeminal neuralgia, ascending myelitis, transverse myelitis, postinfectious encephalomyelitis, and recurrent (Mollaret) meningitis.

ETIOLOGY: HSVs are large, enveloped, double-stranded DNA viruses. They are members of the family *Herpesviridae* and, along with varicella-zoster virus (human herpesvirus 3), are in the subfamily *Alphaherpesviridae*. Two distinct HSV types exist: HSV-1 and HSV-2. Infections with HSV-1 traditionally involve the face and skin above the waist; however, an increasing number of genital herpes cases are attributable to HSV-1. Infections with HSV-2 usually involve the genitalia and skin below the waist in sexually active adolescents and adults. Both HSV-1 and HSV-2 cause herpetic disease in neonates. HSV-1 and HSV-2 establish latency in sensory neurons following primary infection, with periodic reactivation causing recurrent symptomatic disease or asymptomatic viral shedding. Genital HSV-2 infection is more likely to recur than is genital HSV-1 infection.

EPIDEMIOLOGY: HSV infections can be transmitted from people who are symptomatic or asymptomatic with primary or recurrent infections.

Neonatal. The incidence of neonatal HSV infection in the United States has increased over the past 2 decades to approximately 1 in 2000 live births. HSV is transmitted to a neonate most often during birth through an infected genital tract but can be caused by an ascending infection through ruptured or apparently intact amniotic membranes. Other less common sources of neonatal infection include postnatal transmission from a parent, sibling, or other caregiver, most often from a nongenital infection (eg, mouth or hands), transmission from the mouth of a religious circumciser ("mohel") to the infant

penis during ritual Jewish circumcisions that include direct orogenital suction (metzit-zah b'peh), and intrauterine infection causing congenital malformations.

The risk of transmission to a neonate born to a person who acquires primary genital HSV infection near the time of delivery is estimated to be 25% to 60%. In contrast, the risk to a neonate born to a person shedding HSV as a result of reactivation of infection acquired during the first half of pregnancy or earlier is less than 2%. More than three quarters of infants who contract HSV infection are born to a person with no history or clinical findings suggestive of genital HSV infection during or preceding pregnancy. Therefore, a lack of history of genital HSV infection in the birthing parent does not preclude a diagnosis of neonatal HSV disease.

Children Beyond the Neonatal Period and Adolescents. Patients with primary gingivostomatitis or genital herpes usually shed virus for at least 1 week and occasionally for several weeks. Patients with symptomatic recurrences shed virus for a shorter period, typically 3 to 4 days. Intermittent asymptomatic reactivation of oral and genital herpes is common and likely occurs throughout the remainder of a person's life. The greatest concentration of virus is shed during symptomatic primary infections and the lowest during asymptomatic reactivation.

Several single gene defects have been reported that predispose to HSE. The ones characterized so far are mainly involved in the toll-like receptor 3 (TLR3) pathway, including deficiencies of TLR3 itself or in downstream signal transduction pathways (UNC93B1, TRIF/TICAM1, TRAF, TBK1) or deficiencies in innate/type 1 interferon pathways (IFN- α /- β , IFN- λ , STAT1, IRF3).

The **incubation period** for HSV infection occurring beyond the neonatal period ranges from 2 days to 2 weeks, with an average of 4 days.

DIAGNOSTIC TESTS: A nucleic acid amplification test (NAAT) usually can detect HSV DNA in CSF from neonates with CNS infection (neonatal HSV CNS disease) and from older children and adults with HSE and is the diagnostic method of choice for CNS HSV involvement. A NAAT of CSF can yield negative results in cases of HSE, especially early in the disease course. In difficult cases in which HSV CNS disease is expected but repeated CSF NAAT results are negative, histologic examination and viral culture of a brain tissue biopsy specimen is the most definitive method of confirming the diagnosis of HSE. Detection of intrathecal antibody against HSV also can assist in the diagnosis but may not be specific because of alterations in the blood-brain barrier. Viral cultures of CSF from a patient with HSE usually are negative.

HSV grows readily in traditional cell culture. Special transport media are available that allow transport to local or regional laboratories for culture. Cytopathogenic effects typical of HSV infection usually are observed 1 to 3 days after inoculation. Methods of culture confirmation include fluorescent antibody staining, enzyme immunoassays (EIAs), and monolayer culture with typing. Cultures that are negative on day 5 likely will remain negative. A viral isolate by culture is required if phenotypic antiviral susceptibility studies are to be performed.

For diagnosis of neonatal HSV infection, all of the following specimens should be obtained for each patient: (1) swab specimens from the conjunctivae, mouth, nasopharynx, and anus ("surface specimens") for HSV culture (if available) or NAAT (can use a separate swab for each site, or a single swab starting with the conjunctivae); (2) specimens of skin vesicles for HSV culture (if available) or NAAT; (3) CSF sample for

HSV NAAT; (4) whole blood sample for HSV NAAT; and (5) whole blood sample for measuring alanine aminotransferase (ALT). The performance characteristics of NAAT on skin and mucosal specimens from neonates has not been studied. Positive cultures obtained from any of the surface sites more than 12 to 24 hours after birth indicate viral replication and are, therefore, suggestive of infant infection, and therefore risk of progression to neonatal HSV disease, rather than merely contamination after intrapartum exposure. As with any NAAT, false-negative and false-positive results can occur. Any of the 3 manifestations of neonatal HSV disease (disseminated, CNS, SEM) can have associated viremia, so a positive whole blood NAAT result does not define an infant as having disseminated HSV and, therefore, should not be used to determine extent of disease and duration of treatment. Likewise, no data exist to support use of serial blood NAAT to monitor response to therapy. Rapid diagnostic techniques are available, such as direct fluorescent antibody staining of vesicle scrapings or EIA detection of HSV antigens. These techniques are as specific but less sensitive than culture.

HSV NAAT is the preferred method for detecting HSV in genital lesions. The sensitivity of viral culture is low, especially for recurrent lesions, and declines rapidly as lesions begin to heal. NAATs for HSV DNA are more sensitive and are widely available. Failure to detect HSV in genital lesions by culture or NAAT does not rule out HSV infection, because viral shedding is intermittent.

Type-specific antibodies to HSV develop during the first several weeks after infection and persist indefinitely. Approximately 20% of patients with a first episode of HSV-2 seroconvert for type-specific IgG antibody by 10 days, and the median time to seroconversion is 21 days with a type-specific enzyme-linked immunosorbent assay (ELISA); more than 95% of people seroconvert by 12 weeks following infection. Although type-specific HSV-2 antibody usually indicates previous anogenital infection, the presence of HSV-1 antibody does not distinguish anogenital from orolabial infection reliably because a substantial proportion of initial genital infections and virtually all initial orolabial infections are caused by HSV-1. Serologic testing is not useful in neonates. IgM testing for HSV-1 or HSV-2 is not useful because of the lack of a reliable commercially available IgM assay.

TREATMENT: For recommended antiviral dosages and duration of therapy with systemically administered acyclovir, valacyclovir, and famciclovir for different HSV infections, see Non-HIV Antiviral Drugs (p 1044). In pediatric patients who cannot swallow large pills, instructions for preparing a compounded liquid suspension of valacyclovir with a 28-day refrigerated shelf-life are provided in the drug's package insert.

Neonatal. Parenteral acyclovir is the treatment for neonatal HSV infections. The dosage of acyclovir is 60 mg/kg per day in 3 divided doses (20 mg/kg/dose), administered intravenously for 14 days in SEM disease and for a minimum of 21 days in CNS disease or disseminated disease. All infants with CNS involvement should have a repeat lumbar puncture performed near the end of therapy to document that the CSF is negative for HSV DNA on NAAT; in the unlikely event that the NAAT result remains positive near the end of a 21-day treatment course, intravenous acyclovir should be administered for another week, with repeat CSF NAAT performed near the end of the extended treatment period and another week of parenteral therapy if the result remains positive. Parenteral antiviral therapy should not be stopped until the CSF NAAT result for HSV DNA is negative. Consultation with a pediatric infectious diseases specialist is warranted in these cases.

Infants surviving neonatal HSV disease of any classification (disseminated, CNS, or SEM) should receive oral acyclovir suppression at 300 mg/m²/dose, administered 3 times daily for 6 months after the completion of parenteral therapy for acute disease; the dose should be adjusted monthly to account for growth. Absolute neutrophil counts should be assessed at 2 and 4 weeks after initiating suppressive acyclovir therapy and then monthly during the treatment period. Longer durations or higher doses of antiviral suppression do not further improve neurodevelopmental outcomes. Valacyclovir has not been studied for longer than 5 days in young infants, so it should not be used routinely for antiviral suppression in this age group.

All infants with neonatal HSV disease, regardless of disease classification, should have an ophthalmologic examination and neuroimaging to establish baseline brain anatomy; magnetic resonance imaging is the most sensitive imaging modality but may require sedation, so computed tomography or ultrasonography of the head are acceptable alternatives. Topical ophthalmic drug (1% trifluridine or 0.15% ganciclovir), in addition to parenteral antiviral therapy, may be indicated in infants with ocular involvement attributable to HSV infection, including a positive virologic test result from a conjunctival swab sample, and an ophthalmologist should be involved in the management and treatment of acute neonatal ocular HSV disease. The older topical antiviral agents vidarabine and iododeoxyuridine are no longer available in the United States.

Genital Infection.

Primary. Oral acyclovir therapy shortens the duration of illness and viral shedding. Valacyclovir and famciclovir are not more effective than acyclovir but offer the advantage of less frequent dosing. Intravenous acyclovir is indicated for patients with a severe or complicated primary infection that requires hospitalization. Treatment of primary herpetic lesions does not affect the subsequent frequency or severity of recurrences. Antiviral drug dosages for primary genital HSV infection are found on p 1046 in Table 4.10, Non-HIV Antiviral Drugs.

Recurrent. Antiviral therapy for recurrent genital herpes can be administered either episodically to ameliorate or shorten the duration of lesions or continuously as suppressive therapy to decrease the frequency of recurrences. Many patients benefit from antiviral therapy, and treatment options should be discussed with patients with recurrent disease. Acyclovir, valacyclovir, and famciclovir have been approved for suppression of genital herpes in immunocompetent adults. Acyclovir and valacyclovir are most commonly used in pregnant people with first-episode genital herpes or severe recurrent herpes, and acyclovir should be administered intravenously to pregnant people with severe HSV infection. Antiviral drug dosages for episodic and suppressive treatment of recurrent genital HSV infection are found on p 1046 in Table 4.10, Non-HIV Antiviral Drugs.

Mucocutaneous.

Immunocompromised Hosts. Intravenous acyclovir is effective for treatment of mucocutaneous HSV infections. Acyclovir-resistant strains of HSV have been isolated from immunocompromised people receiving prolonged treatment with acyclovir. Because these strains will also be resistant to valacyclovir, and most are also resistant to famciclovir, foscarnet is the drug of choice for acyclovir-resistant HSV isolates.

Immunocompetent Hosts. Limited data are available on effects of acyclovir on the course of primary or recurrent nongenital mucocutaneous HSV infections in immunocompetent hosts. Therapeutic benefit has been noted in a limited number of children with primary gingivostomatitis treated with oral acyclovir. A small therapeutic benefit of oral acyclovir therapy has been demonstrated among adults with recurrent herpes labialis. Famciclovir or valacyclovir also can be considered. Topical acyclovir is not therapeutic. Antiviral drug dosages for acyclovir, famciclovir, and valacyclovir for episodic and suppressive treatment of recurrent orolabial HSV infection are found on p 1046, p 1050, and p 1062–1063, respectively, in Table 4.10, Non-HIV Antiviral Drugs.

Other HSV Infections.

Central Nervous System. Patients with HSE should be treated for 21 days with intravenous acyclovir. Use of concomitant corticosteroids has not been adequately studied in people and is not routinely recommended.

Ocular. Treatment of eye lesions should be undertaken in consultation with an ophthalmologist. Several topical drugs, such as 1% trifluridine and 0.15% ganciclovir, have proven efficacy for superficial keratitis. Topical corticosteroids administered without concomitant antiviral therapy are contraindicated in suspected HSV conjunctivitis; however, ophthalmologists may choose to use corticosteroids in conjunction with antiviral drugs to treat locally invasive infections. For children with recurrent ocular lesions, oral suppressive therapy with acyclovir may be of benefit and may be indicated for months or even years.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, the following recommendations should be followed.

Neonates With HSV Infection. Neonates with HSV infection should be hospitalized and managed with contact precautions if mucocutaneous lesions are present.

Neonates Exposed to HSV During Delivery. An infant born to a person with active genital HSV lesions should be managed with contact precautions during the incubation period. The risk of HSV infection in an infant born to a person with a history of recurrent genital herpes who has no genital lesions at delivery is low, so special precautions are not necessary. Specific management options for neonates born to people with active genital HSV lesions are detailed in “Prevention of Neonatal Infection.”

Postpartum Persons With HSV Infection. People with active HSV lesions should be instructed about the importance of careful hand hygiene before and after caring for their infants. A parent or caregiver with herpes labialis or stomatitis should wear a disposable surgical mask when touching the newborn infant until the lesions have crusted. The caregiver should not kiss or nuzzle the newborn infant until lesions have resolved. Herpetic lesions on other skin sites should be covered.

Breastfeeding is acceptable if no lesions are present on the breasts and if active lesions elsewhere on the caregiver are covered (see Breastfeeding and Human Milk, p 135).

Children With Mucocutaneous HSV Infection. Contact precautions are recommended for patients with severe mucocutaneous HSV infection. Patients with localized recurrent lesions should be managed with standard precautions.

Table 3.24. Infection Classification by Genital HSV Viral Type and Type-Specific Serologic Test Results From the Birthing Parent^a

Classification of Infection in Birthing Parent	NAAT/Culture From Genital Lesion	HSV-1 and HSV-2 IgG Type-Specific Antibody Status of Birthing Parent
Documented first-episode primary infection	Positive, either virus	Both negative
Documented first-episode nonprimary infection	Positive for HSV-1	Positive for HSV-2 AND negative for HSV-1
	Positive for HSV-2	Positive for HSV-1 AND negative for HSV-2
Assumed first-episode (primary or nonprimary) infection	Positive for HSV-1 OR HSV-2	Not available
	Negative OR not available ^b	Negative for HSV-1 and/or HSV-2, OR not available
Recurrent infection	Positive for HSV-1	Positive for HSV-1
	Positive for HSV-2	Positive for HSV-2

HSV indicates herpes simplex virus; NAAT, nucleic acid amplification test; IgG, immunoglobulin G.

^aTo be used for people without a clinical history of genital herpes.

^bWhen a genital lesion is strongly suspicious for HSV, clinical judgment should supersede the virologic test results for the conservative purposes of this neonatal management algorithm. Conversely, if, in retrospect, the genital lesion was not likely to be caused by HSV and the NAAT result/culture is negative, departure from the evaluation and management in this conservative algorithm may be warranted.

Patients With HSV Infection of the CNS. Standard precautions are recommended for patients with infection limited to the CNS.

CONTROL MEASURES:

Prevention of Neonatal Infection.

During Pregnancy. The American College of Obstetricians and Gynecologists recommends that people with a primary or nonprimary first-episode outbreak (defined in Table 3.24) in pregnancy, as well as those with a clinical history of genital herpes, be offered suppressive antiviral therapy at or beyond 36 weeks of gestation. However, cases of neonatal HSV disease have occurred among infants born to people who received such antiviral prophylaxis. First-episode primary and nonprimary genital infections can result in shedding of HSV in the genital tract for several weeks even after lesions resolve.

Care of Newborn Infants Whose Birthing Parent Has Active Genital Lesions at Delivery. Neonates exposed to active HSV genital lesions at delivery should not have delayed bathing.¹ The risk of transmitting HSV to the newborn infant during delivery is influenced directly by the classification of HSV infection of the birthing individual (Table 3.24); those with primary genital HSV infections who are shedding HSV at delivery are

¹ Nolt D, O’Leary ST, Aucott SW; American Academy of Pediatrics, Committee on Infectious Diseases, Committee on Fetus and Newborn. Risks of infectious diseases in newborns exposed to alternative perinatal practices. *Pediatrics*. 2022;149(2):e2021055554

10 to 30 times more likely to transmit the virus to their newborn infants, compared with those with a recurrent genital infection. With the commercial availability of serologic tests that can reliably distinguish type-specific HSV antibodies, the means to further refine management of asymptomatic neonates delivered to people with active genital HSV lesions now is possible. The American Academy of Pediatrics developed algorithms (Fig 3.7 and 3.8) addressing evaluation and management of asymptomatic neonates following vaginal or cesarean delivery to people with active genital HSV lesions.¹ The algorithms are intended to outline one approach to the management of these neonates and may not be feasible in settings with limited access to NAATs for HSV DNA or to type-specific serologic tests. If, at any point during the evaluation outlined in the evaluation algorithm (Fig 3.7), an infant develops symptoms that could indicate neonatal HSV disease (eg, fever, hypothermia, lethargy, irritability, vesicular rash, seizures, etc), a full diagnostic evaluation should be undertaken and intravenous acyclovir therapy should be initiated. In applying this algorithm, obstetric and pediatric providers will need to work closely with their diagnostic laboratories to ensure that serologic and virologic testing is available and turnaround times are acceptable. In situations in which this is not possible, the approach detailed in the algorithm will have limited, and perhaps no, applicability.

Care of Newborn Infants Whose Birthing Parent Has a History of Genital Herpes But No Active Genital Lesions at Delivery. Most infants whose birthing parent has a history of genital herpes but no genital lesions at delivery should be observed for signs of infection (eg, vesicular lesions of the skin, respiratory distress, seizures, or signs of sepsis) but should not have specimens for surface cultures for HSV obtained at 12 to 24 hours of life and should not receive empiric parenteral acyclovir. The exception are infants born to persons with documented first-episode primary or nonprimary infections (defined in Table 3.24) during the third trimester but who have no genital lesions at delivery. These infants should have HSV surface cultures, if available, and NAATs and HSV blood NAAT obtained at ~24 hours of age, regardless of mode of delivery or birthing parent's receipt of antiviral suppressive therapy. Results of these tests should be responded to as outlined in the right side of Fig 3.7. The rationale for this recommendation is that the American College of Obstetricians and Gynecologists states that cesarean delivery may be offered to people with documented first-episode infections during the third trimester because of the possibility of prolonged viral shedding.² Education of parents and caregivers about the signs and symptoms of neonatal HSV infection during the first 6 weeks of life is prudent.

Infected Health Care Professionals. Health care professionals with cold sores who have contact with infants should cover and not touch their lesions and should comply with hand hygiene policies. Transmission of HSV infection from health care professionals with genital lesions is not likely as long as they comply with hand hygiene policies. Health care professionals with an active herpetic whitlow should not have responsibility for direct care of neonates or immunocompromised patients and should wear gloves and use hand hygiene during direct care of other patients.

FIG 3.7. ALGORITHM FOR THE EVALUATION OF ASYMPTOMATIC NEONATES FOLLOWING VAGINAL OR CESAREAN DELIVERY TO PEOPLE WITH ACTIVE GENITAL HERPES LESIONS

This algorithm should be applied only in facilities where access to NAAT and type-specific serologic testing is readily available and turnaround time for test results is appropriately short. In situations where this is not possible, the approach detailed in the algorithm will have limited, and perhaps no, applicability.

* Evaluation and treatment is indicated prior to 24 hours of age if the infant develops signs and symptoms of neonatal HSV disease. In addition, immediate evaluation and treatment may be considered if:

- There is prolonged rupture of membranes (>4–6 hours)
 - The infant is premature (≤ 37 weeks gestation)
- [†] Conjunctivae, mouth, nasopharynx, and rectum, and scalp electrode site, if present

[‡] HSV blood PCR is not utilized for assignment of disease classification

[§] Discharge following 48 hours of negative HSV cultures (if sent) is acceptable if other discharge criteria have been met, there is ready access to medical care, and a person who is able to comply fully with instructions for home observation will be present. Discharge does not need to be delayed awaiting NAAT results if all other above criteria have been met and a clear plan to follow-up on all virology results is in place. If any of these conditions is not met, the infant should be observed in the hospital until all HSV testing is finalized as negative or HSV cultures are negative for 96 hours after being set up in cell culture, whichever is shorter.

FIG 3.8. ALGORITHM FOR THE TREATMENT OF ASYMPTOMATIC NEONATES FOLLOWING VAGINAL OR CESAREAN DELIVERY TO PEOPLE WITH ACTIVE GENITAL HERPES LESIONS

Adapted from Kimberlin DW, Baley J; American Academy of Pediatrics, Committee on Infectious Diseases. Guidance on management of asymptomatic neonates born to women with active genital herpes lesions. *Pediatrics*. 2013;131(2):e635-e646

Infected Household, Family, and Other Close Contacts of Newborn Infants. Household members with herpetic skin or mouth lesions (eg, stomatitis, herpes labialis, or herpetic whitlow) should be counseled about the risk of transmission and should avoid contact of their lesions with neonates by taking the same measures as recommended for infected health care professionals, as well as avoiding kissing and nuzzling the infant while they have active lip/mouth lesions or touching the neonate while they have a herpetic whitlow.

Care of People With Extensive Dermatitis. Patients with dermatitis should not have oral contact with people with cold sores or touched by people with herpetic whitlow.

Care of Children With Mucocutaneous Infections Who Attend Child Care or School. Oral HSV infections are common among children who attend child care or school. Most of these infections are asymptomatic, with shedding of virus in saliva occurring in the absence of clinical disease. See Table 2.3 (Children in Group Child Care and Schools, p 145) for recommendations on exclusion from schools and group child care.

HSV Infections Among Wrestlers and Rugby Players.¹ HSV-1 has been identified as a cause of outbreak of skin infections among wrestlers (herpes gladiatorum) and rugby players (herpes rugbiorum) on numerous occasions, affecting up to 2.6% of high school and 7.6% of college wrestlers in the United States. During outbreaks, up to 34% of all high school wrestlers have been documented to be infected. The primary risk factor is direct skin-to-skin exposure to opponents with cutaneous lesions.

Athletes with active herpes gladiatorum or rugbiorum infections should be excluded from competition and contact practice. Prior to return to competition, skin lesions must have a firm adherent crust, athletes must have no evidence of secondary bacterial infection, and any systemic symptoms must have resolved. In addition, the athlete must have developed no new skin lesions for 72 hours and have been on appropriate antiviral therapy for at least 120 hours. When given within 24 hours of symptoms onset, valacyclovir has been shown to shorten the duration of time to HSV NAAT negativity from lesions of adolescent and adult wrestlers with recurrent herpes gladiatorum. Wrestlers receiving valacyclovir should be advised about the importance of good hydration to minimize the likelihood of nephrotoxicity. Efforts to reduce transmission should include: (1) examination of wrestlers and rugby players for vesicular or ulcerative lesions on exposed areas of their bodies and around their mouths or eyes before practice or competition by a person familiar with the appearance of mucocutaneous infections (including HSV, herpes zoster, and impetigo); (2) excluding athletes with these lesions from competition until all lesions are fully crusted or production of a physician's written statement indicating that their condition is noninfectious; and (3) cleaning of wrestling mats with a freshly prepared solution of household bleach (one quarter cup of bleach in 1 gallon of water), applied for a minimum contact time of 15 seconds at least daily, and preferably, between matches. Athletes with a history of *recurrent* herpes gladiatorum, herpes rugbiorum, or herpes labialis should be considered for suppressive antiviral therapy, again with cautionary guidance about the importance of maintaining good hydration to avoid the likelihood of nephrotoxicity. There is strong evidence that using prophylactic antiviral therapy can be useful in preventing both primary and secondary herpes outbreaks in high-risk environments, such as large wrestling camps.

Histoplasmosis

CLINICAL MANIFESTATIONS: *Histoplasma capsulatum* causes symptoms in fewer than 5% of infected people. Clinical manifestations are classified according to site (pulmonary or disseminated), duration (acute, subacute, or chronic), and pattern (primary or reactivation) of infection. Most symptomatic patients have acute pulmonary histoplasmosis, a brief, self-limited illness characterized by fever, chills, nonproductive cough, and malaise. Radiographic findings may consist of hilar or mediastinal adenopathy, diffuse interstitial or reticulonodular pulmonary infiltrates, or pulmonary nodules. Most patients recover without treatment 2 to 3 weeks after onset of symptoms.

Exposure to a large inoculum of conidia can cause severe pulmonary infection associated with high fevers, hypoxemia, diffuse reticulonodular infiltrates, and acute respiratory distress syndrome (ARDS). Mediastinal involvement, a rare complication

¹ Davies HD, Jackson MA; American Academy of Pediatrics, Committee on Infectious Diseases. Infectious diseases associated with organized sports and outbreak control. *Pediatrics*. 2017;140(4):e20172477

of pulmonary histoplasmosis, includes mediastinal lymphadenitis, which can cause airway encroachment in young children. Inflammatory syndromes (pericarditis and rheumatologic syndromes) can develop; erythema nodosum can occur in adolescents and adults. Primary cutaneous infections after trauma are uncommon. Chronic cavitary pulmonary histoplasmosis is extremely rare in children.

Progressive disseminated histoplasmosis (PDH) may occur in otherwise healthy infants and children younger than 2 years or in older children with primary or acquired cellular immune dysfunction. It can be a rapidly progressive illness following acute infection or can be a more chronic, slowly progressive disease. Early manifestations of PDH in children include prolonged fever, failure to thrive, and hepatosplenomegaly; if untreated, malnutrition, diffuse adenopathy, pneumonitis, mucosal ulceration, pancytopenia, disseminated intravascular coagulopathy, and gastrointestinal tract bleeding can ensue. PDH in older children and adults occurs most often in people with underlying immune deficiency (eg, human immunodeficiency virus/acquired immunodeficiency syndrome, solid organ transplant, hematologic malignancy, and biologic response modifiers including tumor necrosis factor antagonists). Central nervous system involvement occurs in 5% to 10% of patients with disseminated disease. Manifestations include chronic meningitis, focal brain or spinal cord lesions, encephalitis, stroke, and hydrocephalus. Chronic PDH generally occurs in adults with immune suppression and is characterized by prolonged fever, night sweats, weight loss, and fatigue; signs include hepatosplenomegaly, mucosal ulcerations, adrenal insufficiency, and pancytopenia. Clinicians should be alert to the risk of disseminated endemic mycoses in patients receiving tumor necrosis factor- α antagonists and disease-modifying antirheumatic drugs.

ETIOLOGY: *Histoplasma* strains, which may be classified into at least 8 distinct clades, are thermally dimorphic, endemic fungi that grow in the environment as a spore-bearing mold but convert to the yeast phase at 37°C.

EPIDEMIOLOGY: *H capsulatum* is highly endemic in the central and eastern United States, particularly the Mississippi, Ohio, and Missouri River valleys; Central America; the northernmost part of South America; and Argentina, but it can be found in most parts of the world (including Africa, the Americas, Asia, and Europe). *H capsulatum* case distribution may be affected by a warming climate. *H capsulatum* var *duboisii* is found only in central and western Africa.

Infection is acquired following inhalation of conidia that are aerosolized by disturbance of soil, especially when contaminated with bat guano or bird droppings. Infections occur sporadically or rarely in point-source epidemics after exposure to activities that disturb contaminated sites. In regions with endemic disease, recreational activities, such as playing in hollow trees and caving, and occupational activities, such as construction, excavation, demolition, farming, and cleaning of contaminated buildings, have been associated with outbreaks. Person-to-person transmission may occur via transplantation of infected organs, vertical transmission, and possibly through exposure to cutaneous lesions. Prior infection confers partial immunity; reinfection can occur but may require a larger inoculum.

The **incubation period** is variable but usually is 3 to 17 days.

DIAGNOSTIC TESTS: Detection of *H capsulatum* polysaccharide antigen in serum, urine, bronchoalveolar lavage fluid, or cerebrospinal fluid using a quantitative enzyme

immunoassay is the preferred method of testing. Antigen detection is most sensitive for progressive disseminated infections. Combining both urine and serum antigen testing increases the likelihood of antigen detection. Results often are transiently positive early in the course of acute, self-limited pulmonary infections. A negative test result does not exclude infection. If the result initially is positive, the antigen test also is useful for monitoring treatment response and, thereafter, identifying relapse or reinfection. Cross-reactions may occur in patients with dimorphic fungal diseases (eg, blastomycosis, coccidioidomycosis, paracoccidioidomycosis, sporotrichosis, *Emergomyces africanus* disease, and talaromycosis [formerly penicilliosis]); clinical and epidemiologic distinctions aid in differentiating these entities.

Antibody detection testing is available and is most useful in patients with subacute or chronic pulmonary disease and central nervous system involvement. Enzyme immunoassay, complement fixation and immunodiffusion are available. A fourfold increase in mycelial-phase complement fixation titers or a single titer of $\geq 1:32$ in either test is strong presumptive evidence of active or recent infection in patients exposed to or residing within endemic regions. Cross-reacting antibodies can result most commonly from *Blastomyces* and *Coccidioides* species. The immunodiffusion test is a qualitative method that is more specific, but slightly less sensitive than the complement fixation test. It commonly is used in conjunction with the complement fixation test and detects the H and M glycoproteins of *H capsulatum* found in histoplasmin. The M band develops with acute infection, generally by 6 weeks after infection, is often present in chronic forms of histoplasmosis, and persists for months to years after the infection has resolved. The H band is much less common; is rarely, if ever, found without an M band; and is indicative of chronic or severe acute forms of histoplasmosis.

Culture is the definitive method of diagnosis. *H capsulatum* organisms from bone marrow, blood, sputum, and tissue specimens grow in the mycelia (mold) phase on standard mycologic media, including Sabouraud dextrose or potato dextrose agar incubated at 25°C to 30°C in 1 to 6 weeks. The yeast phase of the organism can be recovered on primary culture using enriched media, such as brain-heart infusion agar with blood (BHIB) incubated at 35°C to 37°C. Mycelial-phase organisms in culture can be confirmed as *H capsulatum* by conversion to yeast-phase organisms by repeated passage on BHIB at 35°C to 37°C. The lysis-centrifugation method is preferred for blood and bone marrow cultures. A DNA probe for *H capsulatum* permits rapid identification of cultured isolates. Care should be taken in working with the organism in the laboratory, because mold-phase growth may release large numbers of infectious microconidia into the air.

Demonstration of typical intracellular yeast forms by examination with Wright or Giemsa stains of blood, bone marrow, or bronchoalveolar lavage specimens strongly supports the diagnosis of histoplasmosis when clinical, epidemiologic, and other laboratory studies are compatible.

TREATMENT¹: Immunocompetent children with uncomplicated or mild-to-moderate acute pulmonary histoplasmosis may not require antifungal therapy, because infection

¹ Thompson GR III, Le T, Chindamporn A, et al. Global guideline for the diagnosis and management of the endemic mycoses: an initiative of the European Confederation of Medical Mycology in cooperation with the International Society for Human and Animal Mycology [Erratum in: *Lancet Infect Dis*. 2021;21(11):e341]. *Lancet Infect Dis*. 2021;21(12):e364-e374

usually is self-limited. If the patient does not improve within 4 weeks, itraconazole should be given for 6 to 12 weeks.

Treatment is imperative for all forms of disseminated histoplasmosis, which can be either an acute (rapid onset and progression, usually in an immunocompromised patient) or chronic (slower evolution, usually in an immunocompetent patient) illness. Treatment with a lipid formulation of amphotericin B is recommended for severe acute pulmonary infection (see Table 4.7, p 1021). Methylprednisolone during the first 1 to 2 weeks of therapy may be considered if severe respiratory complications develop but should be used only in conjunction with antifungals.

After clinical improvement occurs in 1 to 2 weeks, itraconazole is recommended for an additional 12 weeks. Itraconazole is preferred over other mold-active azoles by most experts; when used in adults, itraconazole is more effective, has fewer adverse effects, and is less likely to induce resistance than is fluconazole. Serum trough concentrations of itraconazole should be 1 to 2 µg/mL. A trough level should be checked 10 days or later following initiation to ensure adequate drug exposure. When measured by high-pressure liquid chromatography, both itraconazole and its bioactive hydroxyitraconazole metabolite are reported, the sum of which should be considered in assessing the trough concentration. The itraconazole oral solution formulation is preferred over the capsule formulation because of improved absorption and should be taken on an empty stomach. However, a super bioavailable (SUBA) itraconazole is now approved by the US Food and Drug Administration for the treatment of pulmonary and extrapulmonary blastomycosis in individuals 18 years or older, with pharmacokinetic studies of this formulation demonstrating less variable absorption than conventional itraconazole capsules and a similar side effect profile; data in children are lacking.

All patients with chronic pulmonary histoplasmosis (eg, progressive cavitation of the lungs) should be treated. Mild to moderate cases should be treated with itraconazole for 1 to 2 years. Severe cases should be treated initially with a lipid formulation amphotericin B followed by itraconazole for the same duration.

Mediastinal and inflammatory manifestations of infection generally do not need to be treated with antifungal agents. Mediastinal adenitis that causes obstruction of a bronchus, the esophagus, or another mediastinal structure may improve with a brief course of corticosteroids. In these instances, itraconazole should be used concurrently and continued for 6 to 12 weeks thereafter. Dense fibrosis of mediastinal structures without an associated granulomatous inflammatory component does not respond to antifungal therapy, and surgical intervention may be necessary for severe cases. Pericarditis and rheumatologic syndromes may respond to treatment with nonsteroidal anti-inflammatory agents (indomethacin).

For treatment of moderately severe to severe progressive disseminated histoplasmosis (PDH) in an infant or child, a lipid formulation of amphotericin B is the drug of choice and usually is given for a minimum of 2 weeks. When the child has demonstrated substantial clinical improvement and a decline in the serum concentration of *Histoplasma* antigen, oral itraconazole is administered for a total of at least 12 months. Lifelong suppressive therapy with itraconazole may be required for patients with primary immunodeficiency syndromes, acquired immunodeficiency that cannot be reversed, or patients who relapse despite appropriate therapy. For those with mild to moderate PDH, itraconazole for at least 12 months is recommended. After

completion of treatment for PDH, urine antigen concentrations should be monitored for 12 months. Stable, low, and decreasing concentrations that are unaccompanied by signs of active infection may not necessarily require prolongation or resumption of treatment.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: Histoplasmosis is a reportable disease in some states.

Investigation for a common source of infection is indicated in outbreaks. Exposure to soil and dust from areas with significant accumulations of bird and bat droppings should be avoided, especially by immunocompromised individuals, including those receiving tumor necrosis factor inhibitors or disease-modifying antirheumatic drugs. If exposure is unavoidable, it should be minimized through use of respiratory protection (eg, N95 or higher respirator), gloves, and disposable clothing. Although an N95 or higher respirator is adequate in most circumstances, in environments with extremely high inoculum, powered air purifying respirators (PAPRs) with high-efficiency particulate air (HEPA) filters are recommended.

Areas suspected of being contaminated with *Histoplasma* species should be remediated. Old or abandoned structures likely to have been contaminated with bird or bat droppings should be saturated with water to reduce aerosolization of spores during demolition. Guidelines for preventing histoplasmosis have been designed for health and safety professionals, environmental consultants, and people supervising workers involved in activities in which contaminated materials are disturbed. Additional information about these guidelines is available from the National Institute for Occupational Safety and Health at www.cdc.gov/niosh/topics/histoplasmosis/default.html.

Hookworm Infections

(*Necator americanus* and *Ancylostoma* species)

CLINICAL MANIFESTATIONS: Early manifestations of hookworm infection may relate to skin penetration (stinging, burning, pruritus [“ground itch”], rash), migration through the lungs (Löfller-like pneumonitis), and early infection in the intestines (colicky abdominal pain, nausea, diarrhea). Wakana syndrome, characterized by pharyngeal itching, hoarseness, nausea, vomiting, cough, and dyspnea, may develop after ingestion of *Ancylostoma duodenale* larvae. These early features are usually mild. Individuals who are chronically infected may also have mild nonspecific or no symptoms. However, the most common clinical manifestation from chronic infection is iron deficiency anemia resulting from direct blood loss at the site where adult worms attach to the mucosa of the small intestine. Blood loss secondary to hookworm infection begins 5 to 8 weeks after initial infection. Chronic hookworm infection is a common cause of moderate and severe hypochromic, microcytic anemia in people living in resource-limited tropical countries, and heavy infection can also cause hypoproteinemia with edema. Chronic infection in children may lead to physical growth delay, deficits in cognition, and developmental delay.

ETIOLOGY: Hookworms are intestinal parasites that are included in the group of nematode pathogens infecting millions of people worldwide called soil-transmitted

helminths (STHs). The anthropophilic species infecting humans include *Necator americanus* and *Ancylostoma duodenale*. A third species, *Ancylostoma ceylanicum*, is known to infect dogs and cats but is also highly prevalent among humans in focal areas across the globe. Several other zoonotic hookworms that can cause human disease (*Ancylostoma braziliense*, *Ancylostoma caninum*, *Uncinaria stenocephala*) mainly are responsible for causing cutaneous larva migrans when filariform larvae penetrate the skin and migrate in the upper dermis, causing an intensely pruritic track. *A. caninum* rarely can migrate to the intestine and cause eosinophilic enteritis.

EPIDEMIOLOGY: Hookworm is the third most common human STH infection following ascariasis and trichuriasis. It has worldwide distribution but is most prominent in rural, tropical, and subtropical areas where soil is conducive to organism development and where contamination with human feces is common. *N. americanus* is the most widespread and prevalent human hookworm. Human hookworm infections occur in the Americas, Africa, Asia, Australia, on a number of Pacific islands, and in the Mediterranean region. Hookworm larvae and eggs survive in loose, sandy, moist, shady, well-aerated, warm soil (optimal temperature 23°C–33°C [73°F–91°F]). Hookworm eggs from stool hatch in soil in 1 to 2 days as rhabditiform larvae. These larvae develop into infective filariform larvae in soil within 5 to 10 days and can survive for 3 to 4 weeks. *N. americanus* and *Ancylostoma* transmission occur via skin penetration. *A. duodenale* infection can also occur via oral ingestion of third-stage larvae, including from human milk. Untreated infected patients can remain colonized with *A. duodenale* for approximately 1 year and can remain colonized with *N. americanus* for approximately 3 to 5 years.

The **incubation period** from exposure to development of noncutaneous symptoms is 4 to 12 weeks. Eggs appear in feces approximately 5 to 8 weeks from the time of infection.

DIAGNOSTIC TESTS: Microscopy of stool to identify eggs morphologically is the most common method for diagnosing hookworm infections. Microscopy can be performed on fresh or frozen stool samples, with direct smears or stools preserved with fixatives such as formalin; preserving stool decreases sensitivity. There are several concentrating methods that can improve sensitivity and estimation of burden of disease through egg counting (formalin-ether concentration, Kato-Katz method, McMaster technique, FLOTAC, and mini-FLOTAC). Most commercial laboratories in the United States rely on preserved stool samples and use the formalin-ether concentration method or a variation thereof. Multiple samples may be needed to detect infection; some experts recommend examining at least 3 consecutive samples using concentration techniques when index of suspicion of infection is high. Molecular techniques include qualitative or quantitative nucleic acid amplification tests (NAATs) and multiplex polymerase chain reaction (PCR) assays, but these are only available in the United States through research laboratories.

Nonspecific laboratory tests may include those for peripheral eosinophilia, anemia, and hypoproteinemia. Cutaneous larva migrans attributable to transient cutaneous infection with dog or cat hookworms is diagnosed clinically.

TREATMENT: Albendazole and mebendazole are recommended, and pyrantel pamoate is an effective alternative in the treatment of hookworm infection; only mebendazole is approved by the US Food and Drug Administration for this indication (see Drugs

for Parasitic Infections, p 1068). Albendazole should be taken with food; a fatty meal increases oral bioavailability. Pyrantel pamoate suspension can be mixed with milk or fruit juice. Studies in children as young as 1 year of age suggest that albendazole can be administered safely to this population. Retreatment is indicated for persistent or recurrent infection. Nutritional supplementation, including iron, is important when addressing associated iron deficiency anemia. Severely affected children may require blood transfusion.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended. Direct person-to-person transmission does not occur.

CONTROL MEASURES: Sanitary disposal of feces to prevent contamination of soil is necessary in areas with endemic infection. Treatment of all known infected people and screening of high-risk groups (ie, children and agricultural workers) in areas with endemic infection may help decrease environmental contamination. Wearing shoes protects against hookworm infection, although infection risk remains if other body surfaces are in contact with the soil. Periodic deworming treatments targeting preschool-aged and school-aged children have been advocated to prevent morbidity associated with heavy intestinal helminth infections. Certain populations immigrating to the United States (eg, refugees) receive presumptive albendazole treatment for STHs, including hookworm, before departure for the United States.

Human Herpesvirus 6 (Including Roseola) and 7

CLINICAL MANIFESTATIONS: Human herpesvirus 6 comprises 2 distinct viral species, HHV-6B and HHV-6A. Clinical manifestations of primary infection with human herpesvirus 6B (HHV-6B) commonly include fever, fussiness, and rhinorrhea; generalized rash occurs in almost one-third of children and roseola (exanthem subitum) occurs in 20% to 25%. Acute HHV-6B infection may also be accompanied by cervical and characteristic postoccipital lymphadenopathy, gastrointestinal tract or respiratory tract signs, and inflamed tympanic membranes. Fever may be high (temperature $>39.5^{\circ}\text{C}$ [103.0°F]) and persist for 3 to 7 days. Approximately 20% of all emergency department visits for febrile children 6 through 12 months of age are attributable to HHV-6B. Roseola is distinguished by an erythematous maculopapular rash that typically appears once fever resolves and can last hours to days. Febrile seizures, sometimes leading to status epilepticus, are the most common complication and reason for hospitalization among children with primary HHV-6B infection. Primary HHV-6B infection has been shown to account for 20% to 30% of first-time febrile seizures in young children evaluated in emergency care settings. Other reported neurologic manifestations include a bulging fontanelle and encephalopathy or rarely, encephalitis; the latter more commonly noted in infants in Japan than in the United States or Europe. Hepatitis has been reported as a rare manifestation of primary HHV-6B infection. In contrast to HHV-6B, primary infection with HHV-6A has not been associated with any recognized disease. Congenital infection with HHV-6B and HHV-6A, which occurs in approximately 1% of newborn infants, has not been linked to any clinical disease, and most cases have been shown to be attributable to inherited chromosomally integrated HHV-6 (iciHHV-6).

The clinical manifestations occurring with human herpesvirus 7 (HHV-7) infection are less clear than with HHV-6B. Most primary infections with HHV-7 presumably are asymptomatic or mild and not distinctive. Some initial infections can present as typical roseola and may account for second or recurrent cases of roseola. Febrile illnesses associated with seizures also have been documented to occur during primary HHV-7 infection.

Following infection, HHV-6B, HHV-6A, and HHV-7 remain in a latent state and may reactivate. The clinical circumstances and manifestations of reactivation in healthy people are unclear. Illness associated with HHV-6B reactivation has been described primarily among recipients of solid organ and hematopoietic cell transplants. Clinical findings associated with HHV-6B reactivation include fever, rash, hepatitis, bone marrow suppression, acute graft-versus-host disease, graft rejection, pneumonia, delirium, and encephalitis. The best characterized of these is post-transplantation acute limbic encephalitis (PALE), a specific syndrome associated with HHV-6B reactivation in the central nervous system characterized by anterograde amnesia, seizures, insomnia, confusion, and the syndrome of inappropriate antidiuretic hormone secretion. It is estimated that approximately 2% of allogeneic hematopoietic cell transplant recipients will experience HHV-6B encephalitis, with cord blood transplant recipients being at highest risk. Significant morbidity and mortality has been attributed to this complication. A few cases of central nervous system symptoms have been reported in association with HHV-7 reactivation in immunocompromised hosts, but clinical findings generally have been reported much less frequently with HHV-7 than with HHV-6B reactivation.

ETIOLOGY: HHV-6B, HHV-6A, and HHV-7 are lymphotropic viruses that are closely related members of the *Herpesviridae* family, subfamily *Betaherpesvirinae*. As betaherpesviruses, HHV-6B, HHV-6A, and HHV-7 are most closely related to cytomegalovirus. As with all human herpesviruses, they establish lifelong latency after initial acquisition. In 2012, HHV-6A and HHV-6B were recognized as distinct species rather than as variants of the same species. This increased the number of known human herpesviruses to 9.

EPIDEMIOLOGY: HHV-6B and HHV-7 cause ubiquitous infections in children worldwide. Humans are the only known natural host. Nearly all children acquire HHV-6B infection within the first 2 years of life, probably from contact with asymptotically shed infectious virus from upper respiratory secretions of a healthy family member or other close contact. Virus-specific antibody in pregnant people, which is present uniformly in the sera of infants at birth, provides transient partial protection. As transplacentally acquired antibody concentration decreases during the first year of life, the infection rate increases rapidly, peaking between 6 and 24 months of age. During the acute phase of primary infection, HHV-6B and HHV-7 can be isolated from peripheral blood mononuclear cells and HHV-7 from saliva of some children. Viral DNA subsequently may be detected throughout life by a nucleic acid amplification test (NAAT) in multiple body sites, including blood mononuclear cells, saliva, and salivary glands. Infections occur throughout the year without a seasonal pattern. Secondary cases rarely are identified. Occasional outbreaks of roseola have been reported.

Several genetic mutations have been associated with severe central nervous system disease during primary HHV-6B infection. These include RandBP2, POLG, and carnitine palmitoyl-transferase 2 gene mutations.

Congenital infection occurs in approximately 1% of newborn infants, as determined by the presence of HHV-6A or HHV-6B DNA in cord blood. Most congenital infections appear to result from the germline passage of inherited chromosomally integrated HHV-6 (iciHHV-6) from either parent, a unique mechanism of transmission of human viral congenital infection. Transplacental HHV-6 infection also may occur from reinfection or reactivation of HHV-6 in the pregnant person or possibly from reactivated iciHHV-6 in the pregnant person. HHV-6 has not been identified in human milk. Congenital infection typically is asymptomatic, and the clinical implications of iciHHV-6 are not fully known. However, reactivation of iciHHV-6 in severely immunocompromised hosts is possible and can be associated with disease.

HHV-7 infection usually occurs later in childhood than HHV-6B infection. By adulthood, the seroprevalence of HHV-7 is approximately 85%. Infectious HHV-7 is present in more than 75% of saliva specimens obtained from healthy adults. Acquisition of virus via infected respiratory tract secretions of healthy contacts is the probable mode of transmission of HHV-7 to young children. HHV-7 DNA has been detected in human milk, peripheral blood mononuclear cells, cervical secretions, and other body sites. Congenital HHV-7 infection has not been demonstrated.

The mean **incubation period** for HHV-6B is 9 to 10 days. For HHV-7, the **incubation period** is not known.

DIAGNOSTIC TESTS: Multiple assays for detection of HHV-6 and HHV-7 DNA have been developed; some are available commercially, but because laboratory diagnosis of HHV-6 or HHV-7 usually does not influence clinical management (infections among the severely immunocompromised are an exception), these tests have limited utility in clinical practice.

Reference laboratories offer diagnostic testing for HHV-6B, HHV-6A, and HHV-7 infections by detection of viral DNA by NAAT in blood, cerebrospinal fluid (CSF), other body fluids, or tissue specimens. However, detection of HHV-6A, HHV-6B, or HHV-7 DNA by NAAT might not differentiate between new infection, persistence or reactivation of virus from past infection, or iciHHV-6. At least 1 multiplexed NAAT diagnostic panel designed to detect agents of meningitis and encephalitis in CSF containing HHV-6 as one of its target pathogens has been cleared by the US Food and Drug Administration; however, given the prevalence of iciHHV-6 (1%), which yields a positive CSF NAAT result, a positive test result should be interpreted with caution in a patient with no underlying risk factors and no findings to suggest encephalitis. Quantitative NAATs have been used for monitoring the effectiveness of antiviral treatment in immunocompromised patients with viral reactivation.

Inherited chromosomal integration of HHV-6 is suggested when NAAT results are consistently positive for HHV-6 DNA in whole blood, tissue, or other fluids, often with high viral loads (eg, 1×10^6 copies in whole blood, which with a normal white blood cell count is approximately 1 copy of HHV-6 DNA per nucleated cell). Droplet digital polymerase chain reaction (PCR) or quantitative comparison of viral DNA copies to human cell number copies in whole blood samples may also be used to identify iciHHV-6. iciHHV-6 can be suggested by testing whole blood from both parents to see if one of them has a high viral load and can be confirmed by detection of HHV-6 DNA in hair follicles in research settings. HHV-6 viral loads in acellular fluids, such as plasma and CSF, are variable in people with iciHHV-6 because of unpredictable degrees of contamination with cell contents and cannot be used to infer chromosomal integration.

Serologic tests including immunofluorescent antibody assay, virus neutralization, immunoblot, and enzyme immunoassay (EIA) are often difficult to interpret. A fourfold increase in serum antibody concentration alone does not necessarily indicate new infection, because an increase in titer may occur with reactivation and in association with other infections, especially other betaherpesvirus infections. However, documented seroconversion is considered evidence of recent primary infection in infants and young children, and serologic tests may be useful for epidemiologic studies. Detection of specific immunoglobulin (Ig) M antibody is not reliable for diagnosing new infection, because IgM antibodies to HHV-6 and HHV-7 are not always detectable in children with primary infection and also may be present in asymptomatic previously infected people. These antibody assays do not differentiate HHV-6A from HHV-6B infections. Detection of low-avidity HHV-6 or HHV-7 antibody with subsequent maturation to high-avidity antibody has been used in such situations to identify recent primary infection.

TREATMENT: Management is supportive. The use of ganciclovir (and, therefore, valganciclovir) or foscarnet may be beneficial for immunocompromised patients with HHV-6B or HHV-7 disease and is recommended for treatment of HHV-6B encephalitis in hematopoietic cell and solid organ transplant patients. Antiviral resistance may occur. Routine monitoring of HHV-6 and HHV-7 DNA concentrations in blood during transplantation is not recommended. HHV-6 and HHV-7 have been reported as associated with various additional clinical syndromes in immunocompetent hosts, including multiple sclerosis, drug hypersensitivity, and uterine infection leading to infertility. None of these associations are generally accepted as etiologic, and treatment of HHV-6 or HHV-7 in association with these syndromes is not recommended.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: None.

Human Herpesvirus 8

CLINICAL MANIFESTATIONS: Human herpesvirus (HHV-8), also known as Kaposi sarcoma-associated herpesvirus (KSHV), is the cause of Kaposi sarcoma (KS), primary effusion lymphoma, multicentric Castleman disease (MCD), and the Kaposi sarcoma herpesvirus-associated inflammatory cytokine syndrome (KICS). HHV-8 also is a potential trigger of hemophagocytic lymphohistiocytosis (HLH). In regions of the world with endemic HHV-8, a nonspecific primary infection syndrome in immunocompetent children consists of fever and a maculopapular rash, often accompanied by upper respiratory tract symptoms. Primary infection among immunocompromised people tends to present with more severe manifestations including pancytopenia, fever, rash, lymphadenopathy, splenomegaly, diarrhea, arthralgia, disseminated disease, and/or KS. In parts of Africa where HHV-8 is endemic, KS is a frequent, aggressive malignancy among children both with and without human immunodeficiency virus (HIV) infection. Clinical presentations can vary, but younger children most often present with prominent (>2 cm), firm, nontender lymphadenopathy, associated cytopenias (significant anemia and thrombocytopenia), and frequently without the characteristic cutaneous lesions or “woody” edema more commonly seen in adults. In the United States, KS is rare in children and occurs primarily in adults with poorly controlled HIV

infection. Immune reconstitution inflammatory syndrome (IRIS)-KS can occur, most notably among HIV-positive children adopted from countries with endemic HHV-8. Among solid organ and, less often, hematopoietic cell transplant recipients, KS is an important cause of cancer-related deaths. Primary effusion lymphoma is rare among children. MCD has been described in immunosuppressed and immunocompetent children, but the proportion of cases attributable to infection with HHV-8 is unknown.

ETIOLOGY: HHV-8 is a member of the family *Herpesviridae*, the *Gammaherpesvirinae* subfamily, and the *Rhadinovirus* genus, and is a DNA virus closely related to Epstein-Barr virus and to herpesvirus saimiri of monkeys.

EPIDEMIOLOGY: In areas of Africa, the Amazon basin, the Mediterranean, and the Middle East with endemic HHV-8, seroprevalence ranges from approximately 30% to 80%. Low rates of seroprevalence, generally less than 5%, have been reported in the United States, Northern and Central Europe, and most areas of Asia. Higher rates, however, occur in specific geographic regions, among adolescents and adults with or at high risk of acquiring HIV infection, injection drug users, and children adopted from endemic regions including some Eastern European countries.

Acquisition of HHV-8 in areas with endemic infection frequently occurs before puberty, likely by exposure to saliva of close contacts. Virus is shed frequently in saliva of infected people and becomes latent for life in peripheral blood mononuclear cells and lymphoid tissue. In areas where infection is not endemic, sexual transmission appears to be the major route of infection, especially among men who have sex with men. Studies from areas with endemic infection have suggested transmission may occur by blood transfusion, but in the United States, evidence for this is lacking. Transplantation of infected donor organs has been documented to result in HHV-8 infection in the recipient. HHV-8 DNA has been detected in blood drawn at birth from infants born to HHV-8 seropositive people, but vertical transmission seems to be rare. Viral DNA has also been detected in human milk, but transmission via human milk is yet to be proven.

The **incubation period** of HHV-8 is unknown.

DIAGNOSTIC TESTS: Nucleic acid amplification tests (NAATs) and serologic assays for HHV-8 are available. NAATs may be used on peripheral blood, fluid from body cavity effusions, and tissue biopsy specimens. When KS is suspected, biopsy with histologic confirmation is the gold standard. Detection of HHV-8 in peripheral blood specimens by NAAT also has been used to identify exacerbations of other HHV-8-associated diseases, primarily MCD and KICS (especially at high copy number in these 2 diseases); however, HHV-8 DNA can be detected in the peripheral blood of asymptotically infected people, and conversely HHV-8 infected people may not have active viremia.

Currently available serologic assays measuring antibodies to HHV-8 include immunofluorescence antibody (IFA) assay, enzyme immunoassays (EIAs), and Western blot assays using recombinant HHV-8 proteins. These serologic assays detect both latent and lytic infection, but each has challenges with accuracy or convenience, with resulting limitations on their use in the diagnosis and management of acute clinical disease.

TREATMENT: Epidemic KS (KS in children with HIV) should be treated with both antiretroviral therapy plus chemotherapy based on clinical staging. Retrospective cohort studies and in vitro assays suggest that antiretroviral therapy may inhibit

HHV-8 replication. In acquired immunodeficiency syndrome (AIDS)-associated KS, for participants receiving highly active antiretroviral therapy, monotherapy with either paclitaxel or pegylated liposomal doxorubicin are preferred agents. For clinically significant disease with tissue or fluid (primary effusion lymphoma) burden, the most widely used treatment modality is chemotherapy. Treatment of transplant KS may benefit from reduction in immunosuppressive therapy and use of sirolimus in lieu of tacrolimus as the suppressive agent.

Several antiviral agents have in vitro activity against HHV-8. Valganciclovir has been shown to inhibit HHV-8 replication in the only randomized trial of an antiviral drug for this infection. Case reports document an effect of ganciclovir, valganciclovir, ganciclovir combined with zidovudine, cidofovir, and foscarnet. Valacyclovir and famciclovir more modestly reduce HHV-8 replication. Antiviral therapy may play a more significant role in the treatment of diseases associated with active, lytic HHV-8 replication, specifically MCD and KICS, but this remains to be well established.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: Although there are no standard guidelines on preventing HHV-8 transmission, avoidance of behavioral practices that lead to exposure to saliva might be effective.

Human Immunodeficiency Virus Infection¹

CLINICAL MANIFESTATIONS: Human immunodeficiency virus (HIV) infection results in a wide array of clinical manifestations. HIV type 1 (HIV-1) is much more common in the United States than HIV type 2 (HIV-2). Unless otherwise specified, this chapter addresses HIV-1 infection. Acquired immunodeficiency syndrome (AIDS) is the name given to an advanced stage of HIV infection based on specific criteria for children, adolescents, and adults that are established by the Centers for Disease Control and Prevention (CDC).

Acute retroviral syndrome is estimated to develop in 40% to 90% of adolescents and adults within the first few weeks after they become infected with HIV and is characterized by nonspecific mononucleosis-like symptoms, including fever, malaise, lymphadenopathy, and skin rash.

Clinical manifestations of untreated pediatric HIV infection include unexplained fevers, generalized lymphadenopathy, hepatomegaly, splenomegaly, failure to thrive, persistent oral and diaper candidiasis, recurrent diarrhea, parotitis, hepatitis, central nervous system (CNS) disease (eg, encephalopathy, hyperreflexia, hypertonia, floppiness, developmental delay), lymphoid interstitial pneumonia, recurrent invasive bacterial infections, and viral, parasitic, and fungal opportunistic infections (OIs).²

¹ For a complete listing of current policy statements from the American Academy of Pediatrics regarding human immunodeficiency virus and acquired immunodeficiency syndrome, see <https://publications.aap.org/pediatrics/collection/537/Committee-on-Pediatric-and-Adolescent-HIV>.

² Panel on Opportunistic Infections in Children with and Exposed to HIV. Guidelines for the Prevention and Treatment of Opportunistic Infections in Children With and Exposed to HIV. Department of Health and Human Services. Available at: <https://clinicalinfo.hiv.gov/en/guidelines/hiv-clinical-guidelines-pediatric-opportunistic-infections/whats-new>

In the era of antiretroviral therapy (ART), there has been a substantial decrease in frequency of all OIs. In the pre-ART era, the most common OIs observed among children in the United States were infections caused by invasive encapsulated bacteria, *Pneumocystis jirovecii* (previously called *Pneumocystis carinii*, hence the still-used acronym PCP for *Pneumocystis carinii* pneumonia), varicella-zoster virus, cytomegalovirus, herpes simplex virus, *Mycobacterium avium* complex, *Cryptococcus neoformans*, and *Candida* species. Less commonly observed opportunistic pathogens included Epstein-Barr virus (EBV), *Mycobacterium tuberculosis*, *Cryptosporidium* species, *Cystoisospora* (formerly *Isospora*) species, other enteric pathogens, *Aspergillus* species, and *Toxoplasma gondii*.

Immune reconstitution inflammatory syndrome (IRIS) is a paradoxical clinical deterioration often seen in severely immunosuppressed individuals that occurs shortly after the initiation of ART. Local and/or systemic symptoms develop secondary to an inflammatory response as cell-mediated immunity is restored. IRIS is observed in patients with previous infections with mycobacteria (including *Mycobacterium tuberculosis*), bacille Calmette-Guérin (BCG) vaccine, herpesviruses, and fungi (including *Cryptococcus* species).

Malignant neoplasms in children living with HIV infection are relatively uncommon, but leiomyosarcomas and non-Hodgkin B-cell lymphomas of the Burkitt type (including those in the CNS) occur more commonly in children living with HIV infection than in immunocompetent children. Kaposi sarcoma, caused by human herpesvirus 8, is rare in children in the United States but has been documented in children living with HIV who have emigrated from sub-Saharan African countries. The incidence of malignant neoplasms in children living with HIV has decreased during the ART era.

ETIOLOGY: HIV-1 and HIV-2 are cytopathic lentiviruses (genus *Lentivirus*) belonging to the family *Retroviridae*. Four distinct genetic groups of HIV exist: M, N, O, and P. Group M viruses are the most prevalent worldwide and comprise 10 genetic subtypes, or clades, known as A, B, C, D, F, G, H, J, K, and L, each of which has a distinct geographic distribution.

HIV-2, the second AIDS-causing virus, is found predominantly in West Africa. Nine HIV-2 groups (A through I) have been documented, of which groups A and D are presently circulating. HIV-2 has a milder disease course with a longer time to development of AIDS than HIV-1. Accurate diagnosis of HIV-2 is important clinically, because HIV-2 is intrinsically resistant to nonnucleoside reverse transcriptase inhibitors (NNRTIs) and the fusion inhibitor enfuvirtide.

EPIDEMIOLOGY: Humans are the only known reservoir for HIV-1 and HIV-2. Latent virus persists in peripheral blood mononuclear cells and in cells of the brain, bone marrow, and genital tract even when plasma viral load is undetectable. Only blood, semen, preseminal fluid, rectal fluids, cervicovaginal secretions, and human milk have been implicated in transmission of infection.

Established modes of HIV transmission include: (1) sexual contact (vaginal, anal, or orogenital); (2) percutaneous blood exposure (from contaminated needles or other sharp materials); (3) mucous membrane exposure to contaminated blood or other body fluids; (4) perinatal transmission during prepartum, intrapartum, and postpartum periods, including breastfeeding postnatally; and (5) transfusion with contaminated blood

products. Cases of HIV transmission from caregivers living with HIV to children through feeding blood-contaminated premasticated food and from contact of nonintact skin with blood-containing body fluids have been reported in the United States. As a result of highly effective screening assays and protocols, transfusion of blood, blood components, and clotting factors has virtually been eliminated as a cause of HIV transmission in the United States since 1985. Since the mid-1990s, the number of reported pediatric AIDS cases has decreased significantly, primarily because of effective measures to prevent perinatal transmission of HIV and the widespread availability of ART for children living with HIV.

In the absence of breastfeeding, the risk of HIV infection for infants born to untreated people living with HIV (PWH) in the United States is approximately 25%, with most transmission occurring near the time of delivery. Viral load of the birthing person is the most critical determinant of perinatal transmission of HIV, although transmission has been observed across the entire range of viral loads. Current US guidelines recommend cesarean section before labor and before rupture of membranes at 38 completed weeks of gestation for PWH with HIV RNA >1000 copies/mL (irrespective of antiretroviral [ARV] use in pregnancy) or unknown HIV RNA near time of delivery (within 4 weeks of delivery) to minimize perinatal transmission of HIV. Cesarean delivery is not needed for reduction of HIV perinatal transmission risk in people receiving ART with HIV RNA ≤1000 copies/mL near time of delivery and should not be performed unless otherwise indicated. (<https://clinicalinfo.hiv.gov/en/guidelines/perinatal/intrapartum-care-for-people-with-hiv?view=full>).

The rate of acquisition of HIV infection among infants has decreased significantly in the United States. The rate of new HIV infections among adolescents and young adults aged 13 to 24 years overall also is decreasing but is increasing among young men who have sex with men (MSM) in this age group. HIV infection in adolescents occurs disproportionately among youth from racial or ethnic minority groups and is attributable primarily to sexual exposure.

INCUBATION PERIOD: The usual age of onset of symptoms is approximately 12 to 18 months of age¹ for untreated infants and children in the United States who acquire HIV infection through perinatal transmission. However, some children living with HIV become ill in the first few months of life, whereas others remain relatively asymptomatic for more than 5 years and, rarely, until early adolescence.

Acute retroviral syndrome occurring in adolescents and adults following HIV acquisition occurs 7 to 14 days following viral acquisition and lasts for 5 to 7 days. Only a minority of patients are ill enough to seek medical care for acute retroviral syndrome, although more may recall a prior viral illness when queried later.

DIAGNOSTIC TESTS:

Serologic Assays. Immunoassays are used widely as the initial test for serum HIV antibody or for p24 antigen (see below) and HIV antibody. Serologic assays that are cleared by the US Food and Drug Administration (FDA) for the diagnosis of HIV include:

¹ Centers for Disease Control and Prevention. HIV Surveillance Report, 2017. Vol 29. Centers for Disease Control and Prevention; November 2018. Available at: www.cdc.gov/hiv/pdf/library/reports/surveillance/cdc-hiv-surveillance-report-2017-vol-29.pdf

- Antigen/antibody combination immunoassays (fourth-generation tests) that detect HIV-1/HIV-2 antibodies as well as HIV-1 p24 antigen (see below): recommended for initial testing
- HIV-1/HIV-2 immunoassays that detect both IgG and IgM (third-generation antibody tests): alternative for initial testing
- HIV-1/HIV-2 antibody differentiation immunoassay that differentiates HIV-1 antibodies from HIV-2 antibodies (HIV-1/HIV-2 test): recommended for supplemental testing to confirm the results from the initial test
- HIV-1 and HIV-2 antibodies (separate results for each) as well as p24 antigen (fifth-generation test): FDA cleared for initial HIV screening but not as a confirmatory test

The 2018 CDC HIV laboratory testing algorithm (<https://stacks.cdc.gov/view/cdc/50872>) recommends an initial FDA-approved HIV-1/HIV-2 antigen/antibody combination immunoassay (fourth-generation assay). Specimens with a reactive antigen/antibody immunoassay result should be tested with an FDA-approved HIV-1/HIV-2 antibody differentiation immunoassay. Specimens that are reactive on the initial antigen/antibody immunoassay and nonreactive or indeterminate on the HIV-1/HIV-2 antibody differentiation immunoassay should be tested with an FDA-approved HIV-1 nucleic acid amplification test (NAAT). If acute HIV infection or previously undiagnosed HIV with end-stage AIDS is suspected, virologic testing may be indicated because of false-negative antibody assay results in these populations.

Nucleic Acid Amplification Tests. Plasma HIV DNA or RNA assays have been used to diagnose HIV infection. DNA nucleic acid amplification tests (NAATs) can detect 1 to 10 DNA copies of proviral DNA in peripheral blood mononuclear cells and are used qualitatively to diagnose HIV infection. Quantitative RNA NAATs (viral load) cleared by the FDA provide results that serve as a predictor of disease progression and are useful in monitoring changes in plasma HIV RNA levels during treatment with ART.

Reprogramming of T lymphocytes using gammaretroviral or lentiviral vectors in chimeric antigen receptor T cell (CAR-T cell) and lentiviral-based gene therapy may interfere with long terminal repeat (LTR) genomes in HIV NAATs, resulting in false-positive result. Laboratories should have appropriate alternate HIV-1 NAAT testing platforms made available for this emerging patient population.

HIV-2 Detection. Most HIV immunoassays currently approved by the FDA detect but do not routinely differentiate between HIV-1 and HIV-2 antibodies. It is important to notify the laboratory when ordering serologic tests for a patient in whom HIV-2 infection is a possibility so that FDA-approved HIV-1/HIV-2 antibody differentiation immunoassays can be used. There is at least 1 FDA approved qualitative diagnostic RNA test that detects and can confirm HIV-2 infection.

Diagnosis of Perinatally and Postnatally Acquired Infection. Because children born to PWH passively acquire antibodies from the birthing parent, antibody assays are not informative for the diagnosis of infection in children younger than 18 months unless assay results are negative. Therefore, laboratory diagnosis of HIV infection during the first 18 months of life is based on HIV NAATs (Table 3.25). In children 18 to 24 months and older, HIV antibody assays can be used for diagnosis. Most children serorevert by 18 months of age; however, delayed seroreversion beyond 18 months of age can occur. In one study, seroreversion occurred at a median age of 13.9 months, but 14%

Table 3.25. Laboratory Diagnosis of HIV Infection^a

Test	Comment
HIV DNA NAAT or RNA NAAT	Preferred tests to diagnose HIV infection in infants and children younger than 18–24 months; highly sensitive and specific by 2 weeks of age and available; DNA test performed on peripheral blood mononuclear cells; RNA test performed on plasma.
HIV p24 Ag	Less sensitive, false-positive results during first month of life, variable results; not recommended.
ICD p24 Ag	Negative test result does not rule out infection; not recommended.
HIV culture	Expensive, not readily available, requires up to 4 weeks for results; not recommended.

Ag indicates antigen; HIV, human immunodeficiency virus; ICD, immune complex dissociated; NAAT, nucleic acid amplification test.

^aAdapted from Read JS; American Academy of Pediatrics, Committee on Pediatric AIDS. Diagnosis of HIV-1 infection in children younger than 18 months in the United States, *Pediatrics*. 2007;120(6):e1547–e1562 (Reaffirmed April 2010, February 2015)

of infants remained seropositive after 18 months, 4.3% remained seropositive after 21 months, and 1.2% remained seropositive after 24 months.

HIV-1 RNA or DNA NAATs for diagnosis of infection in infants are equally recommended in current diagnostic guidelines (<https://clinicalinfo.hiv.gov/en/guidelines/perinatal/whats-new-guidelines>). Because DNA NAAT detects proviral DNA in cells while HIV RNA tests measure viral RNA in plasma, there is the potential for DNA testing to be more sensitive in infants with very low viral loads. However, studies have shown that RNA and DNA NAATs for the diagnosis of HIV-1 infection in infants produce comparable results, leading to the current recommendation that either assay can be used in this setting. HIV-1 RNA assays will identify 25% to 58% of infants infected with HIV in the first week of life, 89% by 1 month of age, and 90% to 100% by 2 to 3 months of age. An HIV RNA assay result with only a low HIV RNA copy number in an HIV-exposed infant may indicate a false-positive result. Repeat testing is recommended, and consultation with a pediatric HIV expert should be considered in these circumstances.

In HIV-exposed infants, diagnostic testing with HIV DNA or RNA assays is recommended at 14 to 21 days of age and, if results are negative, again at 1 to 2 months of age and at 4 to 6 months of age (Fig 3.9). An infant is considered infected if 2 samples from 2 different time points have positive results by DNA or RNA NAAT. For infants at higher risk of perinatal HIV transmission, additional virologic diagnostic testing is recommended at birth and at 8 to 10 weeks of life (which is 2 to 4 weeks after cessation of antiretroviral prophylaxis) (Fig 3.9). If testing is performed shortly after birth, umbilical cord blood should not be used because of possible contamination with the birthing parent's blood. Infants in whom HIV infection is diagnosed should promptly be transitioned from neonatal ARV prophylaxis to antiretroviral treatment (ART) if not already on presumptive HIV therapy for high-risk infants as per perinatal guidelines (<https://clinicalinfo.hiv.gov/en/guidelines/perinatal/antiretroviral-management-newborns-perinatal-hiv-exposure-or-hiv-infection?view=full>).

FIG 3.9. RECOMMENDED VIROLOGIC TESTING SCHEDULES FOR INFANTS EXPOSED TO HIV BY PERINATAL HIV TRANSMISSION RISK

	Birth	2 weeks	3 weeks	4 weeks	8 weeks	10 weeks	4 months	6 months
Low Risk		NAT		NAT			NAT	
Higher Risk	NAT*	NAT		NAT	NAT*		NAT	

NAT indicates nucleic acid amplification test (referred to as NAAT in this chapter).

Low Risk: Infants born to people who received standard antiretroviral therapy (ART) during pregnancy with sustained viral suppression (usually defined as confirmed HIV RNA level below the lower limits of detection of an ultrasensitive assay) and no concerns related to adherence.

Higher Risk: Infants born to people with HIV infection who did not receive prenatal care, did not receive antepartum or intrapartum antiretrovirals (ARVs), received intrapartum ARV drugs only, initiated ART late in pregnancy (late second or third trimester), received a diagnosis of acute HIV infection during pregnancy, or had detectable HIV viral loads close to the time of delivery, including those who received ARV drugs and did not have sustained viral suppression.

*For higher-risk infants, additional virologic diagnostic testing should be considered at birth and 2 to 4 weeks after cessation of ARV prophylaxis (ie, at 8–10 weeks of life).

Reproduced with permission from Spach DH. Preventing Perinatal HIV Transmission. Seattle, WA: National HIV Curriculum, Infectious Diseases Education and Assessment, University of Washington. Available at: www.hiv.uw.edu/go/prevention/preventing-perinatal-transmission/core-concept/all.

No additional HIV testing of any kind (HIV RNA, DNA NAAT, HIV antibody, HIV antigen/antibody) is routinely needed for nonbreastfed infants who meet the criteria for definitive exclusion of HIV and who have had no known or suspected HIV exposure after birth. Definitive exclusion of HIV infection in nonbreastfed infants is based on 2 or more negative virologic test results with 1 negative test result obtained at age ≥ 1 month and 1 at age ≥ 4 months, or 2 negative HIV antibody test results from separate specimens that were obtained at age ≥ 6 months (<https://clinicalinfo.hiv.gov/en/guidelines/perinatal/diagnosis-hiv-infection-infants-and-children?view=full>).

Adolescents and HIV Testing. The American Academy of Pediatrics (AAP) recommends that routine HIV antibody screening be offered to all youth 15 years or older at least once in health care settings. Following initial screening, youth at increased risk, including those who are sexually active, should be rescreened at least annually, potentially as frequently as every 3 to 6 months if at very high risk (MSM, active injection drug users, transgender youth; having sexual partners with known HIV infection; exchanging sex for drugs or money; or those who have had a diagnosis of or request testing for other sexually transmitted infections [STIs], including mpox).^{1,2} Use of any FDA-

¹ Hsu KK, Rakhmanina NY; American Academy of Pediatrics, Committee on Pediatric AIDS. Clinical report. Adolescents and young adults: the pediatrician's role in HIV testing and pre- and post-exposure HIV prophylaxis. *Pediatrics*. 2022;149(1):e2021055207

² Curran KG, Eberly K, Russell OO, et al. HIV and sexually transmitted infections among persons with monkeypox—eight U.S. jurisdictions, May 17–July 22, 2022. *MMWR Morb Mortal Wkly Rep*. 2022;71(36):1141–1147

cleared HIV antibody test is appropriate, except in youth with recent or ongoing antiretroviral prophylaxis use, such as HIV-1 preexposure prophylaxis (PrEP) and post-exposure prophylaxis (PEP). Recent data have shown that performance of HIV tests in persons who acquire HIV infection while taking ARV medications for such indications may be suboptimal compared with persons not exposed to these medications at or after the time of HIV acquisition because of inhibition of early viral replication that can affect the timing of the antibody development. In youth who have taken oral PrEP or PEP in the past 3 months or have received a long-acting PrEP injection in the past 12 months, an HIV antigen/antibody test **and** a qualitative or quantitative HIV-1 RNA test should be used. For any positive test result, immediate referral to an HIV specialist is appropriate to confirm diagnosis and initiate management. HIV testing is recommended and should be routine for all patients in STI clinics and those seeking treatment for STIs in other clinical settings.

Suspicion of acute retroviral syndrome should prompt urgent assessment with an antigen/antibody immunoassay or HIV RNA NAAT in conjunction with an antibody test. If the immunoassay result is negative or indeterminate, then testing for HIV RNA using a NAAT should follow. Clinicians should not assume that a laboratory report of a negative HIV antibody test result indicates that the necessary RNA screening for acute HIV infection has been conducted. HIV self-testing kits only detect HIV antibodies and, therefore, will not detect acute HIV infection.

TREATMENT:

Antiretroviral Therapy. Consultation with an expert in pediatric HIV infection is recommended in the care of infants, children, and adolescents living with HIV. Current treatment recommendations for HIV-infected infants and children (<https://clinicalinfo.hiv.gov/en/guidelines/pediatric-arv/whats-new-guidelines>; <https://nccc.ucsf.edu/clinician-consultation/hiv-aids-management/>) as well as adolescents (<https://clinicalinfo.hiv.gov/en/guidelines/adult-and-adolescent-arv/whats-new-guidelines>) are available online. Whenever possible, enrollment of infants, children, and adolescents living with HIV in clinical trials should be encouraged. Information about clinical trials for infants, children, and adolescents living with HIV can be obtained by contacting the AIDS Clinical Trials Information Service (www.actis.org/).

ART is indicated all for pediatric patients living with HIV and should be initiated as soon as possible after diagnosis of HIV infection is established. Initiation of treatment of adolescents generally follows guidelines for adults and is recommended strongly for all adolescents or adults living with HIV regardless of CD4+ T-lymphocyte count if medication adherence readiness is apparent. In general, ART with at least 3 active drugs is recommended for all individuals requiring ARV therapy. ARV resistance testing (viral genotyping) is recommended before starting treatment, but ART can be initiated prior to results in most cases. Sustained suppression of virus to undetectable levels is the desired goal. A change in ART should be considered if there is evidence of disease progression (virologic, immunologic, or clinical), drug toxicity or intolerance, development of drug resistance, or availability of data suggesting the possibility of a superior or simpler regimen.

Opportunistic Infections. Guidelines for prevention and treatment of OIs in children (<https://clinicalinfo.hiv.gov/en/guidelines/pediatric-opportunistic>

infection/whats-new) and adolescents and adults (**<https://clinicalinfo.hiv.gov/en/guidelines/adult-and-adolescent-opportunistic-infection/whats-new-guidelines>**) provide indications for administration of drugs for prevention, as well as treatment, of infection with *P jirovecii*, *M avium* complex, cytomegalovirus, *T gondii*, and other organisms.

Immunization Recommendations (also see Immunization in Special Clinical Circumstances, p 87, and Table 1.17, p 94).¹ All recommended childhood immunizations should be administered to HIV-exposed infants. If HIV infection is confirmed, guidelines for children living with HIV should be followed. Children and adolescents living with HIV should be immunized as soon as is age appropriate with all non-live and mRNA vaccines. Inactivated (non-live) influenza vaccine (IIV) should be administered annually according to the most current recommendations. The 3-dose series of human papillomavirus vaccine is indicated in adolescents living with HIV (**https://redbook.solutions.aap.org/SS/Immunization_Schedules.aspx**).

The live-virus measles, mumps, and rubella (MMR) vaccine and monovalent varicella vaccine can be administered to children and adolescents living with HIV without severe immunosuppression. Severely immunocompromised infants, children, adolescents, and young adults living with HIV (for people ≤ 5 years of age, defined as a CD4+ T-lymphocyte percentage $<15\%$; for people >5 years of age, defined as a CD4+ T-lymphocyte percentage $<15\%$ **or** a CD4+ T-lymphocyte count <200 lymphocytes/mm³) should not receive measles virus-containing vaccine, because vaccine-related pneumonia has been reported. The quadrivalent measles, mumps, rubella, and varicella (MMRV) vaccine should not be administered to any infant or child living with HIV, regardless of degree of immunosuppression, because of lack of safety data in this group.

Rotavirus vaccine should be administered to all infants exposed to or infected with HIV irrespective of CD4+ T-lymphocyte percentage or count.

All children living with HIV should receive a dose of 23-valent polysaccharide pneumococcal vaccine after turning 24 months of age if at least 8 weeks have passed since the last 13-valent or 15-valent pneumococcal conjugate vaccine and they have not previously received at least 1 dose of 20-valent pneumococcal conjugate vaccine (see *Streptococcus pneumoniae* [Pneumococcal] Infections, p 810).

Children living with HIV who are 5 years and older and have not received *Haemophilus influenzae* type b (Hib) vaccine should receive 1 dose of Hib vaccine (see Table 3.13, p 408).

Children and adolescents living with HIV should receive COVID-19 vaccine, if authorized or approved by the FDA for their age group. Preliminary data in individuals living with HIV who have received COVID-19 vaccines indicate good humoral responses in those with well-controlled infection on ART with normal CD4+ T-lymphocyte counts. However, diminished responses were noted in individuals with advanced or untreated HIV infection.

Infants and children 2 months or older living with HIV infection should receive an age-appropriate series of the meningococcal ACWY conjugate vaccine (MenACWY)

¹ Rubin LG, Levin MJ, Ljungman P, et al. 2013 IDSA clinical practice guideline for vaccination of the immunocompromised host. *Clin Infect Dis*. 2014;58(3):309-318

(see Meningococcal Infections, p 585).¹ The same vaccine product should be used for all doses. However, if the product used for previous doses is unknown or unavailable, the vaccination series may be completed with any age- and formulation-appropriate meningococcal ACWY conjugate vaccine. Although no data on interchangeability of meningococcal conjugate vaccines in people living with HIV are available, limited data from a postlicensure study in healthy adolescents suggests safety and immunogenicity of MenACWY-CRM are not adversely affected by prior immunization with MenACWY-D. For children living with HIV 2 through 23 months of age, only MenACWY-CRM (Menveo) should be used, because interference with the immune response to pneumococcal conjugate vaccine occurs with MenACWY-D (Menactra), and MenACWY-TT (MenQuadfi) is not licensed for use in children younger than 2 years.

Children Who Are HIV Uninfected Residing in the Household of a Person Living With HIV.

Members of households in which an adult or child has HIV infection can receive MMR vaccine, because these vaccine viruses are not transmitted from person to person. To decrease the risk of transmission of influenza to patients with symptomatic HIV infection, all household members 6 months or older should receive yearly influenza immunization (see Influenza, p 511). Live attenuated influenza vaccine (LAIV) may be administered to healthy household and other close contacts of people with altered immunocompetence (see Household Members of Immunocompromised Patients, p 103). Likewise, all household members should receive a COVID-19 vaccine if authorized or approved by the FDA for their age group. Siblings and susceptible adult caregivers of patients living with HIV should be immunized with varicella vaccine to prevent acquisition of wild-type varicella-zoster virus infection, which can cause severe disease in immunocompromised hosts. Although the risk of transmission is low, immunocompromised patients should avoid contact with people who develop skin lesions after receipt of varicella vaccine until the lesions clear (see Household Members of Immunocompromised Patients, p 103).

Postexposure Passive Immunization of Children Living With HIV.

Measles (see Measles, p 570).² Children living with HIV who are exposed to measles require prophylaxis based on immune status and measles vaccine history. Children living with HIV with no to moderate immunosuppression who have evidence of immunity (eg, serologic evidence of immunity to measles or who received 2 doses of measles vaccine after initiation of ART) do not require any additional measures to prevent measles following an exposure. Mildly or moderately immunocompromised people living with HIV without evidence of immunity to measles (eg, no serologic evidence of immunity to measles and who have not received 2 doses of measles vaccine after initiation of ART) should receive immune globulin intramuscular (IGIM) at a dose of 0.5 mL/kg (maximum 15 mL). Severely immunocompromised hosts (for people ≤ 5 years of age, defined as a CD4+ T-lymphocyte percentage $<15\%$; for people >5 years of age, defined as a CD4+ T-lymphocyte percentage $<15\%$ **or** a CD4+ T-lymphocyte count <200 lymphocytes/mm³) who are exposed to measles should receive immune

¹ Centers for Disease Control and Prevention. Recommendations for use of meningococcal conjugate vaccines in HIV-infected persons—Advisory Committee on Immunization Practices, 2016. *MMWR Morb Mortal Wkly Rep.* 2016;65(43):1189–1194

² Centers for Disease Control and Prevention. Prevention of measles, rubella, congenital rubella syndrome, and mumps, 2013 summary: recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR Recomm Rep.* 2013;62(RR-4):1–34

globulin intravenous (IGIV) prophylaxis, 400 mg/kg, after exposure to measles, regardless of prior vaccination status, because they may not be protected by the vaccine. Children living with HIV who have received IGIV within 3 weeks of exposure do not require additional passive immunization.

Tetanus. Children living with HIV with severe immune suppression (for people ≤ 5 years of age, defined as a CD4+ T-lymphocyte percentage $<15\%$; for people >5 years of age, defined as a CD4+ T-lymphocyte percentage $<15\%$ **or** a CD4+ T-lymphocyte count <200 lymphocytes/mm³) who sustain wounds classified as tetanus prone (see Tetanus, p 848) should receive tetanus immune globulin regardless of immunization status.

Varicella. Children living with HIV who lack evidence of immunity to varicella (eg, serologic evidence of immunity to varicella, or documentation of receipt of 2 doses of varicella vaccine after initiation of ART, or health care provider-confirmed clinical diagnosis of varicella), or who have severe immune suppression (for people ≤ 5 years of age, defined as a CD4+ T-lymphocyte percentage $<15\%$; for people >5 years of age, defined as a CD4+ T-lymphocyte percentage $<15\%$ **or** a CD4+ T-lymphocyte count <200 lymphocytes/mm³) should receive varicella zoster immune globulin, if available, ideally within 96 hours but potentially beneficial up to 10 days, after close contact with a person who has chickenpox or shingles (see Varicella-Zoster Infections, p 938). An alternative to varicella-zoster immune globulin for passive immunization is oral valacyclovir or acyclovir beginning 7 days after exposure, and if this is not available then IGIV, 400 mg/kg, administered once within 10 days after exposure (see Fig 3.22, p 945). Children who have received IGIV for other reasons within 3 weeks of exposure do not require additional passive immunization.

Hepatitis A.¹ All people with HIV who experience high-risk exposure to a person with hepatitis A infection, regardless of the exposed person's hepatitis A vaccination history or current degree of HIV-associated immunosuppression, should receive IGIM at a dose of 0.1 mL/kg.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions should be followed by all health care professionals regardless of suspected or confirmed HIV infection status of the patient.

CONTROL MEASURES:

Perinatal Transmission Prophylaxis.

Management of Infected Pregnant Person. Pregnant PWH should receive ART regimens, both for treatment of HIV infection and for prevention of perinatal transmission of HIV. Sustained virologic suppression is the goal both during pregnancy and following delivery. Detailed recommendations for use of ARVs in pregnant PWH can be found online (<https://clinicalinfo.hiv.gov/en/guidelines/perinatal/whats-new-guidelines>). Ideally, PWH initiating such a regimen during pregnancy should be tested for the presence of ARV resistance. However, initiation of ART should not be delayed pending results of resistance testing, especially if decisions are being made late in pregnancy. Intrapartum intravenous (IV) zidovudine should be given to PWH who present in labor or at least 3 hours prior to scheduled cesarean delivery with HIV RNA >1000 copies/

¹ Brennan J, Moore K, Sizemore L, et al. Notes from the field: acute hepatitis A virus infection among previously vaccinated persons with HIV infection—Tennessee, 2018. *MMWR Morb Mortal Wkly Rep*. 2019;68(14):328–329

mL near the time of delivery, unknown HIV RNA, known or suspected ART nonadherence since last HIV RNA result, or positive rapid antigen/antibody HIV result obtained around time of delivery in a person without a previous diagnosis of HIV. Intrapartum IV zidovudine may be considered on a case-by-case basis for PWH with HIV RNA ≥ 50 copies/mL and ≤ 1000 copies/mL within 4 weeks of delivery, but data are insufficient to determine whether IV zidovudine provides any additional protection against perinatal transmission in such cases (<https://clinicalinfo.hiv.gov/en/guidelines/perinatal/intrapartum-care-for-people-with-hiv?view=full>). In situations in which IV administration is not possible, oral administration can be considered.

Management of Exposed Infant. The newborn infant should be bathed and cleaned of secretions (especially bloody secretions) immediately after birth¹ and should begin ARV prophylaxis as soon as possible to the time of birth, preferably within 6 hours. Management options for evaluation and prophylactic therapy of newborn infants in the United States at low risk are presented in Fig 3.10. Presumptive therapy recommendations for newborn infants at higher risk of perinatal transmission are presented in Fig 3.11. Duration of ARV prophylaxis in the neonate is 2 to 6 weeks for low-risk perinatal HIV exposure (Fig 3.10), and the duration of presumptive therapy for high-risk perinatal HIV exposure is 6 weeks (Fig 3.11).

The newborn infant's physician should obtain the birthing parent's HIV infection status so appropriate care and follow-up of the infant can be accomplished. Infants born to people who (1) did not have HIV testing during pregnancy; (2) did not have third trimester HIV testing in areas where third trimester testing is recommended by the CDC; or (3) were diagnosed with other STIs during pregnancy (particularly syphilis) but were not tested for HIV should be tested with a rapid HIV antibody test as soon as possible after delivery. A positive antibody test would not be diagnostic for the infant, but would identify an undiagnosed HIV infection in the parent which in turn would necessitate presumptive HIV treatment and an HIV NAAT at birth in the infant. Whenever possible, PWH and their infants should be referred to a facility that provides HIV-related services for both the birthing parent and the baby.

Breastfeeding (Also See Breastfeeding and Human Milk, p 135).² Transmission of HIV by breastfeeding accounted for one third to one half of perinatal transmission of HIV worldwide in the pre-ART era. Transmission is more likely among pregnant people who acquire HIV infection late in pregnancy or during the postpartum period. In resource-limited settings, the World Health Organization recommends that people living with HIV breastfeed their infants exclusively for the first 6 months of life, because infant morbidity associated with formula feeding is unacceptably high and safe alternatives to human milk may not be readily available.

Replacement (formula) feeding is recommended for all infants born to people living with HIV infection in the United States, since this is the option that eliminates risk of transmission of HIV to the infant.³ Replacement feeding should be recommended

FIG 3.10. NEWBORN TESTING AND PROPHYLAXIS RECOMMENDATIONS FOLLOWING LOW-RISK PERINATAL HIV EXPOSURE*

ART indicates antiretroviral therapy.

*Low-risk criteria: (1) person with HIV who received ART throughout pregnancy or from the early 1st/2nd trimester; **AND** (2) confirmed HIV RNA <50 copies/mL near delivery (within 4 weeks); **AND** (3) no concerns regarding ART adherence; **AND** (4) person did not have primary or acute HIV infection during pregnancy.

#Birthing people with previous negative HIV test at risk for seroconversion in late pregnancy are those with: documented STI, unprotected sex, partner with HIV, multiple partners, or IV drug use.

†If birthing parent has been on ART for at least 10 consecutive weeks during pregnancy and has maintained viral suppression (defined as at least 2 consecutive viral load measurements of <50 copies/mL at least 4 weeks apart), the infant can receive 2 weeks of ZDV. All other infants, and all infants <37 weeks' gestational age, should receive 4-6 weeks of ZDV.

Algorithm adapted by Paul Spearman, Rana Chakraborty and Athena Kourtis from Management of Infants Born to Women with HIV Infection, in Recommendations for the Use of Antiretroviral Drugs in Pregnant Women with HIV Infection and Interventions to Reduce Perinatal HIV Transmission in the United States, clinicalinfo.hiv.gov.

FIG 3.11. NEWBORN TESTING AND PROPHYLAXIS RECOMMENDATIONS FOLLOWING HIGHER-RISK PERINATAL HIV EXPOSURE*

* Higher-risk criteria: birthing parents (1) who received neither antepartum nor intrapartum ARVs; **OR** (2) who received only intrapartum ARVs; **OR** (3) who received ante- and intrapartum ARVs but who do not have viral suppression (HIV RNA <50 copies/mL) near delivery, particularly if delivery was vaginal; **OR** (4) with acute or primary HIV infection during pregnancy or breastfeeding, in which case, the person should discontinue breastfeeding.

For newborns who are unable to tolerate oral agents, the IV dose of zidovudine is 75% of the oral dose, while maintaining the same dosing interval.

† All infants at higher risk of perinatal HIV exposure should be tested by HIV RNA or DNA PCR at birth. If birth HIV virologic testing in newborn is negative, some experts would discontinue lamivudine and nevirapine after 2 weeks and complete 6 weeks of prophylaxis with zidovudine alone.

^ ARV doses (such as ZDV and nevirapine) may need to be changed and the ARV regimen may need to be optimized if the infant has confirmed HIV infection. See clinicalinfo.hiv.gov for full dosing guidelines for infants with confirmed HIV infection.

§ If the birthing person has taken raltegravir 2–24 hours prior to delivery, the neonate's first dose of raltegravir should be delayed until 24–48 hours after birth; additional ARV drugs should be started as soon as possible. Do not use raltegravir if gestational age <37 weeks.

Algorithm adapted by Paul Spearman, Rana Chakraborty and Athena Kourtis from Management of Infants Born to Women with HIV Infection, in Recommendations for the Use of Antiretroviral Drugs in Pregnant Women with HIV Infection and Interventions to Reduce Perinatal HIV Transmission in the United States, clinicalinfo.hiv.gov.

if the birth parent is not receiving ART, or is not adherent and has a detectable viral load. Parents with HIV infection with fully suppressed viral load and who are adherent with ART who wish to breastfeed should be supported in their decision to do so. If a parent chooses to breastfeed, an appropriate plan of management can be developed, including encouraging adherence with ART during breastfeeding, use of antiretrovirals in the infant as prophylaxis while breastfeeding, exclusive breastfeeding for 6 months followed by weaning and introduction of complementary foods, lactation counseling, frequent viral load monitoring in the breastfeeding parent, and frequent infant testing for HIV infection (<https://clinicalinfo.hiv.gov/en/guidelines/perinatal-counseling-and-managing-women-living-hiv-united-states-who-desire-breastfeed>).

Prewarming or Premastication. Probable transmission of HIV by caregivers who prewarmed in their mouth or premasticated food for infants has been described in the United States. The CDC recommends that caregivers living with HIV be asked about whether they practice premastication and counseled not to prewarm or premasticate food for infants.

HIV in the Athletic Setting. Athletes and staff of athletic programs can be exposed to blood during certain athletic activities. Recommendations have been developed by the AAP for prevention of transmission of HIV and other bloodborne pathogens in the athletic setting (see Children in Group Child Care and Schools, Bloodborne Infections, p 148).

Sexual Abuse. In cases of proven or suspected sexual abuse, the child should be tested with an HIV antibody test at the original assessment, with testing repeated at approximately 6 weeks and <3 months (see Sexual Assault and Abuse in Children and Adolescents/Young Adults, p 182). Serologic evaluation for HIV infection of the perpetrator should be attempted as soon after the incident as possible. Counseling of the child and family needs to be provided (<https://stacks.cdc.gov/view/cdc/38856>).

Prevention of HIV Transmission Through Sexual Activity. Abstinence from sexual activity is the only certain way to prevent sexual transmission of HIV. Safer sex practices, including use of condoms for all sexual encounters (vaginal, anal, and oral sex) can reduce HIV transmission significantly by reducing exposure to body fluids containing HIV. Sustained HIV RNA to blood levels <200 copies/mL with ART eliminates the risk of HIV sexual transmission in discordant couples.

PrEP with ARVs (eg, tenofovir plus emtricitabine; cabotegravir) reduces the risk of HIV acquisition from sex by 99% when taken consistently. Among people who inject drugs, PrEP reduces the risk of acquiring HIV infection by at least 74% when taken consistently. PrEP is much less effective if it is not taken consistently. PrEP is FDA approved for adolescents and adults weighing at least 35 kg (77 lb). The AAP recommends that youth at substantial risk for HIV acquisition be routinely offered HIV PrEP.¹ Detailed guidance is available from CDC at www.cdc.gov/hiv/risk/prep/index.html and www.cdc.gov/hiv/pdf/risk/prep/cdc-hiv-prep-guidelines-2021.pdf. If advice is needed, clinicians may consult the National Clinician Consultation Center PrEP Line at 1-855-448-7737 (9:00 AM–8:00 PM Eastern Time).

¹ Hsu KK, Rakhmanina NY; American Academy of Pediatrics, Committee on Pediatric AIDS. Clinical report. Adolescents and young adults: the pediatrician's role in HIV testing and pre- and post-exposure HIV prophylaxis. *Pediatrics*. 2022;149(1):e2021055207

ARV-based vaginal microbicides and ARV-coated vaginal rings have reduced HIV acquisition in uninfected women. Data from clinical trials conducted in African countries also provide evidence that medical penile circumcision can reduce HIV acquisition in heterosexual male individuals by 38% to 66% over 24 months.

Postexposure Prophylaxis for Possible Sexual or Other Nonoccupational Exposure to HIV.

Decisions to provide ARVs after possible nonoccupational (ie, community) exposure to HIV must balance the potential benefits and risks. Decisions regarding the need for ARV prophylaxis in such instances are predicated on the probability that the source is infected or contaminated with HIV, the likelihood of transmission by the particular exposure, and the interval between exposure and initiation of therapy, balanced against expected adverse effects associated with the regimen.

The risk of transmission of HIV from a puncture wound attributable to a needle found in the community likely is much lower than 0.3%, which is the estimated probability of HIV transmission from a puncture wound involving a known HIV-contaminated needle in a health care setting. The actual risks of HIV infection in an infant or child after a needlestick injury or sexual abuse are unknown, but to date there are no confirmed transmissions of HIV from accidental nonoccupational needlestick injuries (needles found in the community). The estimated risk of HIV transmission from receptive penile-anal sexual exposure is 138 per 10 000 exposures. The estimated risk per episode of receptive vaginal exposure is 8 per 10 000 exposures.

ARVs generally should not be used if the risk of transmission is low (eg, trivial needlestick injury with a drug needle from an unknown nonoccupational source) or if care is sought more than 72 hours after the reported exposure (see *Injuries From Needles Discarded in the Community*, p 198). The benefits of PEP are greatest when risk of infection is high, intervention is prompt, and adherence is likely. Consultation with an experienced pediatric HIV health care professional is essential. Detailed guidelines for PEP for children can be found at <https://stacks.cdc.gov/view/cdc/38856> and <https://nccc.ucsf.edu/clinician-consultation/pep-post-exposure-prophylaxis/>. The AAP recommends that youth be offered HIV PEP following high-risk sexual exposures.¹

Postexposure Prophylaxis for Occupational Exposure to HIV. Guidelines for use of occupational PEP have been published by CDC and should be started as soon as possible after the exposure but within 72 hours for maximal effectiveness (<https://stacks.cdc.gov/view/cdc/38856>). In addition, the National Clinician Consultation Center at 1-888-448-4911 provides guidance seven days a week between 9 AM and 9 PM Eastern Time and can provide valuable support to providers.

Public Health Reporting. HIV infection is a nationally notifiable disease in the United States.

Human Papillomaviruses

CLINICAL MANIFESTATIONS: Most human papillomavirus (HPV) infections are subclinical, and 90% spontaneously become undetectable within 2 years. However, persistent HPV infection can cause benign epithelial proliferation (warts) of the

¹ Hsu KK, Rakhmanina NY; American Academy of Pediatrics, Committee on Pediatric AIDS. Clinical report. Adolescents and young adults: the pediatrician's role in HIV testing and pre- and post-exposure HIV prophylaxis. *Pediatrics*. 2022;149(1):e2021055207

skin and mucous membranes as well as cancers of the lower anogenital tract and the oropharynx. HPV types can be grouped into cutaneous and mucosal types. The cutaneous types cause common skin warts, plantar warts, flat warts, and thread-like (filiform) warts. These cutaneous warts are benign. Certain mucosal types (referred to as low risk) are associated with warts or papillomas of mucous membranes, including the upper respiratory tract and anogenital, oral, nasal, and conjunctival areas. Other mucosal types (referred to as high risk) can cause precancers and cancers, including cervical, anogenital, and oropharyngeal cancers.

Warts are common benign lesions, although they may be associated with significant clinical problems. Common **skin warts** are dome-shaped with conical projections that give the surface a rough appearance. Skin warts usually are painless and multiple, occurring commonly on the hands and around or under the nails. When small dermal vessels become thrombosed, black dots appear in the warts.

Plantar warts on the foot often are larger than warts at other sites and may not project through much of the skin surface. They can be painful when walking and are characterized by marked hyperkeratosis, sometimes with black dots.

Flat warts commonly are found on the face and extremities of children and adolescents. Flat warts usually are small, multiple, and flat topped, seldom exhibit papillomatosis, and rarely cause pain. **Filiform warts** occur on the face and neck.

Anogenital warts, also called **condylomata acuminata**, are skin-colored warts with a papular, flat, or cauliflower-like surface that range in size from a few millimeters to several centimeters. These warts often occur in groups, and may be found on the penis, urethra, scrotum, vulva, anal or perianal areas and, less commonly, in the vagina or on the cervix. Warts usually are painless, although they may cause itching, burning, local pain, or bleeding and may have significant psychological impact.

Invasive cancers attributable to HPV include those of the cervix, vagina, vulva, penis, anus, and oropharynx (back of throat, base of tongue, and tonsils). Cervical cancer is the most common HPV-attributable cancer in the female population.¹ Oropharyngeal cancer is the most common HPV-attributable cancer in the male population and the most common HPV-related cancer overall in the United States. Anogenital low-grade squamous intraepithelial lesions (LSILs) can result from infection with low-risk or high-risk HPV types, whereas high-grade squamous intraepithelial lesions (HSILs) result mostly from persistent infection with high-risk HPV types. In the cervix, HSILs include cervical intraepithelial neoplasia (CIN) grades 2 or 3, and adenocarcinoma in situ (AIS), which are precancerous lesions. LSIL and HSIL are lesions detected through routine screening with cytologic testing (Papanicolaou [Pap] test); tissue biopsy is required to make the diagnosis of CIN.

Recurrent respiratory papillomatosis (RRP) is a rare condition characterized by recurring papillomas in the larynx or other areas of the upper or lower respiratory tract. Onset can occur in childhood or adulthood. The disease is referred to as juvenile-onset RRP (JORRP) when it occurs before 12 years of age and as adult-onset RRP (AORRP) when it occurs at an older age. JORRP is believed to result most frequently from vertical transmission of HPV at the time of delivery. JORRP is diagnosed most commonly in children between 2 and 5 years of age, with manifestations of voice change (eg, hoarseness or abnormal cry), stridor, chronic cough, or respiratory distress.

¹ The terms female and male refer to sex assigned at birth.

Respiratory papillomas can cause respiratory tract obstruction in young children, and repeated surgeries often are needed. Most cases of JORRP are caused by HPV 6 or 11. AORRP most frequently occurs between 20 and 40 years of age, with causal HPV infections most likely acquired through sexual behavior. Most cases of JORRP and AORRP are caused by HPV 6 or 11. Prevalence of HPV type 6 in JORRP (50%–70%) and AORRP (~60%) is generally higher than that of HPV 11 (6%–29%).

Epidermodysplasia verruciformis is a rare, inherited disorder believed to be a consequence of a deficiency of cell-mediated immunity, resulting in an abnormal susceptibility to certain HPV types and manifesting as chronic cutaneous lesions and skin cancers. Lesions may resemble flat warts or pigmented plaques covering the torso and upper extremities. Most appear during the first decade of life, but malignant transformation, which occurs in 30% to 60% of affected people, usually is delayed until adulthood.

ETIOLOGY: HPVs are small, nonenveloped, double-stranded DNA viruses of the *Papillomaviridae* family, which are grouped into genera, species, and types based on DNA sequence variation. More than 200 types are recognized, but specific tissue tropism and disease associations are limited to date to less than 40 types. Types 6 and 11 cause anogenital warts (condylomata acuminata), recurrent respiratory papillomatosis, and conjunctival papillomas but rarely are found in cancer. High-risk HPV types (HPV 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 66, and 68) can be detected in almost all cervical precancers and invasive cervical cancers. Approximately 50% of cervical cancers worldwide are attributable to HPV type 16; 70% are attributable to either type 16 or 18. The majority of other HPV-related cancers—anogenital cancers (vulvar, vaginal, penile, anal) and oropharyngeal cancers—also are attributable to HPV type 16. Infection with a high-risk HPV type is considered necessary but not sufficient to cause cancer. The vast majority of people with an HPV infection will not develop cancer. Risk of developing cancer precursors or cancers is greater in people with certain immunocompromising conditions, such as human immunodeficiency virus (HIV) infection, cellular immune deficiencies, organ transplantation, and autoimmune diseases.

EPIDEMIOLOGY: Virtually all adults will be infected with some type of HPV during their lives. In the United States, it is estimated that 42 million people are infected with disease-associated HPV and 13 million people acquire a new anogenital HPV infection each year. Although HPV is common in the general population, specific risk factors include higher lifetime number of sex partners, earlier age at first sex, and immunocompromising conditions, including HIV infection. Groups that are disproportionately affected include transgender women and gay, bisexual, and other men who have sex with men.

Nongenital hand and foot warts occur commonly among school-aged children. Acquisition can occur through casual contact and is facilitated by minor skin trauma. Autoinoculation can result in spread of lesions. The intense and often widespread appearance of cutaneous warts in people with compromised cellular immunity (particularly those who have undergone transplantation or who have HIV infection) suggests that alterations in T-lymphocyte immunity may impair clearance of infection.

Genital HPV infections are transmitted by intimate contact through sexual intercourse or other close genital contact. In female individuals in the United States, the

highest prevalence of infection is in 20- to 24-year-olds. Most infections are subclinical and clear spontaneously within 1 or 2 years. Cancer is an uncommon outcome of infection that generally requires decades of persistent infection with high-risk HPV types. There are more than 33 000 cases of HPV-attributable cancers annually in the United States. HPV-attributable cervical cancer accounts for approximately one third of new HPV-attributable cancer cases and 4000 deaths annually in the United States. HPV-attributable oropharyngeal cancer accounts for more than one third of new HPV-attributable cancer cases per year. HPV is the cause of at least 90% of all cervical cancers, 70% to 90% of oropharyngeal cancers, and most vulvar, vaginal, penile, and anal cancers.

Rarely, HPV infection is perinatally transmitted to a child during passage through an infected birth canal at delivery, or postnatally transmitted from nongenital sites. When anogenital warts are diagnosed in a child, the possibility of sexual abuse must be considered while noting the possibility of vertical transmission to neonates (see STI Evaluation After Sexual Assault of a Prepubertal Child, p 184, and Table 2.5, p 183).

The **incubation period** for symptoms of warts is estimated to range from 3 to 6 months. The period from infection to LSIL is likely similar. The period from infection to neoplastic changes is usually years to decades.

DIAGNOSTIC TESTS: Most cutaneous and anogenital warts can be diagnosed through clinical inspection. Serologic testing for HPV antibodies does not inform clinical decisions and is not commercially available. HPV-associated cervical lesions are detected through screening methods (described below). Anal, vulvar, vaginal, and penile lesions may be identified using visual inspection, sometimes using magnification; in some cases, cytologic screening is used and suspicious lesions are biopsied, but to date there is no routine screening recommended for cancers at these sites. Many dentists screen for oral cancer but there is no widely implemented screening program.

For all anogenital, oropharyngeal, and respiratory tract precancers and cancers, diagnosis is made histologically. Identifying the presence of HPV requires detection of viral nucleic acid (DNA or RNA) in a cellular sample from the lesion. Routine cervical cancer screening guidelines have been established by multiple professional societies (see Cervical Cancer Screening, p 508). Because high-risk HPV is a sensitive biomarker for cervical disease, primary screening with nucleic acid amplification tests (NAATs) for high-risk HPV types is increasingly favored for female individuals starting at age 25 years. The increased sensitivity of HPV testing allows longer screening intervals for people with negative test results. HPV tests may also be used in combination with cytologic testing in female individuals 30 years or older and for triage of equivocal cytology test abnormalities (atypical squamous cells of undetermined significance [ASCUS]) in those 21 years or older. Clinical HPV testing requires use of an assay approved by the US Food and Drug Administration (FDA) conducted in a CLIA-approved laboratory. There are differences in the appropriate clinical applications for each of these assays, including whether they can be used as an initial standalone test (ie, without cervical cytology) or in a primary screening algorithm; none is recommended for use in female individuals younger than 21 years or for male individuals. Criteria for abnormalities that require colposcopic evaluation and biopsy are included as part of professional societies' guidelines.

TREATMENT¹: There is no FDA-approved treatment for HPV infection. Treatment may be directed toward lesions caused by HPV.

Regression of **nongenital and genital warts** occurs in approximately 30% of cases within 6 months and 90% within several years, even without treatment. Most methods of treatment of cutaneous warts use chemical or physical destruction of the infected epithelium, including cryotherapy with liquid nitrogen, laser or surgical removal of warts, application of salicylic acid products, or application of topical immune-modulating agents. Many agents used for treatment of warts have not been tested for safety and efficacy in children, and some are contraindicated in pregnancy.

Daily treatment with tretinoin has been useful for widespread flat warts in children. Systemic treatments, including cimetidine, have been used for refractory warts with variable success. Treatments for genital warts are characterized as patient-applied or provider administered. Interventions include ablational/excisional treatments, topical antiproliferative medications, or immune-modulating medications. Oral warts can be removed through cryotherapy, electrocautery, or surgical excision. Although most forms of therapy are successful for initial removal of warts, treatment may not eradicate HPV infection from the surrounding tissue and recurrences are common.

Cancer precursor lesions that are identified in the cervix (eg, AIS, CIN 2, CIN 3) or elsewhere in the genital tract may require excision or destruction. Treatment of cervical lesions can cause substantial economic, emotional, and reproductive adverse effects, including higher risk of preterm birth and perinatal mortality. Management of invasive cervical and other anogenital and oropharyngeal cancers requires a specialist and should be conducted according to current guidelines.

Respiratory papillomatosis is difficult to treat and is best managed by an experienced otolaryngologist. Local recurrence is common, and repeated surgical debulking procedures are often necessary to relieve airway obstruction, especially in young children because of their small airway diameter. Extension or dissemination of respiratory papillomas from the larynx into the trachea, bronchi, or lung parenchyma happens rarely but results in increased morbidity and mortality; malignant transformation occurs rarely. Intralesional interferon, oral indole-3-carbinole, systemic or intralesional bevacizumab, intralesional cidofovir, and HPV vaccination have been used as investigational treatments; however, efficacy with any of these is unproven.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES AND CARE OF EXPOSED PEOPLE: Sexual abuse should be considered if anogenital warts are found in a child. When anogenital warts are found in a child who is prepubertal, the patient should be referred to a child abuse management pediatrician for an abuse evaluation (see STI Evaluation After Sexual Assault of a Prepubertal Child, p 184, and Table 2.5, p 183). Suspected child sexual abuse should be reported to the appropriate local agency.

Most cancer-causing HPV infections can be prevented by vaccination (see below). Delaying sexual debut and minimizing the lifetime number of sex partners are other modes of reducing risk of HPV infection. Consistent and correct use of latex condoms

¹ Centers for Disease Control and Prevention. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(RR-4):1-187. Available at: www.cdc.gov/std/treatment-guidelines/hpv.htm

may reduce the risk of anogenital HPV infection when infected areas are covered or protected by the condom. The degree and duration of contagiousness in patients with a history of genital HPV infection is unknown. People with genital warts should refrain from sex with new partners while warts are present and should inform their current sex partners, who also may benefit from a clinical evaluation for anogenital warts or other sexually transmitted infections.

Although JORRP is believed to be caused by perinatal transmission of HPV types 6 and 11 during passage through the birth canal, this condition has occurred in infants born by cesarean delivery. Because the preventive value of cesarean delivery is unknown, it should not be performed solely to prevent transmission of HPV to the newborn infant.

Cervical Cancer Screening. Female individuals who have received HPV vaccine should continue to have regular cervical cancer screening. HPV vaccines do not provide protection against all HPV types associated with development of cervical cancer and do not alter the course of infections existing before vaccination. Several professional organizations offer guidance on cervical cancer screening, including the American College of Obstetricians and Gynecologists (www.acog.org), the American Cancer Society (www.cancer.org), the American Society for Colposcopy and Cervical Pathology (www.asccp.org), and the US Preventive Services Task Force (www.uspreventiveservicestaskforce.org). These organizations, with one exception, all recommend that cervical cytologic testing begin at 21 years of age for all healthy female individuals, regardless of sexual history (the American Cancer Society recommends testing begin at 25 years of age). HIV-infected female adolescents who have initiated sexual intercourse should have cervical cytologic screening (liquid-based or Pap smear) performed twice at 6-month intervals during the first year after diagnosis of HIV infection, and if the results are normal, annually thereafter (<https://clinicalinfo.hiv.gov/en/guidelines>). Sexually active female adolescents who have had an organ transplant or are receiving long-term corticosteroid therapy also should undergo similar cervical cytologic screening.

HPV Vaccines. Three HPV vaccines have been licensed by the FDA for use in the United States, but only one, Gardasil 9, a 9-valent vaccine (types 6, 11, 16, 18, 31, 33, 45, 52, and 58), licensed in 2014, is currently on the US market. A quadrivalent vaccine (4vHPV [types 6, 11, 16, and 18], Gardasil) was licensed in 2006, and a bivalent vaccine (2vHPV [types 16 and 18], Cervarix) was licensed in 2009.

Immunogenicity. More than 97% of healthy vaccine recipients develop antibodies to HPV vaccine types after vaccination. Antibody titers are higher in adolescents aged 9 through 15 years compared with those 16 through 26 years of age.

Antibody titers for all HPV vaccines decrease over time but plateau by 18 to 24 months after vaccination. Follow-up studies through 8 and 10 years after 4vHPV and 2vHPV vaccination, respectively, have shown no waning of protection. Studies of 9vHPV vaccine have found that antibody titers after 2 doses administered 6 to 12 months apart to 9- through 14-year-olds are similar to 3 doses administered to women 16 through 26 years of age, the age group in which efficacy was demonstrated in clinical trials.

Efficacy. 4vHPV and 2vHPV have been shown to be highly effective in preventing cervical precancers related to HPV types 16 and 18 in clinical trials among females

15 through 26 years of age. 4vHPV has been shown to be highly effective in preventing genital warts related to HPV types 6 and 11 in clinical trials among female and male individuals 16 through 26 years of age. 4vHPV also has been shown to be highly effective in preventing anal precancers in male individuals 16 through 26 years of age. 9vHPV has been shown in a clinical trial among female individuals 16 through 26 years of age to provide 97% protection against the additional 5 HPV types in the 9-valent product (31, 33, 45, 52, and 58) and to produce noninferior immunogenicity for the 4 HPV types in the quadrivalent product (6, 11, 16, and 18). Clinical trials of 2vHPV and 4vHPV have been conducted in female individuals older than 26 years; in those without evidence of prior HPV vaccine type infection, efficacy has been demonstrated for a combined endpoint of vaccine-type infection and cervical precancers. HPV vaccines have not been proven to have a therapeutic effect on existing HPV infection or disease and do not offer protection against progression of infection to disease from HPV acquired before immunization. Therefore, HPV vaccines are most effective when administered before exposure to any of the HPV types included in the vaccine.

Assessment of the full impact of HPV vaccination on anogenital and oropharyngeal cancers will take decades, given the natural history of HPV-driven oncogenesis. However, studies have already demonstrated significant reductions in HPV-related outcomes since the vaccines were introduced, including declines in vaccine-type HPV prevalence, anogenital warts, JORPP, cervical precancers, and cervical cancers. Long-term follow-up studies are being conducted to determine the duration of protection for all HPV vaccines.

Vaccine Recommendations.¹ The American Academy of Pediatrics (AAP) and the Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention recommend routine HPV vaccination for all adolescents. The AAP recommends starting the series between the ages of 9 and 12 years, at an age the pediatric health care professional deems optimal for acceptance and completion of the vaccination series. The ACIP recommends starting the series at age 11 or 12 years and states that vaccination can be administered starting at age 9 years. When HPV vaccination is initiated at 9 or 10 years of age, other adolescent vaccines (eg, MenACWY and Tdap) still are recommended to be administered at 11 to 12 years of age.

Pediatric health care professionals are encouraged to recommend HPV vaccination as they do other routine childhood and adolescent vaccines. Research has demonstrated that parents are influenced by effectively delivered recommendations and personal testimonials from their child's pediatrician. Opportunities to prevent cancers and deaths are being missed by clinicians who describe HPV vaccine as a sexually transmitted infection vaccine rather than a cancer prevention vaccine or who fail to inform patients and their parents or guardians that HPV vaccination is routinely recommended.

Catch-up HPV vaccination is recommended for all people through age 26 years who are not adequately vaccinated. Catch-up HPV vaccination is not recommended

¹ Meites E, Szilagyi PG, Chesson HW, Unger ER, Romero JR, Markowitz LE. Human papillomavirus vaccination for adults: updated recommendations of the Advisory Committee on Immunization Practices. *MMWR Morb Mortal Wkly Rep*. 2019;68(32):698–702. Available at: www.cdc.gov/mmwr/volumes/68/wr/mm6832a3.htm

for all adults 27 years or older. Instead, shared clinical decision-making regarding HPV vaccination is recommended for some adults 27 through 45 years of age who are not adequately vaccinated.

Dosage and Administration. HPV vaccine is administered in either 2 or 3 doses of 0.5 mL, intramuscularly, preferably in a deltoid muscle.

- For people initiating vaccination before their 15th birthday, the recommended schedule is 2 doses of HPV vaccine, with the second dose administered 6 to 12 months after the first dose (minimum interval 5 months).
- For people initiating vaccination on or after their 15th birthday, the recommended schedule is 3 doses of HPV vaccine. In a 3-dose schedule, the second dose should be administered at least 1 to 2 months after the first dose (minimum interval 4 weeks), and the third dose should be administered 6 months after the first dose (minimum interval 5 months after first dose, and 12 weeks after second dose).
- People considered adequately vaccinated are those:
 - ♦ Who initiated vaccination before their 15th birthday and received 2 doses of any HPV vaccine (9vHPV, 4vHPV, or 2vHPV) at the recommended dosing schedule (0, 6–12 months), or 3 doses of any HPV vaccine at the recommended dosing schedule (0, 1–2, 6 months).
 - ♦ Who initiated vaccination on or after their 15th birthday and received 3 doses of any HPV vaccine (9vHPV, 4vHPV, or 2vHPV) at the recommended dosing schedule (0, 1–2, 6 months). (Also see section on recommendations for special populations, below).
- If the vaccine schedule is interrupted, the vaccine series can be continued with the next recommended dose and does not need to be restarted.
- 9vHPV may be used to complete a series started with 4vHPV or 2vHPV.
- There is no recommendation regarding additional vaccination with 9vHPV for people who previously completed a 4vHPV or 2vHPV vaccination series.
- Evidence of past HPV exposure or current HPV infection or disease, such as abnormal cytologic test results, cervical lesions, anogenital warts, or a positive HPV DNA test result, are not contraindications to HPV immunization. People in the recommended age ranges still should receive HPV vaccine to protect against any HPV types not already acquired.
- HPV vaccines can be coadministered with any live or non-live vaccine indicated at the same visit.

Recommendations for Special Populations. HPV vaccines are not live vaccines. For people ages 9 through 26 years with immunocompromising conditions (including primary or secondary immunocompromising conditions that might reduce cell-mediated or humoral immunity, such as B-lymphocyte antibody deficiencies, T-lymphocyte complete or partial defects, HIV infection, malignant neoplasms, transplantation, autoimmune disease, or immunosuppressive therapy), a 3-dose schedule of HPV vaccine is recommended regardless of age at initiation. Immune response and vaccine efficacy in immunocompromised people might be less than that in immunocompetent people.

For children with a history of sexual abuse or assault, the HPV vaccination series should be started at 9 years of age, because they may be at higher risk of repeat abuse or assault.

Vaccine Adverse Events, Precautions, and Contraindications. Studies of more than 15 000 people in clinical trials for each of the HPV vaccines have shown no serious safety

concerns. In addition, more than 135 million doses of HPV vaccines have been distributed in the United States without evidence for serious safety concerns. Injection site discomfort or pain, redness, and swelling are the most commonly reported local adverse events. Systemic symptoms after HPV vaccine include headache, fever, nausea, dizziness, and fatigue/malaise. Syncope (fainting) has been reported in adolescents after receipt of any vaccination, including HPV vaccine. Despite common misinformation disseminated mainly on the internet and through social media, HPV vaccine has not been associated with ovarian damage, infertility, or postural orthostatic tachycardia syndrome (POTS).

HPV vaccines can be administered to people with minor acute illnesses. Other considerations include:

- Immunization of people with moderate or severe acute illnesses should be deferred until after their condition improves.
- HPV vaccines are produced in yeast and are contraindicated in people with a history of immediate hypersensitivity to any vaccine component, including yeast.
- HPV vaccines are not recommended for use during pregnancy because of limited information about safety. The health care professional should inquire about pregnancy in patients who are known to be sexually active, but a pregnancy test is not required before starting the HPV vaccination series. If a vaccine recipient becomes pregnant, subsequent doses should be postponed until the person is no longer pregnant. If a dose has been administered inadvertently during pregnancy, no intervention is needed. Data to date show no evidence of adverse effect of any HPV vaccine on outcomes of pregnancy. Health care professionals can report inadvertent administrations of 9vHPV to pregnant people by calling the vaccine manufacturer at 1-877-888-4231.
- HPV vaccines can be administered to lactating people.
- Vaccine providers, particularly when vaccinating adolescents, should observe patients (with patients seated or lying down) for 15 minutes after vaccination to decrease the risk for injury should they faint and as is recommended for all vaccines. If syncope develops, patients should be observed until symptoms resolve.

Influenza

CLINICAL MANIFESTATIONS: Influenza illness typically begins with sudden onset of fever, often accompanied by nonproductive cough, chills or rigors, diffuse myalgia, headache, and malaise. Subsequently, respiratory tract symptoms including sore throat, nasal congestion, rhinitis, and cough become more prominent. Less commonly, abdominal pain, nausea, vomiting, and diarrhea are associated with influenza illness. In some children, influenza can appear as an upper respiratory tract illness or as a febrile illness with few respiratory tract symptoms. In infants, influenza can produce a nonspecific sepsis-like illness, and in infants and young children, influenza can cause otitis media, croup, pertussis like-illness, bronchiolitis, or pneumonia. Acute myositis secondary to influenza can present with calf tenderness and refusal to walk.

Although most children with influenza recover fully after 3 to 7 days of illness, complications may occur, even in previously healthy children. Neurologic complications associated with influenza range from febrile seizures to severe encephalopathy

and encephalitis with status epilepticus, resulting in neurologic sequelae or death. Reye syndrome, now a very rare condition, has been associated with influenza infection and the use of aspirin therapy during the illness. Children with influenza or suspected influenza should not be given aspirin, and children with diseases that necessitate long-term aspirin therapy or salicylate-containing medication, including juvenile idiopathic arthritis or Kawasaki disease, should be recognized as being at increased risk for complications from influenza. Death from influenza-associated myocarditis has been reported. Invasive secondary infections or coinfections with *Staphylococcus aureus* (including methicillin-resistant *S aureus* [MRSA]), *Streptococcus pneumoniae*, group A streptococcus, or other bacterial pathogens can result in severe disease and death.

ETIOLOGY: Influenza viruses are orthomyxoviruses of 3 genera or types (A, B, and C). Annual epidemics are caused by influenza virus types A and B, and both influenza A and B virus antigens are included in seasonal influenza vaccines. Type C influenza viruses can cause sporadic mild influenza-like illness in children. Type C antigens are not included in influenza vaccines. Influenza A viruses are further classified into subtypes based on their surface antigens, hemagglutinin (HA) and neuraminidase (NA). Examples of these virus subtypes include H1N1 and H3N2 influenza A viruses. Specific antibodies to these antigens, especially to hemagglutinin, are important determinants of immunity.

A minor antigenic variation that leads to changes in the HA or NA surface proteins of influenza A or B viruses is termed *antigenic drift*. Antigenic drift occurs continuously and results in new strains of influenza A and B viruses, resulting in seasonal epidemics.

A major antigenic variation that leads to new subtypes containing a unique HA and/or NA is termed *antigenic shift*. If the new virus subtype infects humans and is transmitted efficiently from person to person in a sustained manner, a pandemic can occur because the human population has little or no preexisting immunity to the newly emerged influenza strain. Antigenic shift occurs only among influenza A viruses and has produced 4 influenza pandemics in the 20th and 21st centuries, the most recent in 2009. As with previous antigenic shifts, the 2009 pandemic influenza A (H1N1pdm09) viral strain subsequently replaced the previously circulating seasonal influenza A (H1N1) strain in the ensuing influenza seasons.

Humans of all ages may sporadically be infected with emerging influenza A viruses of swine or avian origin. Most notable among avian influenza viruses are A (H5N1), which emerged in 1997 in Hong Kong, and A (H7N9), first detected in 2013 in China, both of which have been associated with severe disease and high case fatality rates. Since 2017, the Asian (H7N9) subtype is considered the influenza virus with the highest potential pandemic risk.

EPIDEMIOLOGY: Influenza is highly contagious. The virus is spread person to person, primarily through large-particle respiratory droplet transmission (eg, coughing or sneezing), which requires close proximity between the person who is the source and the person who is the recipient because droplets generally only travel short distances. Another mode of transmission comes from contact with influenza virus from droplet-contaminated hands or surfaces, where it can remain viable for up to 24 hours, with transfer from hands to mucosal surfaces of the face. Airborne transmission

via small-particle aerosols in the vicinity of the infectious individual also may occur. Patients may be infectious 24 hours before onset of symptoms. Viral shedding in nasal secretions usually peaks during the first 3 days of illness and ceases within 7 days but prolonged shedding (10 days or longer) can occur in young children and immunocompromised patients.

Influenza activity in the United States typically occurs anytime from October to May, commonly peaking between December and February. Seasonal epidemics can last 8 to 12 weeks or longer. Circulation of 2 or 3 influenza virus strains in a community may be associated with a prolonged influenza season and may produce bimodal peaks in activity.

Seasonal influenza epidemics are associated with an estimated 9.3 to 41 million illnesses, 140 000 to 710 000 hospitalizations, and 12 000 to 52 000 respiratory and circulatory deaths annually in the United States. The CDC estimates that on average, 8% (range, 3%–11%) of the US population develops symptomatic influenza illness during a typical season, depending on the circulating strains. During community outbreaks of influenza, the highest influenza incidence occurs among children, ranging from 10% to 40%, particularly school-aged children. Secondary spread to adults and other children within a family is common. Spread within schools can be a driver of more widespread transmission within the community.

Hospitalization rates are highest in those younger than 5 years and are similar to hospitalization rates among people 65 years and older. Although rates vary across studies (190–480 per 100 000 population) because of differences in methodology and severity of influenza seasons, children younger than 2 years consistently are at a substantially higher risk of hospitalization than are older children. Rates of hospitalization and morbidity attributable to complications, such as pneumonia, are greater in children with high-risk conditions, including chronic pulmonary diseases such as asthma, neurologic and neurodevelopmental disorders, hemodynamically significant cardiac disease, obesity, immunosuppression, metabolic diseases such as diabetes mellitus, and hemoglobinopathies such as sickle cell disease. However, 40% to 50% of all children hospitalized with influenza have no known underlying conditions, and almost half of children who die from influenza do not have an underlying high-risk condition. The total number of reported annual influenza-related deaths in the United States, including both chronically ill and previously healthy children, usually ranges from 35 to 199, with higher numbers reported in some seasons; actual numbers of deaths likely exceed the reported values.

Information about influenza surveillance is available through www.cdc.gov/flu/weekly.

The **incubation period** usually is 1 to 4 days, with a mean of 2 days.

DIAGNOSTIC TESTS: Influenza testing should be performed in children with signs and symptoms of influenza when test results are anticipated to impact clinical management (eg, to inform the decision to initiate antiviral or antibiotic therapy, pursue other diagnostic testing, or initiate infection prevention and control measures). The decision to test is related to the level of local influenza activity, clinical suspicion for influenza, and the sensitivity and specificity of commercially available influenza tests (Table 3.26). These include rapid molecular tests for influenza called nucleic acid amplification tests (NAATs) as part of single-plex or multiplex assays, immunofluorescence assays

Table 3.26. Summary of Influenza Diagnostic Tests

Influenza Diagnostic Test	Method	Availability	Typical Processing Time	Sensitivity	Types Detected
Rapid influenza diagnostic tests (RIDTs) ^a	Antigen detection	Wide	<15 min	Moderate	A and B
Rapid molecular assays ^b	Nucleic acid amplification	Wide	15–30 min	High	A and B
Molecular assays (including RT-PCR) ^c	Nucleic acid amplification	Limited	1–8 h	High	A and B
Direct and indirect Immunofluorescence antibody assays ^c	Antigen detection	Wide	1–4 h	Moderate	A and B
Rapid cell culture (shell vials and cell mixtures) ^c	Virus isolation	Limited	1–3 days	High	A and B
Tissue cell culture ^c	Virus isolation	Limited	3–10 days	High	A and B

RT-PCR indicates reverse transcriptase-polymerase chain reaction. May be single-plex or multiplex, real time, and other RNA-based assays.

^aMost rapid influenza diagnostic tests are CLIA waived.

^bSome rapid influenza molecular assays are CLIA waived, depending on the specimen.

^cNot CLIA waived. Requires laboratory expertise.

Adapted from www.cdc.gov/flu/professionals/diagnosis/overview-testing-methods.htm.

(direct [DFA] or indirect [IFA] fluorescent antibody staining) for antigen detection, rapid influenza diagnostic tests (RIDTs) based on antigen detection, rapid cell culture (shell vial culture), and viral tissue cell culture (conventional) for virus isolation. The optimal choice of influenza test depends on the clinical setting.

The sensitivity and specificity of any influenza test varies by the type of test used (Table 3.26), the time from illness onset, specimen quality and source, and specimen handling and processing. To diagnose influenza in the outpatient or inpatient setting, testing should occur as soon after illness onset as possible, because the quantity of virus shed decreases rapidly as illness progresses. Nasopharyngeal swab specimens have the highest yield of upper respiratory tract specimens for detection of influenza viruses. Mid-turbinate nasal swab or wash specimens are also acceptable. Testing with combined nasal and throat swab specimens may increase the detection of influenza viruses over single specimens from either site (particularly over throat swab specimens alone). Using flocked swabs likely improves influenza virus detection over nonflocked swabs.

When influenza is circulating in the community, hospitalized patients with signs and symptoms of influenza should be tested with a molecular NAAT with high

sensitivity and specificity. For patients with respiratory failure receiving mechanical ventilation, including patients with negative influenza testing results on upper respiratory tract specimens, endotracheal aspirate or bronchoalveolar lavage (BAL) fluid specimens should be obtained. Nonrespiratory specimens such as blood, plasma, serum, cerebrospinal fluid, urine, and stool should not be used for routine diagnosis of influenza.

At-home tests are available for children as young as 2 years. The use of at-home test results to inform treatment decisions should be informed by the sensitivity and specificity of the test, the prevalence of influenza in the community, and the presence and duration of compatible signs and symptoms.

Results of influenza testing should be properly interpreted in the context of clinical findings and local community influenza activity, because the prevalence of circulating influenza viruses influences the positive and negative predictive values of these influenza screening tests. False-positive results are more likely to occur during periods of low influenza activity; false-negative results are more likely to occur during periods of peak influenza activity.

TREATMENT: In the United States, 3 classes of antiviral medications with different mechanisms of action currently are approved for treatment or prophylaxis of influenza infections. Two of these classes are used in clinical management of influenza disease: 3 drugs in the neuraminidase inhibitor class (oral oseltamivir, inhaled zanamivir, and intravenous peramivir) and 1 drug in the cap-dependent endonuclease inhibitor class (oral baloxavir marboxil). Guidance for use of these antiviral agents is summarized in Table 3.27 and at <https://publications.aap.org/redbook/resources/15189> and www.cdc.gov/flu/professionals/antivirals/index.htm. Recommended dosages for drugs approved for treatment and prophylaxis of influenza are provided in Table 4.10 (p 1044).

Oseltamivir is the preferred antiviral medication for patients with influenza A and B. The US Food and Drug Administration (FDA) has approved oseltamivir for influenza treatment in children as young as 2 weeks of age. However, the available pharmacokinetic and safety data suggest that oseltamivir can be used to treat influenza in both term and preterm infants from birth, because benefits of therapy are likely to outweigh possible risks of treatment. Initiation of antiviral therapy should be based on signs and symptoms consistent with influenza infection and epidemiologic factors. Provision of antiviral therapy does not require a positive test result for influenza.

Inhaled zanamivir is an acceptable alternative for children 7 years and older. Intravenous peramivir is approved for use in people 6 months and older. Oral baloxavir is approved for people 5 years and older.

Resistance to oseltamivir and zanamivir has been documented in less than 1% of the tested influenza viral samples during the past seasons. Decreased susceptibility to baloxavir has been reported in Japan, where use has been more common; surveillance for resistance among circulating influenza viruses is ongoing in the United States but remains rare. Each year, options for treatment or chemoprophylaxis of influenza in the United States will depend on influenza strain resistance patterns.

Regardless of influenza vaccination status, antiviral treatment should be offered as early as possible to the following individuals:

- Any hospitalized child with suspected or confirmed influenza disease, regardless of the duration of symptoms;

Table 3.27. Antiviral Drugs for Influenza^a

Drug (Trade Name)	Virus	Adminis- tration	Treatment Indications	Chemopro- phylaxis Indications	Adverse Effects
Oseltamivir (Tamiflu)	A and B	Oral twice daily for 5 days	Birth or older ^b	3 mo or older	Nausea, vomiting, headache; skin reactions; diarrhea (children <1 year)
Zanamivir (Relenza)	A and B	Inhalation twice daily for 5 days	7 y or older	5 y or older	Bronchospasm, skin reactions
Peramivir (Rapivab)	A and B ^c	Intravenous as a single dose	6 m or older	Not recommended	Diarrhea, skin reactions
Baloxavir marboxil (Xofluxe) ^d	A and B	Oral as a single dose	5 y or older	5 y or older	Nausea, vomiting, diarrhea

^aRecommended dosages for drugs approved for treatment and prophylaxis of influenza are provided in Table 4.10 (p 1044). For current recommendations about treatment and chemoprophylaxis of influenza, including specific dosing information, see <https://publications.aap.org/redbook> and www.cdc.gov/flu/professionals/antivirals/index.htm. Antiviral susceptibilities of viral strains are reported weekly at www.cdc.gov/flu/weekly/fluactivitysurv.htm.

^bApproved by the FDA for children as young as 2 weeks of age. Given available pharmacokinetic data and limited safety data, the AAP believes that oseltamivir can be used to treat influenza in both term and preterm infants from birth because benefits of therapy are likely to outweigh possible risks of treatment.

^cPeramivir efficacy is based on clinical trials in which the predominant influenza virus type was influenza A; a limited number of subjects infected with influenza B virus were enrolled.

^dLong-acting endonuclease inhibitor with different mechanism of action than neuraminidase inhibitors. Greater activity on influenza B reported compared with oseltamivir. No data on use in pregnancy or breastfeeding. Not recommended in severely immunocompromised patients.

- Any child, inpatient or outpatient, with severe, complicated, or progressive illness attributable to influenza, regardless of the duration of symptoms or presence of high-risk conditions; and
- Any child, inpatient or outpatient, with influenza virus infection of any severity who is at high risk of complications of influenza, regardless of the duration of symptoms.

Antiviral treatment may be considered for the following individuals in the outpatient setting:

- Any child with suspected or confirmed influenza disease who is not at high risk for influenza complications, if treatment can be initiated within 48 hours of illness onset; and
- Any child with suspected or confirmed influenza disease whose siblings or household contacts are either younger than 6 months or at high risk for influenza complications.

Children with severe influenza should be evaluated carefully for possible coinfection with bacterial pathogens (eg, *S aureus* or *S pneumoniae*) that might require antimicrobial therapy.

The most common adverse effects of oseltamivir are nausea and vomiting. Postmarketing reports, almost exclusively from Japan, have noted self-injury and delirium with use of oseltamivir among pediatric patients, but other data suggest that these occurrences may have been related to influenza disease itself rather than antiviral therapy. An FDA review of controlled clinical trial data and ongoing surveillance did not establish a link between oseltamivir (or any influenza antiviral medication) and neurologic or psychiatric events. Zanamivir use has been associated with bronchospasm in some people and is not recommended for use in patients with chronic respiratory diseases, such as asthma or chronic obstructive pulmonary disease, which increase the risk of bronchospasm. Zanamivir is contraindicated in patients with milk protein allergy. The most common adverse effects of baloxavir are nausea, vomiting, and diarrhea.

Control of fever with acetaminophen or another appropriate nonsalicylate-containing antipyretic agent may be important in some children, because fever and other symptoms of influenza could exacerbate underlying chronic conditions. Children and adolescents with influenza should not receive aspirin or any salicylate-containing products because of the potential risk of developing Reye syndrome.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, droplet precautions are recommended for children hospitalized with influenza or an influenza-like illness for the duration of illness.

CONTROL MEASURES:

Influenza Vaccines.¹ All people 6 months and older should be vaccinated annually against influenza. Two types of influenza vaccines are available for children: inactivated (non-live) influenza vaccines (IIVs), which contain no live virus and are given via intramuscular (IM) injection; and the live attenuated influenza vaccine (LAIV), which is given as a nasal spray. All influenza vaccines are formulated to protect against the same viral strains. The influenza virus strains selected for inclusion in the seasonal vaccine may change yearly in anticipation of the predominant influenza strains expected to circulate in the northern hemisphere in the upcoming influenza season on the basis of influenza circulation in the southern hemisphere and/or in the northern hemisphere's prior season. All pediatric influenza vaccines available in the United States since the 2019–2020 season are quadrivalent, containing 2 influenza A strains and 2 influenza B strains. All licensed pediatric vaccines in the United States are manufactured using virus grown in eggs (egg-based), except for 1 non-live cell-based vaccine. One recombinant vaccine is licensed for individuals 18 years and older. The age indication and dose vary among licensed influenza vaccines for children (see Fig 3.12, p 518). FDA-approved formulations of licensed influenza vaccines are available for children 6 months and older (see Table 3.28, p 519). The American Academy of Pediatrics (AAP) has no preference for any type of vaccine (IIV or LAIV) or formulation over another.

An adjuvanted, cell-based vaccine designed to protect against H5N1 in the event of a pandemic has been approved for children 6 months or older. Recommendations for its use would be made in the event that such a pandemic develops.

Immunogenicity and Dosing in Children. Children 9 years and older require only 1 dose of influenza vaccine annually, regardless of their influenza immunization history.

¹ American Academy of Pediatrics, Committee on Infectious Diseases. Policy statement. Recommendations for prevention and control of influenza in children, 2023–2024. *Pediatrics*. 2023;152(4):e2023063722

FIG 3.12. AVAILABLE INFLUENZA VACCINES IN THE UNITED STATES, BY FDA-LICENSED AGE INDICATION

Vaccine Type	6 through 23 mo	2 through 3 y	4 through 17 y	18 through 49 y	50 through 64 y	≥65 y
IIV4s (egg-based)	Afluria Quadrivalent Fluarix Quadrivalent FluLaval Quadrivalent Fluzone Quadrivalent					
IIV4 (cell-based)	Flucelvax Quadrivalent					
RIV4 (recombinant)				Flublok Quadrivalent		
Adjuvanted IIV3 and IIV4 (egg-based)						Fluad
High-dose IIV3 (egg-based)						Fluzone High-dose
LAIV4 (egg-based)			FluMist Quadrivalent			

Children 6 months through 8 years of age who are receiving the influenza vaccine for the first time or who have received only 1 dose before the upcoming influenza season should receive 2 doses of influenza vaccine administered at least 4 weeks apart. For children requiring 2 doses, vaccination should not be delayed to obtain a specific product for either dose. Any available, age-appropriate vaccine can be used. The doses do not need to be the same brand, and a child may receive a combination of IIV and LAIV if appropriate for age and health status. Protection against disease is achieved 1 to 2 weeks after the second dose. For children 8 years of age who require 2 doses of influenza vaccine, both doses should be administered even if the child turns age 9 years between dose 1 and dose 2.

Coadministration With Other Vaccines. Influenza vaccines can be administered simultaneously with other live and non-live vaccines, including COVID-19 vaccines. Receipt of recommended childhood vaccines during a single visit has important benefits of protecting children against many infectious diseases and minimizing the number of visits that parents or caregivers and children must make.

Recommendations for Influenza Immunization.^{1–3} All people 6 months and older should receive influenza vaccine annually. Influenza vaccine should be offered as soon as it

Table 3.28. Schedule for Influenza Vaccine Dosing by Age^a

Age	Dose, mL ^b	No. of Doses	Route ^c
6 through 35 mo	0.25	1–2 ^d	Intramuscular (Afluria, Fluzone) ^e
	0.5	1–2 ^d	Intramuscular (Fluzone, Fluarix, FluLaval, Afluria, Flucelvax)
3 y through 8 y	0.5	1–2 ^d	Intramuscular
9 y through 17 y	0.5	1	Intramuscular
18 y or older	0.5	1	Intramuscular
2 y through 49 years (healthy)	0.2	1–2 ^d	Intranasal (Flumist)

^aManufacturers include Sanofi Pasteur (Fluzone Quadrivalent, split-virus vaccines licensed for people 6 months or older; Fluzone High-Dose, and Flublok Quadrivalent, recombinant vaccine licensed for people 18 years or older), Seqirus (Afluria Quadrivalent, split virus vaccine for people 6 months and older; Flucelvax Quadrivalent cell-based vaccine licensed for people 6 months and older; and Flud adjuvanted trivalent vaccine for people 65 years and older), GlaxoSmithKline Biologicals (Fluarix Quadrivalent and FluLaval Quadrivalent split-virus vaccines licensed for people 6 months or older), and AstraZeneca (live attenuated influenza vaccine for otherwise healthy persons 2–49 years of age).

^bFrom: Grohskopf LA, Blanton LH, Ferdinands JM, et al. Prevention and control of seasonal influenza with vaccines: recommendations of the Advisory Committee on Immunization Practices—United States, 2022–23 influenza season. *MMWR Recomm Rep.* 2022;71(RR-1):1–28. Available at: www.cdc.gov/mmwr/volumes/71/rr/rr7101a1.htm. Dosages are those recommended in recent years. Refer to the product circular each year to ensure that the appropriate dosage is given for each available formulation.

^cFor adults and older children, the recommended site of immunization is the deltoid muscle. For infants and young children, the preferred site is the anterolateral aspect of the thigh.

^dTwo doses administered at least 4 weeks apart are recommended for children 6 months through 8 years who are receiving influenza vaccine for the first time, who have received a single dose prior to the start of the current season or whose immunization history is unknown.

^eThe 0.25-mL prefilled syringes for Afluria are no longer available. For children aged 6 through 35 months, a 0.25-mL dose must be obtained from a multidose vial for Afluria, or from a single-dose or a multidose vial for Fluzone.

becomes available, especially to children who require 2 doses, with the recommended dose(s) ideally received by the end of October (www.cdc.gov/flu/). Providers should continue to offer vaccine until the vaccine expiration date (typically June 30, marking the end of the influenza season), because influenza circulation is unpredictable. Particular efforts should focus on vaccination of all children and adolescents with factors associated with an elevated risk of complications from influenza, including the following:

- Age <5 years, and especially <2 years, regardless of the presence of underlying medical conditions.
- Residence in a chronic care facility or nursing home.
- Chronic pulmonary disease (including asthma, cystic fibrosis, and compromised respiratory function, eg, tracheostomy or requiring mechanical ventilation), hemodynamically significant cardiovascular disease (except hypertension alone), or renal (including chronic kidney disease, end-stage kidney disease, and dialysis), hepatic (including chronic liver disease and cirrhosis), hematologic (including sickle cell disease and other hemoglobinopathies), or metabolic disorders (including diabetes mellitus).

- Immunosuppression attributable to any cause, including that caused by medications (see Special Considerations) or by human immunodeficiency virus (HIV) infection (see Human Immunodeficiency Virus Infection, p 489).
- Neurologic and neurodevelopment conditions (including disorders of the brain, spinal cord, peripheral nerve, and muscle such as cerebral palsy, epilepsy, stroke, intellectual disability, moderate-to-severe developmental delay, muscular dystrophy, or spinal cord injury).
- Being pregnant or in the postpartum period during the influenza season.
- Receipt of long-term aspirin therapy or salicylate containing medications (including those with Kawasaki disease and rheumatologic conditions) because of increased risk of Reye syndrome.
- Extreme obesity (not well defined in children but could consider body mass index $\geq 99^{\text{th}}$ percentile for age).

Special Considerations. The optimal time to provide inactivated influenza vaccine to children with malignant neoplasms is not well defined, but generally vaccine should be administered ≥ 2 weeks before cytotoxic chemotherapy when clinically possible. In children receiving immunosuppressive chemotherapy, influenza immunization may result in a less robust response than in immunocompetent children. IIV should be deferred in children who have received anti-B lymphocyte therapies in the previous 6 months until there is evidence of B lymphocyte recovery. Children who have completed chemotherapy ≥ 3 months prior generally have adequate rates of seroconversion. Transplantation recipients should receive IIV vaccination starting 4 to 6 months after hematopoietic cell transplantation and 3 months after solid organ transplantation (SOT), although IIV may be considered ≥ 1 month after SOT during the influenza season.

Corticosteroids administered daily for brief periods or every other day seem to have a minimal effect on antibody response to influenza vaccine. Prolonged administration (eg, ≥ 14 days) of high doses of corticosteroids (ie, a dose of prednisone of either 2 mg/kg or greater or a total of 20 mg/day or greater for children who weigh 10 kg or more or an equivalent dose of other corticosteroids) may impair antibody response. Influenza immunization can be deferred during the time of receipt of high-dose corticosteroids, provided deferral does not compromise the likelihood of immunization before the start of influenza season (see Vaccine Administration, p 52).

Children with hemodynamically unstable cardiac disease are at high risk of complications of influenza. The immune response to and safety of IIV in these children are comparable to the immune response and safety in healthy children.

Breastfeeding. Breastfeeding is not a contraindication for influenza immunization. Special effort should be made to vaccinate all persons who are breastfeeding during the influenza season if they were not vaccinated during pregnancy.

Influenza Control in Peri- and Postpartum Settings. Strategies to decrease the likelihood of transmission from a birth parent to the newborn child during the birth hospitalization are provided at www.cdc.gov/flu/professionals/infectioncontrol/peri-post-settings.htm.

Close Contacts of High-Risk Patients. Immunization of everyone who is in close contact with children younger than 5 years or children with high-risk conditions (see Recommendations for Influenza Immunization, p 518) is an important strategy to ensure protection for these children who may not benefit from adequate protection from vaccination alone.

Health Care Personnel. The AAP supports mandatory annual immunization programs for health care personnel (HCP), because HCP frequently come into contact with patients at high risk of influenza illness in clinical settings.¹

Reactions, Adverse Effects, and Contraindications. The most common reactions after IIV administration are local injection site pain and tenderness. Fever may occur within 24 hours after immunization in approximately 10% to 35% of children younger than 2 years but rarely in older children and adults. Mild systemic symptoms, such as nausea, lethargy, headache, muscle aches, and chills, may occur after administration of IIV. LAIV may result in nasal congestion, rhinorrhea, and sore throat, as well as wheezing, particularly in younger children and those with chronic respiratory diseases such as asthma.

Anaphylaxis after receipt of any influenza vaccine is a contraindication to influenza vaccination. Children who have had an allergic reaction after a previous dose of any influenza vaccine should be evaluated by an allergist to help determine the vaccine component responsible for the reaction and whether or not future receipt of an influenza vaccine is appropriate. Children who are allergic to gelatin (very rare) should receive IIV rather than LAIV.

Minor illnesses, with or without fever, are not contraindications to the use of influenza vaccines, including among children with mild upper respiratory infection symptoms or allergic rhinitis. In children with a moderate to severe febrile illness (eg, high fever, active infection, requiring hospitalization, etc), on the basis of the judgment of the clinician, vaccination should be deferred until resolution of the illness. Similarly, children with an amount of nasal congestion that would notably impede vaccine delivery into the nasopharyngeal mucosa should have LAIV vaccination deferred until resolution, or should receive IIV since nasal congestion would not impact its delivery. LAIV is contraindicated in immunocompromised hosts and pregnant individuals as well as in patients with asplenia or central nervous system anatomic barrier defects (eg, cochlear implant, congenital dysplasia of the inner ear, persistent cerebrospinal fluid communication with nasopharynx/oropharynx) (see Table 1.17, p 94). LAIV may be administered to healthy household and other close contacts of people with altered immunocompetence (see Household Members of Immunocompromised Patients, p 103).

Although most influenza vaccines are produced in eggs and contain measurable amounts of egg protein, they are well tolerated by recipients with egg allergy of any severity. Special precautions for recipients of IIV or LAIV with egg allergy are not warranted, as the rate of anaphylaxis after administration is no greater in recipients with egg allergy versus those without egg allergy or from other universally recommended vaccines.

History of Guillain-Barré syndrome (GBS) following influenza vaccine is considered a precaution for the administration of influenza vaccines. Data on the risk of GBS following vaccination with seasonal influenza vaccine are variable and have been inconsistent across seasons. GBS is rare, especially in children, and there is a lack of evidence on risk of GBS following influenza vaccine in children. The decision not to immunize should be thoughtfully balanced against the potential morbidity and mortality associated with influenza for that individual.

¹ Bernstein HH; Starke JR; and the American Academy of Pediatrics, Committee on Infectious Diseases. Policy statement: Influenza immunization for all health care personnel: keep it mandatory. *Pediatrics*. 2015;136(4):809-818 (Reaffirmed March 2020)

Chemoprophylaxis. Chemoprophylaxis with influenza antivirals should not be considered a substitute for immunization. If not contraindicated, influenza vaccine always should be offered, even after influenza virus has begun circulating in the community. Health care professionals should inform recipients of antiviral chemoprophylaxis that the risk of influenza is lowered but still remains while taking medication, and susceptibility to influenza returns when medication is discontinued.

Chemoprophylaxis is not a contraindication to immunization with IIV and does not interfere with the immune response to IIV. Chemoprophylaxis should not be administered in conjunction with LAIV immunization, because antivirals will interfere with LAIV replication. On the basis of drug half-lives, it is prudent to assume interference is possible during the following periods: (1) for oseltamivir and zanamivir, from 48 hours before to 2 weeks after LAIV; (2) for peramivir, from 5 days before to 2 weeks after LAIV; and (3) for baloxavir, from 17 days before to 2 weeks after LAIV. Chemoprophylaxis is not recommended for infants younger than 3 months, unless the situation is judged critical, because of limited safety and efficacy data in this age group.

Antiviral options for influenza chemoprophylaxis are listed in Table 3.27 (p 516), with dosing information provided in Table 4.10 (p 1044). For current recommendations about chemoprophylaxis against influenza, see www.cdc.gov/flu/professionals/antivirals/index.htm or <https://publications.aap.org/redbook/resources/15189>.

Public Health Reporting. All influenza-associated pediatric deaths as well as all infections with a novel influenza A virus are nationally notifiable and should be reported to the Centers for Disease Control and Prevention (CDC) through state health departments.

Kawasaki Disease

CLINICAL MANIFESTATIONS: Kawasaki disease is a vasculitis of medium-sized arteries. The diagnosis is made in patients with fever in addition to the presence of the following clinical criteria:

1. Bilateral injection of the bulbar conjunctivae with limbic sparing and without exudate;
2. Erythematous mouth and pharynx, strawberry tongue, and/or red, cracked lips;
3. A polymorphous, generalized, erythematous rash, often with accentuation in the groin, which can be morbilliform, maculopapular, scarlatiniform, or erythema multiforme-like;
4. Changes in the peripheral extremities consisting of erythema of the palms and soles and firm, sometimes painful, induration of the hands and feet, often followed by periungual desquamation;
5. Acute, nonsuppurative, usually unilateral, anterior cervical lymphadenopathy with at least 1 node ≥ 1.5 cm in diameter.

The diagnosis of classic (or complete) Kawasaki disease is based on the presence of ≥ 5 days of fever and ≥ 4 of the 5 principal features above. The diagnosis may be made with only 4 days of fever if ≥ 4 principal clinical findings are present without alternative explanation. Individual clinical manifestations may appear and self-resolve rather than all being present simultaneously. It is important to inquire about previous presence of relevant manifestations when evaluating for persistent fever.

The correct diagnosis may be delayed in patients who present with fever and unilateral neck swelling, which mistakenly is believed to be attributable to bacterial lymph

node or para- or retropharyngeal infection. A distinguishing clinical and imaging feature in these cases is that suppuration is not observed in Kawasaki disease. Concurrent viral upper respiratory infection sometimes is present in patients with Kawasaki disease and, even if confirmed by virus detection, should not delay treatment of Kawasaki disease. (An exception is the patient with fever, exudative conjunctivitis, and exudative pharyngitis, in whom adenovirus is detected. In such cases, Kawasaki disease is considered unlikely.)

The following mucocutaneous or laboratory findings should prompt a search for an alternative diagnosis to Kawasaki disease: bullous, vesicular, or petechial rash; oral ulcers; pharyngeal or conjunctival exudates; generalized lymphadenopathy or splenomegaly; or leukopenia or relative lymphocyte predominance. Prior infection with SARS-CoV-2, the virus that causes COVID-19, increases the likelihood of multisystem inflammatory syndrome in children (MIS-C) as the cause in a child presenting with symptoms suggestive of Kawasaki disease (see Coronavirus Disease 2019 [COVID-19], p 234). Although features of MIS-C overlap with those of Kawasaki disease, MIS-C has a wider spectrum of manifestations and a more severe illness course, with more than half of the patients developing hypotension or shock requiring admission to an intensive care unit. Patients with MIS-C have a median age of 9 years (compared with 2 years in Kawasaki disease), are more commonly Black or Hispanic (compared with being more likely of Asian ancestry in Kawasaki disease), and show greater elevation of inflammatory markers. More than 80% of patients with MIS-C also present with cardiac injury with high concentrations of troponin and brain natriuretic peptide, and some develop arrhythmia or left ventricle dysfunction. Although evidence of recent SARS-CoV-2 infection is necessary to diagnose MIS-C, such evidence does not rule out a diagnosis of Kawasaki disease because of the widespread occurrence of SARS-CoV-2 infection.

The diagnosis of incomplete Kawasaki disease should be considered in children with unexplained fever who have only 2 or 3 principal clinical criteria. Supportive laboratory and echocardiography data should be obtained when considering the diagnosis of incomplete Kawasaki disease. In 2017, the American Heart Association (AHA) published updated guidelines for the diagnosis, treatment, and long-term management of Kawasaki disease,¹ which provides an algorithm for diagnosis and treatment of suspected incomplete Kawasaki disease (reproduced in Fig 3.13). A high index of suspicion for Kawasaki disease should be maintained for infants, particularly those younger than 6 months, because compared with older children, infants have heightened risk of incomplete manifestations, delayed diagnosis, and development of coronary artery abnormalities. Kawasaki disease should be considered in infants younger than 12 months with prolonged unexplained fever, with or without aseptic meningitis, with evidence of systemic inflammation, even with fewer than 2 of the principal clinical features of Kawasaki disease; the AHA recommends

^aIn the absence of a "gold standard" for diagnosis, this algorithm cannot be evidence based but rather represents the informed opinion of the expert committee. Consultation with an expert should be sought anytime assistance is needed.

^bSee text for clinical findings of Kawasaki disease.

^cInfants ≤6 months of age are the most likely to develop prolonged fever without other clinical criteria for Kawasaki disease; these infants are at particularly high risk of developing coronary artery abnormalities.

^dEchocardiography is considered positive for purposes of this algorithm if any of 3 conditions are met: z score of left anterior descending coronary artery or right coronary artery ≥2.5; coronary artery aneurysm is observed; or ≥3 other suggestive features exist, including decreased left ventricular function, mitral regurgitation, pericardial effusion, or z scores in left anterior descending coronary artery or right coronary artery of 2 to 2.5.

^eTreatment should be given within 10 days of fever onset. See text for indications for treatment after the tenth day of fever.

^fTypical peeling begins under the nail beds of fingers and toes.

Source: McCrindle BW, Rowley AH, Newburger JW, et al; American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee of the Council on Cardiovascular Disease in the Young; Council on Cardiovascular and Stroke Nursing; Council on Cardiovascular Surgery and Anesthesia; and Council on Epidemiology and Prevention. Diagnosis, treatment, and long-term management of Kawasaki disease: a scientific statement for health professionals from the American Heart Association. *Circulation*. Published online March 29, 2017; www.ahajournals.org/doi/full/10.1161/CIR.0000000000000484

echocardiography in all infants with 7 days of fever without another source. Other presentations of Kawasaki disease include infants and children with a shock-like syndrome in whom an inciting infection is not confirmed and those with presumed bacterial cervical lymphadenitis or para- or retropharyngeal phlegmon that fail to respond to appropriate antibiotic therapy.

If coronary artery aneurysm or dilatation is evident (z score ≥ 2.0 for the left anterior descending or right coronary arteries) in any patient evaluated for fever, a presumptive diagnosis of Kawasaki disease should be made. A normal early echocardiographic study is typical and does not exclude the diagnosis but may be useful in evaluation of patients with suspected incomplete Kawasaki disease. In one study, 80% of patients with Kawasaki disease who ultimately developed coronary artery disease had abnormalities (defined as a z score ≥ 2.5) on an echocardiogram obtained during the first 10 days of illness.

Other clinical features of Kawasaki disease include irritability, abdominal pain, diarrhea, and vomiting. Other examination and laboratory findings include urethritis with sterile pyuria (70% of cases), mild anterior uveitis, mild elevation of serum hepatobiliary enzyme concentrations (50%), arthralgia or arthritis (10%–20%), marked irritability with cerebrospinal fluid pleocytosis (40%), hydrops of the gallbladder ($<10\%$), pericardial effusion of at least 1 mm ($<5\%$), myocarditis manifesting as congestive heart failure ($<5\%$), and cranial nerve palsy ($<1\%$). Patients typically have multiple elevated acute phase reactants, such as C-reactive protein (CRP), erythrocyte sedimentation rate (ESR), platelets (after the first week of illness), and white blood cells (with left shift). They commonly have a normocytic, normochromic anemia. Persistent resting tachycardia and a hyperdynamic precordium are common findings, and an S3 gallop can be present. Fine desquamation in the groin area can occur in the acute phase of disease (Fink sign). Inflammation or ulceration may be observed at the inoculation scar of previous bacille Calmette-Guérin immunization. Rarely, Kawasaki disease can present with acute shock; these children often have significant thrombocytopenia attributable to consumption coagulopathy, which also causes a low ESR. Group A streptococcal or *Staphylococcus aureus* toxic shock syndrome should be excluded in such cases.

The average duration of fever in untreated Kawasaki disease is 10 days; however, fever can last 2 weeks or longer. After fever resolves, untreated patients can remain anorexic and/or irritable with decreased activity for 2 to 3 weeks. During this phase, periungual desquamation of the fingers and toes and fine peeling of the hands and feet may occur. Transverse lines across the nails (Beau lines) sometimes are noted month(s) later. Recurrent disease develops in approximately 1% to 2% of patients in the United States a median of 1.5 years after the index episode. The recurrence rate is 3.5% in Asian and Pacific Islander populations, and up to 9% in children of Filipino ancestry.

Coronary artery abnormalities are serious sequelae of Kawasaki disease, occurring in 20% to 25% of untreated children. Increased risk of developing coronary artery abnormalities is associated with male sex; age <12 months or >8 years; fever for more than 10 days; white blood cell count $>15\,000/\text{mm}^3$; high relative neutrophil ($>80\%$) and band count; low hemoglobin concentration (<10 g/dL); hypoalbuminemia, hyponatremia, or thrombocytopenia; and fever persisting or recurring >36 hours after completion of immune globulin intravenous (IGIV) administration.¹ Aneurysms of the coronary arteries most typically occur between 1 and 4 weeks after onset of illness; onset later than 6 weeks is extremely uncommon. Giant coronary artery aneurysms (internal diameter ≥ 8 mm or z score ≥ 10) are highly predictive of long-term complications. Aneurysms occurring in other medium-sized arteries (eg, iliac, femoral, renal, and axillary vessels) are uncommon and do not occur in the absence of significant

¹ The terms male and female refer to sex assigned at birth.

coronary abnormalities. In addition to coronary artery disease, carditis can involve the pericardium, myocardium, or endocardium, and mitral or aortic regurgitation or both can develop.

In children with only mild coronary artery dilation, coronary artery dimensions often return to baseline within 6 to 8 weeks after onset of disease. Approximately 50% of coronary aneurysms (but only a small proportion of giant aneurysms) regress by echocardiography to normal luminal size within 1 to 2 years, although this process can result in luminal stenosis or a poorly compliant, fibrotic vessel wall or both.

The current case fatality rate for acute Kawasaki disease in the United States and Japan is less than 0.2%. The principal cause of death is myocardial infarction resulting from coronary artery occlusion attributable to thrombosis or progressive stenosis. The relative risk of mortality is highest within 6 weeks of onset of acute symptoms, but myocardial infarction and sudden death can occur months to years after the acute episode. There is no current evidence that the vasculitis of Kawasaki disease predisposes to premature atherosclerotic coronary artery disease.

ETIOLOGY: The etiology is unknown. Epidemiologic and clinical features suggest an infectious and/or an environmental cause or trigger in genetically susceptible individuals. The disease was first described in 1967 by Dr. Tomisaku Kawasaki in a landmark paper titled “Acute Febrile Mucocutaneous Syndrome With Lymphoid Involvement With Specific Desquamation of the Fingers and Toes in Children” in the Japanese journal *Arerugi* (“Allergy”). This is now known universally as Kawasaki disease, although he did not use that term himself. Dr. Kawasaki died on June 5, 2020, at age 95.

EPIDEMIOLOGY: Peak age of occurrence in the United States is 6 to 24 months. Fifty percent of patients are younger than 2 years, and 80% are younger than 5 years; cases are uncommon in children older than 8 years, but rare cases have occurred even in young adults. The prevalence of coronary artery abnormalities is higher if treatment (IGIV) is delayed. The male-to-female ratio is approximately 1.5:1. In the United States, 4000 to 5500 cases are estimated to occur each year; the incidence is highest in children of Asian ancestry. More cases, including clusters, occur during winter and spring. Little evidence indicates person-to-person or common-source spread.

The **incubation period** is unknown.

DIAGNOSTIC TESTS: No specific diagnostic test is available. The diagnosis is made based on the presence of established clinical criteria (see Clinical Manifestations, p 522) after consideration of other possible illnesses, such as staphylococcal or streptococcal toxin-mediated disease; drug reactions (eg, Stevens-Johnson syndrome); MIS-C; measles, adenovirus, Epstein-Barr virus, parvovirus B19, or enterovirus infections; rickettsial disease; leptospirosis; rat bite fever; systemic-onset juvenile idiopathic arthritis; and reactive arthritis. The identification of a respiratory virus by molecular testing does not exclude the diagnosis of Kawasaki disease in infants and children who otherwise have met diagnostic criteria. A markedly increased ESR and/or serum C-reactive protein (CRP) concentration during the first 2 weeks of illness and an increased platelet count ($>450\,000/\text{mm}^3$) on days 10 to 21 of illness are almost universal laboratory features. ESR and platelet count usually are normal within 6 to 8 weeks; CRP concentration returns to normal much sooner.

TREATMENT: Management during the acute phase is directed at decreasing inflammation of the myocardium and coronary artery wall and providing supportive care. Therapy should be initiated as soon as the diagnosis is established or strongly suspected. Once the acute phase has subsided, therapy is directed at prevention of thrombosis for patients with coronary artery abnormalities.

Primary Treatment

Immune Globulin Intravenous. A single dose of IGIV, 2 g/kg, administered over 10 to 12 hours, results in rapid resolution of fever and other clinical and laboratory indicators of acute inflammation in approximately 85% of patients and has been proven to reduce the risk of coronary artery aneurysms from 17% to 4%. IGIV plus aspirin (see below) is the treatment of choice and should be initiated as soon as the diagnosis is established or strongly suspected and alternative diagnoses are unlikely, whether or not coronary artery abnormalities are detected. Despite prompt treatment with IGIV and aspirin, approximately 2% to 4% of patients develop coronary artery aneurysms even when treatment is initiated before the onset of coronary artery abnormalities.

Efficacy of therapy initiated later than the 10th day of illness or after detection of coronary artery aneurysms has not been evaluated fully. However, therapy with IGIV and aspirin should be provided for patients in whom the diagnosis is made more than 10 days after the onset of fever who have manifestations of continuing inflammation (ie, elevated ESR or CRP ≥ 3.0 mg/dL) plus either fever or coronary artery luminal dimension z score > 2.5 .

IGIV infusion reactions (chills and hypotension) are not uncommon. Occasionally, Coombs-positive hemolytic anemia can complicate IGIV therapy. The risk of hemolysis is increased in patients receiving high/repeated IGIV doses (usually ≥ 2 g/kg) and those with blood groups A, B, or AB, and usually occurs within 5 to 10 days of infusion. Aseptic meningitis can result from IGIV therapy and resolves quickly without neurologic sequelae. IGIV infusion results in elevation of the ESR; therefore, ESR is not a useful test to monitor disease activity after infusion; CRP is not affected by IGIV administration and can be used.

Aspirin. Aspirin is used for its anti-inflammatory (high-dose) and antithrombotic (low-dose) activity, although aspirin alone does not decrease the risk of coronary artery abnormalities. Guidelines vary with regard to dose. High-dose aspirin (ranging from 30–100 mg/kg per day, depending on country) therapy usually is given until the patient has been afebrile for 48 to 72 hours. This is followed by low-dose aspirin (3 to 5 mg/kg/day, in a single daily dose) until a follow-up echocardiogram 2 to 8 weeks after onset of illness is normal or is continued indefinitely for children in whom coronary artery abnormalities are present. In general, ibuprofen should be avoided in children with coronary aneurysms taking aspirin, because ibuprofen and other nonsteroidal anti-inflammatory drugs with known or potential effects on the cyclooxygenase pathway interfere with the antiplatelet effect of aspirin to prevent thrombosis. Because of the potential risk of Reye syndrome in patients with influenza or varicella receiving salicylates, parents of children receiving aspirin should be instructed to contact their child's physician promptly if the child develops symptoms of or is exposed to either of these diseases. The child and all household contacts older than 6 months should receive influenza vaccine according to seasonal recommendations. Inactivated (non-live) influenza vaccine (not live attenuated influenza vaccine) should be used in the

child receiving aspirin. Family members can receive either IIV or live attenuated influenza vaccine.

Adjunctive Therapies for Primary Treatment. The following are 2017 consensus recommendations of the AHA¹: (1) single-dose pulse methylprednisolone should not be administered with IGIV as routine primary therapy for patients with Kawasaki disease; and (2) patients believed to be at high risk for development of coronary artery aneurysms may benefit from primary adjunctive therapy. Risk factors for development of aneurysms includes baseline z score ≥ 2 , age < 12 months, Asian ancestry, and high inflammation at baseline. Additional anti-inflammatories to be considered in high-risk patients include administration of a longer course of corticosteroids (eg, prednisolone, 2 mg/kg/day IV, divided every 8 hours until afebrile, then an oral corticosteroid until CRP normalizes, with subsequent tapering over 2–3 weeks) or anticytokine biologics such as infliximab together with IGIV and aspirin. Any consideration of additional anti-inflammatory adjunctive therapy (eg, anticytokine biologics) in a patient believed to be at high risk should be discussed in consultation with an expert in Kawasaki disease.

Management of IGIV Resistance and Retreatment. Patients should be monitored daily for fever for a week after IGIV infusion. Approximately 30% of patients who receive IGIV, 2 g/kg, plus aspirin have fever within the first 36 hours after completing the IGIV infusion, which is not an indication of therapeutic failure. However, 10% to 20% of treated patients have recrudescence or persistent fever beyond 36 hours and less than 7 days after completion of their IGIV infusion and are termed IGIV resistant. In these situations, the diagnosis of Kawasaki disease should be reevaluated. If Kawasaki disease still is considered to be most likely, treatment for Kawasaki disease should be intensified as these children have an increased risk of developing coronary artery aneurysms as compared to children with Kawasaki disease who respond to the initial dose of IGIV. In such cases, retreatment with IGIV (2 g/kg) or infliximab (10 mg/kg) may be given and high-dose aspirin should be continued. As an alternative, corticosteroids may be given. In 1 large randomized, controlled study, infliximab as a single infusion was safer (less risk of hemolytic anemia) and more effective (reduced need for additional therapy and shorter hospitalization) when compared with a second infusion of IGIV. Evidence of alteration of coronary artery outcomes associated with different therapies is limited.

Management of patients with Kawasaki disease refractory to a second dose of IGIV, infliximab, or a course of corticosteroids has included use of cyclosporine, other immune modulating therapies, or plasma exchange but should be undertaken in consultation with an expert in Kawasaki disease.¹

Cardiac Care.¹ Echocardiography should be performed at the time of suspected diagnosis and repeated at 2 weeks, and in most patients, 6 to 8 weeks after diagnosis in children with normal coronary arteries on initial evaluation. Coronary abnormalities

¹ For further information on the diagnosis and management of Kawasaki disease, see McCrindle BW, Rowley AH, Newburger JW, et al; American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee of the Council on Cardiovascular Disease in the Young; Council on Cardiovascular and Stroke Nursing; Council on Cardiovascular Surgery and Anesthesia; and Council on Epidemiology and Prevention. Diagnosis, treatment, and long-term management of Kawasaki disease: a scientific statement for health professionals from the American Heart Association. *Circulation*. Published online March 29, 2017. Available at: www.ahajournals.org/doi/full/10.1161/CIR.0000000000000484

warrant closer follow-up with echocardiography. Children at higher risk—for example, children with persistent or recrudescent fever after initial IGIV, baseline coronary artery abnormalities, or very young patients—may require more frequent echocardiograms to guide the need for additional therapies. Children should be assessed during this time for conduction abnormalities, systolic and diastolic dysfunction, and valvular regurgitation. The care of patients with significant cardiac abnormalities should involve a pediatric cardiologist experienced in management of patients with Kawasaki disease and in assessing echocardiographic studies of coronary arteries in children.

Long-term management of Kawasaki disease should be based on the extent of coronary artery involvement. In patients with persistent moderately large coronary artery aneurysms that are not large enough to warrant anticoagulation, clopidogrel (0.2–1 mg/kg/day) to antagonize adenosine diphosphate-mediated platelet activation in combination with prolonged low-dose aspirin are recommended.

Development of giant coronary artery aneurysms (eg, luminal diameter ≥ 8 mm, z score ≥ 10) usually requires addition of anticoagulant therapy, such as warfarin or low-molecular weight heparin, to prevent thrombosis. The AHA has provided recommendations regarding criteria for systemic anticoagulation and frequency of echocardiography in those with coronary aneurysms.¹ The use of non-vitamin K oral anticoagulants (eg, apixaban) is under evaluation and being used in some centers.

Subsequent Immunization. Measles- and varicella-containing vaccines should be deferred until 11 months after receipt of IGIV, 2 g/kg, for treatment of Kawasaki disease because of possible interference with development of an adequate immune response (see Table 1.11, p 69). If the child's risk of exposure to measles or varicella within this period is high, the child should be immunized and then reimmunized at least 11 months after administration of IGIV. Live attenuated varicella-containing vaccines should be avoided during high-dose aspirin therapy because of a theoretical concern of Reye syndrome. The schedule for administration of non-live childhood vaccines should not be interrupted.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are indicated.

CONTROL MEASURES: None.

***Kingella kingae* Infections**

CLINICAL MANIFESTATIONS: The most common infections attributable to *Kingella kingae* are pyogenic arthritis, osteomyelitis, and bacteremia. Other diseases caused by *K kingae* include spondylodiscitis, tenosynovitis, endocarditis (*K kingae* belongs to the HACEK group of organisms), meningitis, ocular infections, and pneumonia. *K kingae* infections typically occur in children between 6 and 48 months of age, with most cases

¹ Giglia TM, Massicotte MP, Tweddell JS, et al. Prevention and treatment of thrombosis in pediatric and congenital heart disease: a scientific statement from the American Heart Association. American Heart Association Congenital Heart Defects Committee of the Council on Cardiovascular Disease in the Young, Council on Cardiovascular and Stroke Nursing, Council on Epidemiology and Prevention, and Stroke Council. *Circulation*. 2013;128(24):2622-2703

occurring in children younger than 2 years, although infections can occur in other age groups. Children with invasive *K kingae* infections other than endocarditis usually present with low-grade fever and normal or only mildly elevated white blood cell counts and acute phase reactants; a high index of suspicion must be maintained for diagnosis. Affected children frequently have concurrent symptoms of respiratory or gastrointestinal tract disease.

K kingae is a primary cause of skeletal infections in the first 4 years of life. *K kingae* pyogenic arthritis generally is monoarticular and most commonly involves the knee, hip, or ankle. *K kingae* osteomyelitis most often involves the femur or tibia. The organism also shows an unusual predilection for the small joints and bones of the chest wall and of the hand and foot. Compared with the clinical manifestations of pyogenic arthritis and osteomyelitis in immunocompetent children caused by other pathogens, skeletal infections caused by *K kingae* can be milder and the clinical course can be more insidious, often resulting in a subacute presentation. Involvement of the apophysis or epiphysis is not unusual in *K kingae* osteomyelitis. Evolution to chronicity or long-term sequelae are rare; however, Brodie abscesses of bone attributable to *K kingae* have been reported.

K kingae bacteremia can occur in previously healthy young children and in children with preexisting chronic medical problems.

ETIOLOGY: *K kingae* is a gram-negative, encapsulated organism that belongs to the *Neisseriaceae* family. It is a fastidious, facultative anaerobic, β -hemolytic coccobacillus that appears as pairs or short chains with tapered ends. It often resists decolorization, sometimes resulting in misidentification as a gram-positive organism.

EPIDEMIOLOGY: The usual habitat of *K kingae* is the human posterior pharynx. The organism colonizes young children more frequently than older children or adults and can be transmitted among children in child care centers, occasionally causing clusters of cases. Infection may be associated with preceding or concomitant viral infections that cause hand, foot, and mouth disease, herpetic gingivostomatitis, or nonspecific upper respiratory tract infections.

The **incubation period** relative to acquisition of colonization is not well defined.

DIAGNOSTIC TESTS: *K kingae* can be isolated from blood, synovial fluid, bone, cerebrospinal fluid, respiratory tract secretions, and other fluid or tissues. Patients with pyogenic arthritis or osteomyelitis attributable to *K kingae* often have negative blood cultures. The organism grows best in aerobic conditions with enhanced carbon dioxide. *K kingae* is difficult to isolate on routinely used solid media. Therefore, synovial fluid and bone aspirates from patients with suspected *K kingae* infection should be inoculated on both solid media and into an aerobic blood culture vial and held for 5 to 7 days to maximize recovery. Once recovered in culture, standard biochemical tests readily identify the organism; alternatively, mass spectrometry of bacterial cellular components may be used for rapid identification.

When available, nucleic acid amplification tests (NAATs) markedly improve detection of *K kingae* in young children with culture-negative skeletal infections. Molecular tests that amplify the species-specific *rtxA*, *cpn60*, and *mdh* genes have higher sensitivity than those targeting the 16S rRNA gene. There currently are no NAATs cleared by the US Food and Drug Administration for *K kingae*, and such tests are available only in specialty laboratories.

TREATMENT: *K kingae* usually is highly susceptible to penicillins and cephalosporins, but in vitro susceptibility to oxacillin is relatively reduced. Nearly all isolates are susceptible to aminoglycosides, macrolides, tetracyclines, and fluoroquinolones. Isolates are resistant to clindamycin, glycopeptide antibiotics (eg, vancomycin), and trimethoprim (although most strains are susceptible to trimethoprim-sulfamethoxazole). Occasional isolates in parts of the United States and other countries have demonstrated beta-lactamase production resulting in low-level resistance to penicillin and ampicillin. The beta-lactamase producing strains are susceptible to beta-lactam/beta-lactamase inhibitor combinations and to cephalosporins.

Ampicillin-sulbactam or a first- or second-generation cephalosporin is recommended as initial therapy for children with osteoarticular infections suspected to be attributable to *K kingae* (definitive therapy can be determined after beta-lactamase production of the isolate is known). For more invasive or severe infections (eg, endocarditis), treatment with a third-generation cephalosporin or, if beta-lactamase production has been ruled out, ampicillin plus an aminoglycoside should be considered. Skeletal system infections usually require 2 to 4 days of intravenous antibiotic therapy, following which a change to an oral antibiotic may be made if the patient's fever has subsided, the clinical condition has improved, and the serum C-reactive protein level is declining. Generally, there is no need for surgical interventions other than a bone or synovial fluid diagnostic aspiration. A total of 2 to 3 weeks of antibiotics suffice for uncomplicated cases of *K kingae* septic arthritis and spondylodiscitis.¹ If an adjacent bone is involved, the antibiotic treatment should probably be extended to 3 to 4 weeks.² Patients with *K kingae* endocarditis are administered antibiotics for 4 to 7 weeks.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: None. Although small clusters of cases have been reported in child care facilities in multiple countries, antimicrobial prophylaxis in contacts of a case is not standard practice. Rifampin administration to close contacts at a dosage of 20 mg/kg/day in 2 divided doses for 2 days, alone or in combination with amoxicillin (80 mg/kg/per day) in 2 divided doses for 2 or 4 days, has been used in the setting of an outbreak. Although no further cases of the disease have been detected in the affected facilities following antibiotic administration, antimicrobial prophylaxis is not standard practice. Public health advice should be sought if more than a single case is identified in young children with close contact.

***Legionella* Infections**

CLINICAL MANIFESTATIONS: Legionellosis is primarily associated with 2 clinically and epidemiologically distinct illnesses: **Legionnaires' disease** and **Pontiac fever**; extrapulmonary legionellosis occurs much less frequently. Legionnaires' disease presents as pneumonia characterized by fever, chills, cough with or without chest pain, and

¹ Woods CR, Bradley JS, Chatterjee A, et al. Clinical practice guideline by the Pediatric Infectious Diseases Society (PIDS) and the Infectious Diseases Society of America (IDSA): 2023 Guideline on diagnosis and management of acute bacterial arthritis in pediatrics. *J Pediatr Infect Dis Soc.* 2023;Nov 6:piad089

² Woods CR, Bradley JS, Chatterjee A, et al. Clinical practice guideline by the Pediatric Infectious Diseases Society and the Infectious Diseases Society of America: 2021 Guideline on diagnosis and management of acute hematogenous osteomyelitis in pediatrics. *J Pediatr Infect Dis Soc.* 2021;10(8):801-844

progressive respiratory distress. Legionnaires' disease can be associated with headache, myalgia, and gastrointestinal tract, central nervous system, and renal manifestations. Overall case fatality rate for Legionnaires' disease (including adults) is approximately 10%. Sites of extrapulmonary legionellosis in children can include liver, spleen, and brain. In addition, persistent cervical lymphadenitis caused by *Legionella* species has been reported. In adults, extrapulmonary legionellosis includes endocarditis, graft infections, joint infections, and cutaneous manifestations including wound infections. Pontiac fever is a milder, self-limited febrile illness without pneumonia that is characterized by an abrupt onset of an influenza-like illness (fever, myalgia, headache, weakness).

ETIOLOGY: *Legionella* species are fastidious, small, gram-negative, aerobic bacilli that grow on buffered charcoal yeast extract (BCYE) media. They constitute a single genus in the family *Legionellaceae*. At least 30 of the more than 60 known *Legionella* species have been implicated in human disease, but the most common species causing infections in the United States is *Legionella pneumophila*, with most isolates belonging to serogroup 1.

EPIDEMIOLOGY: Legionnaires' disease is usually acquired through inhalation of aerosolized water containing *Legionella* species. Rarely, transmission occurs via microaspiration of *Legionella*-containing water. *Legionella longbeachae*, common in some geographic areas such as Australia and New Zealand, is generally acquired through exposure to contaminated soil or compost. In general, Legionnaires' disease and Pontiac fever are not spread person to person. Outbreaks of Legionnaires' disease are commonly associated with buildings or structures that have complex water systems, such as hotels and resorts, long-term care facilities, hospitals, and cruise ships. Sources of infection include *Legionella*-containing water aerosolized from potable water systems (eg, through showerheads or faucets), cooling towers (parts of centralized air-conditioning systems for large buildings), hot tubs, decorative fountains, and other aerosolizing devices (eg, and humidifiers and respiratory therapy equipment). Multiplication of *Legionella* organisms in water sources occurs optimally in temperatures between 25°C (77°F) and 45°C (113°F), although *Legionella* organisms have been recovered from water outside this temperature range.

According to the Centers for Disease Control and Prevention's National Notifiable Disease Surveillance System data, Legionnaires' disease cases have increased by almost 9-fold since 2000; almost 10 000 cases were reported in 2018. Most cases of Legionnaires' disease are sporadic, although they may be associated with unidentified outbreaks or clusters. Health care-associated infections most commonly are related to contamination of the hot water supply. Legionnaires' disease should be considered in the differential diagnosis of patients who develop pneumonia during or after their hospitalization. Legionnaires' disease is more common among older individuals (>50 years), males, smokers, and people with weakened immune systems, malignancy, or chronic disease.¹ Infection in children is rare. Severe disease has occurred in children with malignancy, severe combined immunodeficiency, chronic granulomatous disease, organ transplantation, end-stage renal disease, underlying pulmonary disease, and those treated with systemic corticosteroids or other immunosuppressive agents. Health care-associated cases of *Legionella* infection in newborn infants, including severe

¹ The terms male and female refer to sex assigned at birth.

and sometimes fatal cases, have been associated with a *Legionella*-containing water source. Severe and fatal infections in neonates have occurred after birth in water (eg, use of a birthing pool or hot tub).¹

The **incubation period** for Legionnaires' disease is generally 5 to 6 days but can range from 2 to 14 days. For Pontiac fever, the **incubation period** generally is 1 to 3 days but can be as short as 4 hours.

DIAGNOSTIC TESTS: When a patient is suspected of having Legionnaires' disease, testing should include both culture of a lower respiratory tract specimen and urine antigen testing. Detection of *Legionella* infection from clinical specimens using validated nucleic acid amplification tests (NAATs) is becoming more widely available.

Genus and species-specific NAAT-based assays, including multiplex assays, have been developed that detect *Legionella* DNA in lower respiratory tract specimens, isolates, and blood. NAATs can detect species and serogroups other than *L pneumophila* serogroup 1 and can be performed with quick turnaround. Additionally, the results are less likely to be affected by antibiotic use, because the assay detects genetic material as opposed to a viable organism.

Detection of *Legionella* lipopolysaccharide antigen in urine by commercially available immunoassays is highly specific. This test detects only *L pneumophila* serogroup 1, and thus other testing methods are needed to detect other *L pneumophila* serogroups and other *Legionella* species. Urinary antigen test sensitivity may be increased with increased disease severity.

Culture remains an important diagnostic tool, because it can detect all *Legionella* species and *L pneumophila* serogroups and can generate isolates for further investigation, including whole genome sequencing, which can be helpful in outbreak investigations. Recovery of *Legionella* organisms from lower respiratory tract secretions, lung tissue, pleural fluid, or other normally sterile fluid specimens using buffered charcoal yeast extract (BCYE) media provides definitive evidence of infection, but the sensitivity of culture is laboratory dependent. Specimens should be plated onto both nonselective BCYE and selective BCYE media containing appropriate antimicrobial agents and incubated at 35°C to 37°C for up to 14 days. Suspicious colonies are commonly identified by demonstrating growth dependence on L-cysteine followed by further confirmation and characterization by serologic or molecular tests.

Direct detection of the bacterium in lower respiratory tract specimens by direct immunofluorescent assay is rarely performed, because the specificity is technician dependent and the sensitivity is lower than that for culture or urine immunoassay.

Detection of serum immunoglobulin (Ig) M antibodies is not useful for diagnosis. The positive predictive value of a single elevated IgG titer is low and does not provide definitive evidence of acute infection. A fourfold increase in *L pneumophila*-specific IgG antibody titer, as measured by indirect immunofluorescent antibody (IFA), confirms a recent infection. However, this serologic result is not useful for treatment decisions, because convalescent titers take 3 to 4 weeks to increase (and may be delayed for 8 to 12 weeks). Antibodies to several gram-negative organisms, including *Pseudomonas* species, *Bacteroides fragilis*, and *Campylobacter jejuni*, can cause false-positive IFA test results.

¹ Nolt D, O'Leary ST, Aucott SW; American Academy of Pediatrics, Committee on Infectious Diseases, Committee on Fetus and Newborn. Risks of infectious diseases in newborns exposed to alternative perinatal practices. *Pediatrics*. 2022;149(2):e2021055554

TREATMENT: Patients with Legionnaires' disease should receive antimicrobial agents. Intravenously administered azithromycin or levofloxacin (or another fluoroquinolone for respiratory tract infection) is recommended. Once the patient is improved clinically, oral therapy can be substituted. Doxycycline is an alternative agent; however, *L long-beachae* often is resistant. Duration of therapy is generally 5 to 10 days with azithromycin and 7 to 14 days with other drugs, with the longer courses of therapy for patients who are immunocompromised or who have severe disease. Some patients who are immunocompromised or have complicated infections may require extended therapy.

Antimicrobial treatment for patients with Pontiac fever is not recommended, because the disease is self-limiting.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: The development and implementation of water management programs is the most effective strategy for prevention of Legionnaires' disease infections associated with buildings that have large or complex water systems or with high-risk devices such as cooling towers, hot tubs, decorative fountains, or other centrally installed aerosolizing devices. In 2017, the Centers for Medicare and Medicaid Services (CMS) released a survey and certification memo stating that health care facilities should develop and adhere to the American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE)-compliant water management programs.¹ The Centers for Disease Control and Prevention Toolkit for Controlling *Legionella* in Common Sources of Exposure² and ASHRAE Guideline 12-2020³ are resources that can help facilities develop water management programs to identify hazardous conditions and implement steps to minimize the risk associated with *Legionella* organisms and other waterborne pathogens in building water systems. Adequate levels of disinfectant should be maintained in all building water systems. Hospitals should maintain hot water at the highest temperature allowable by state regulations or codes, preferably stored at 60°C (140°F) or greater with a minimum return temperature of 49°C (120°F); precautions should be taken to avoid scalding. Facilities should store and circulate cold water at temperatures below the favorable range for *Legionella* (25–45°C, 77–113°F) to minimize waterborne *Legionella* growth. *Legionella* may grow at temperatures as low as 20°C (68°F). Some hospitals may choose to perform periodic testing of water samples from the hospital's potable water system to detect *Legionella* bacteria.

When 1 presumptive health care-associated case of *Legionella* infection is identified or when 2 or more possible health care-associated cases occur within 12 months, a

¹ Centers for Medicare and Medicaid Services. Requirement to Reduce *Legionella* Risk in Healthcare Facility Water Systems to Prevent Cases and Outbreaks of Legionnaires Disease (LD). Memo No. 17-30-Hospitals/CAHs/NHs. Centers for Medicare and Medicaid Services; 2018. Available at: www.cms.gov/Medicare/Provider-Enrollment-and-Certification/SurveyCertificationGenInfo/Policy-and-Memos-to-States-and-Regions-Items/Survey-And-Cert-Letter-17-30-

³ American Society of Heating, Refrigerating and Air-Conditioning Engineers. Managing the Risk of Legionellosis Associated with Building Water Systems. ASHRAE Guideline 12-2020. ASHRAE; 2020. Available at: www.techstreet.com/ashrae/standards/guideline-12-2020-managing-the-risk-of-legionellosis-associated-with-building-water-systems?product_id=2111422

full epidemiologic and environmental investigation for the source of *Legionella* organisms in the health care facility is recommended. A presumptive health care-associated case is a patient with 10 or more days of continuous stay at a health care facility during the 14 days before onset of symptoms. A possible health care-associated case is a patient who spent a portion of the 14 days at a health care facility before onset of symptoms.

Hospitals with solid organ or hematopoietic cell transplantation programs should maintain a high index of suspicion for legionellosis, use sterile water for the filling and terminal rinsing of nebulization devices, and consider performing routine testing for *Legionella* species in the potable water supply of the transplant unit. For remedial disinfection, shock chlorination can be used. In addition, targeted application of point-of-use water filters and water restrictions can be immediately implemented and can prevent exposure while remediation is performed and its efficacy verified. Optional supplemental measures for long-term control of *Legionella* in potable water to prevent health care-associated infections include copper-silver ionization; addition of chlorine, monochloramine, or chlorine dioxide; and ultraviolet light when implemented as part of a comprehensive water management program.

Public Health Reporting. Infection with *Legionella* species is a nationally notifiable disease in the United States. Health care providers should promptly report legionellosis cases to the local or state health department.

Leishmaniasis

CLINICAL MANIFESTATIONS:

Cutaneous Leishmaniasis. After inoculation by the bite of an infected female phlebotomine sand fly (approximately 2–3 mm long), parasites proliferate locally in mononuclear phagocytes, leading to an erythematous papule that typically enlarges slowly to become a nodule and then an ulcerative lesion with raised, indurated borders. Ulcerative lesions may become dry and crusted or may develop a moist granulating base with overlying exudate. Lesions can persist as nodules, papules, or plaques and may be single or multiple. Lesions commonly appear on exposed areas of the body (eg, face and extremities) and may be accompanied by satellite lesions, sporotrichoid-like nodules, and regional adenopathy. Spontaneous resolution of lesions may take weeks to years, depending, in part, on the *Leishmania* species/strain, and usually results in a flat, atrophic scar.

Mucosal Leishmaniasis (Espundia). Mucosal leishmaniasis traditionally refers to a metastatic sequela of New World cutaneous infection resulting from dissemination of the parasite from the skin to the naso-oropharyngeal/laryngeal mucosa. This form of leishmaniasis typically is caused by species in the *Viannia* subgenus. Mucosal involvement attributable to local extension of cutaneous facial lesions has a different pathophysiology. Mucosal disease usually becomes evident clinically months to years after the original cutaneous lesions have healed, although mucosal and cutaneous lesions may be noted simultaneously, and some affected people have had subclinical cutaneous infection. Untreated mucosal leishmaniasis can progress to cause ulcerative destruction of the mucosa (eg, perforation of the nasal septum) and facial disfigurement.

Visceral Leishmaniasis (Kala-Azar). After cutaneous inoculation by an infected sand fly, the parasite spreads throughout the reticuloendothelial system (ie, within macrophages in spleen, liver, and bone marrow) leaving no or a minimal skin lesion at the bite site. Clinical manifestations include fever, weight loss, hepatosplenomegaly, pancytopenia (anemia, leukopenia, and thrombocytopenia), hypoalbuminemia, and hypergammaglobulinemia. Hemophagocytic lymphohistiocytosis has been reported as a complication of visceral leishmaniasis. Peripheral lymphadenopathy is common in East Africa (eg, South Sudan). Some patients in South Asia (the Indian subcontinent) develop grayish discoloration of their skin; this manifestation gave rise to the Hindi term kala-azar (“black sickness”). Untreated, advanced cases of visceral leishmaniasis almost always are fatal, either directly from the disease or from complications, such as secondary bacterial infections or hemorrhage. Visceral infection can, alternatively, be asymptomatic or have few symptoms. Latent visceral infection can reactivate years to decades after exposure in people who become immunocompromised (eg, because of coinfection with human immunodeficiency virus [HIV] or immunosuppressive/immunomodulatory therapy). Some patients develop post-kala-azar dermal leishmaniasis (PKDL) during or after treatment of visceral leishmaniasis.

Post-Kala-Azar Dermal Leishmaniasis. PKDL is a dermatosis that generally develops as a sequela after apparent successful cure from visceral leishmaniasis. In the Indian subcontinent variant, polymorphic lesions (coexistence of macules/patches along with papulonodules) are prevalent, whereas the Sudanese variant has papular or nodular lesions.

ETIOLOGY: In the human host, *Leishmania* species are obligate intracellular protozoan parasites of mononuclear phagocytes. Together with *Trypanosoma* species, they constitute the family *Trypanosomatidae*. Approximately 20 *Leishmania* species (in the *Leishmania* and *Viannia* subgenera) are known to infect humans. Cutaneous leishmaniasis typically is caused by Old World species *Leishmania tropica*, *Leishmania major*, and *Leishmania aethiopica* and by New World species *Leishmania mexicana*, *Leishmania amazonensis*, *Leishmania (Viannia) braziliensis*, *Leishmania (V) panamensis*, *Leishmania (V) guyanensis*, and *Leishmania (V) peruviana*. Mucosal leishmaniasis typically is caused by species in the *Viannia* subgenus, especially *L (V) braziliensis* but also *L (V) panamensis* and *L (V) guyanensis*. Most cases of visceral leishmaniasis are caused by *Leishmania donovani* or *Leishmania infantum* (*Leishmania chagasi* is synonymous). *L donovani* and *L infantum* also can cause cutaneous and mucosal leishmaniasis, although people with typical cutaneous leishmaniasis caused by these organisms rarely develop visceral leishmaniasis. Recently, emerging foci of both cutaneous and visceral infection with *Leishmania (Mundinia)* species have been reported from the Caribbean, Ghana, and Southeast Asia. PKDL has been reported to be caused primarily by *L donovani*, both in the Indian subcontinent and Sudan.

EPIDEMIOLOGY: Leishmaniasis is a zoonosis in most settings, with mammalian reservoir hosts, such as rodents or dogs. Some transmission cycles are anthroponotic: infected humans are the primary or only reservoir hosts of *L donovani* in South Asia (potentially also in East Africa) and of *L tropica*. Congenital and parenteral (ie, shared needles, blood transfusion) transmission also have been reported.

Leishmaniasis has been endemic in more than 90 countries in the tropics, subtropics, and southern Europe. Visceral leishmaniasis (50 000–90 000 new cases annually) is found in focal areas in the Old World; in parts of Asia (particularly South, Southeast,

Southwest, and Central Asia), Africa (East and Central Africa, including a recent outbreak in Chad), the Middle East, and southern Europe; and in the New World, particularly in Brazil. In 2020, most (>90%) of the world's reported cases of visceral leishmaniasis occurred in 10 countries: Brazil, China, Eritrea, Ethiopia, India, Kenya, Somalia, South Sudan, Sudan, and Yemen.

Cutaneous leishmaniasis is more common (0.6 to 1 million new cases annually). Approximately 90% of cutaneous leishmaniasis occurs in the Americas, the Mediterranean basin, parts of the Middle East, and Central Asia. Ten countries, Afghanistan, Algeria, Brazil, Colombia, Iraq, Libya, Pakistan, Peru, the Syrian Arab Republic, and Tunisia, accounted for over 85% of new cases of cutaneous leishmaniasis in 2020. In general, the geographic distribution of leishmaniasis cases identified in the United States reflects immigration from and travel patterns to regions with endemic disease. Autochthonous human cases of cutaneous leishmaniasis, mostly associated with *L mexicana*, have been reported in several southwest states including Texas, Oklahoma, and Arizona.

PKDL is confined mainly to 2 regions with endemic kala-azar: the Indian subcontinent (India, Nepal, Sri Lanka, and Bangladesh) and East Africa, mainly Sudan, although case reports have emanated from China, Iraq, and Iran. In the Indian subcontinent, transmission of visceral leishmaniasis is anthroponotic, whereas in Sudan it is zoonotic and anthroponotic; therefore, patients with PKDL are the proposed disease reservoir of visceral leishmaniasis in the Indian subcontinent. Young adults are affected more commonly in the Indian subcontinent and children are affected more commonly in Sudan.

Incubation periods for the various forms of leishmaniasis range from weeks to years. The primary skin lesions of cutaneous leishmaniasis typically appear within several weeks of exposure. The **incubation period** of visceral infection usually ranges from approximately 2 to 6 months. PKDL in Sudan develops within 6 months of treatment but in India can develop decades after cure of visceral leishmaniasis.

DIAGNOSTIC TESTS: Definitive diagnosis is made by detecting the parasite (amastigote stages) in infected tissue (eg, of aspirates, scrapings, touch preparations, or histologic sections) by light-microscopic examination of slides stained with Giemsa, hematoxylin and eosin, or other stains, by in vitro culture (available at reference laboratories), or increasingly by molecular methods (detection of parasite DNA by nucleic acid amplification tests [NAATs]). The latter are reported to be more sensitive than microscopy or culture. The SMART-Leish NAAT used by the US military leishmaniasis diagnostic laboratory is cleared by the US Food and Drug Administration (FDA). In cutaneous and mucosal disease, tissue can be obtained by a 3-mm punch biopsy, lesion scrapings, or needle aspiration of the raised nonnecrotic edge (biopsy) or the ulcer base of the lesion. In visceral leishmaniasis, although the sensitivity is highest (approximately 95%) for splenic aspiration, the procedure can be associated with life-threatening hemorrhage; bone marrow aspiration is safer and generally preferred. Other potential sources of specimens include liver, lymph node, and, in some patients (eg, those infected with HIV), whole blood or buffy coat. Identification of *Leishmania* species (eg, via isoenzyme analysis of cultured parasites or molecular approaches) may affect prognosis and influence treatment decisions. The Centers for Disease Control and Prevention (CDC) (www.cdc.gov/parasites/leishmaniasis) can assist in all aspects of diagnostic testing. Serologic testing usually is not helpful in the evaluation of potential

cases of cutaneous leishmaniasis but can provide supportive evidence for diagnosis of visceral or mucosal leishmaniasis, particularly if the patient is immunocompetent. The rK39 immunochromatographic assay is FDA cleared for presumptive diagnosis of visceral leishmaniasis and is commercially available.

TREATMENT: Guidelines published in 2016 from the Infectious Diseases Society of America and the American Society of Tropical Medicine and Hygiene provide a detailed approach to diagnosis and treatment.¹ Systemic antileishmanial treatment always is indicated for patients with symptomatic visceral or mucosal leishmaniasis, whereas not all patients with cutaneous leishmaniasis need to be treated or require systemic therapy (see Drugs for Parasitic Infections, p 1068, for specific treatment recommendations). Consultation with infectious disease or tropical medicine specialists and with staff of the CDC Division of Parasitic Diseases and Malaria is recommended (telephone: 404-718-4745; e-mail: parasites@cdc.gov; CDC Emergency Operations Center [after business hours and on weekends]: 770-488-7100). The relative merits of various treatment approaches/regimens for an individual patient should be considered, taking into account that the therapeutic response may vary, not only for different *Leishmania* species but also for the same species in different geographic regions. Special considerations apply in the United States regarding availability of particular medications. For example, currently the pentavalent antimonial compounds (eg, sodium stibogluconate) are not available except under an investigator-initiated investigational new drug application.

Liposomal amphotericin B is approved by the FDA for treatment of visceral leishmaniasis. The oral agent miltefosine is approved for treatment of cutaneous, mucosal, and visceral leishmaniasis; the FDA-approved indications are limited to infections caused by particular *Leishmania* species and to patients who are at least 12 years of age, weigh at least 30 kg (66 lb), and are not pregnant or breastfeeding during and for 5 months after the treatment course.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS: Standard precautions are recommended.

CONTROL MEASURES: The best way for travelers to prevent leishmaniasis is by protecting themselves from sand fly bites. Vaccines and drugs for preventing infection are not available. To decrease the risk of being bitten, travelers should take the following measures:

- Stay in well-screened or air-conditioned areas when feasible. Avoid outdoor activities, especially from dusk to dawn, when sand flies generally are most active.
- When outside, wear long-sleeved shirts, long pants, and socks.
- Apply insect repellent on uncovered skin and under the ends of sleeves and pant legs. Follow instructions on the label of the repellent. The most effective repellents generally are those that contain the chemical N,N-diethyl-meta-toluamide (DEET) (see Prevention of Mosquito-borne and Tick-borne Infections, p 207).
- Spray clothing items with a pyrethroid-containing insecticide several days before travel, and allow them to dry. The insecticide should be reapplied after every 5 washings. Permethrin should never be applied to skin.

¹ Aronson N, Herwaldt BL, Libman M, et al. Diagnosis and treatment of leishmaniasis: clinical practice guidelines by the Infectious Diseases Society of America (IDSA) and the American Society of Tropical Medicine and Hygiene (ASTMH). *Clin Infect Dis*. 2016;63(12):e202-e264

- Spray living and sleeping areas with an insecticide.
- Use a bed net tucked under the mattress if not sleeping in an area that is well screened or air conditioned. If at all possible, a bed net that has been soaked in or sprayed with a pyrethroid-containing insecticide should be used; the insecticide will be effective for several months if the bed net is not washed. Because sand flies are much smaller than mosquitoes and can penetrate through smaller holes, fine-mesh netting, which may be uncomfortable in hot weather, is needed for an effective physical barrier against sand flies if the bed net is not impregnated.
- Purchase bed nets, repellents containing DEET, and permethrin before traveling.

Other considerations for prevention of leishmaniasis include early, effective treatment of infected persons, particularly those infected with anthroponotically transmitted parasites for which competent vectors exist; and treatment (to prevent potential congenital transmission) of pregnant people with visceral leishmaniasis. Leukoreduction filtering of blood products may decrease risk of acquiring visceral leishmaniasis through transfusion.

Leprosy

CLINICAL MANIFESTATIONS: Leprosy (Hansen's disease) is a curable infection primarily involving skin, peripheral nerves, and mucosa of the upper respiratory tract. The clinical forms of leprosy reflect the cellular immune response to *Mycobacterium leprae* and, in turn, the number, size, structure, and bacillary content of the lesions. The organism has unique tropism for peripheral nerves, and all forms of leprosy exhibit nerve involvement. Leprosy skin lesions are quite varied and may present as macular hypopigmented or erythematous anesthetic lesions, discolored patches, scaly plaques, sharply defined macules with central clearing, painless ulcers, or nodules. Leprosy lesions usually do not itch or hurt. They lack sensation to heat, touch, and pain but otherwise may be difficult to distinguish from other common maladies. There may be madarosis (loss of eyelashes or eyebrows). Although the nerve injury caused by leprosy is irreversible, early diagnosis and drug therapy can prevent sequelae.

Leprosy manifests over a broad clinical and histopathologic spectrum. In the United States, the Ridley-Jopling scale is used to classify patients according to the histopathologic features of their lesions and organization of the underlying granuloma. The scale is as follows: (1) tuberculoid; (2) borderline tuberculoid; (3) mid-borderline; (4) borderline lepromatous; and (5) lepromatous. A simplified scheme introduced by the World Health Organization for circumstances in which pathologic examination and diagnosis is unavailable is based purely on clinical skin examination. This scheme classifies leprosy by the number of skin patches as either paucibacillary (1–5 lesions, usually tuberculoid or borderline tuberculoid) or multibacillary (>5 lesions, usually mid-borderline, borderline lepromatous, or lepromatous). Patients in the tuberculoid spectrum have active cell-mediated immunity with low antibody responses to *M leprae* and few well-defined lesions containing few bacilli. Lepromatous spectrum cases have high antibody responses with little cell-mediated immunity to *M leprae* and several somewhat diffuse lesions usually containing numerous bacilli.

Serious consequences of leprosy occur from immune reactions and nerve involvement with resulting anesthesia, which can lead to repeated unrecognized trauma, ulcerations, fractures, and even bone resorption. Leprosy is a leading cause of

permanent physical disability among communicable diseases worldwide. Eye involvement can occur, especially corneal scarring, and patients should be examined by an ophthalmologist. A diagnosis of leprosy should be considered in any patient with a hypoesthetic or anesthetic skin rash or skin patches who has a history of residence or travel in areas with endemic leprosy or exposure to armadillos.

Leprosy Reactions. Acute clinical exacerbations reflect abrupt changes in the immunologic balance. These reactions are especially common during initial years of treatment but can occur in the absence of therapy. Two major types of leprosy reactions (LRs) are observed. Type 1 (reversal reaction [LR-1]) is observed predominantly in borderline tuberculoid and borderline lepromatous leprosy and is the result of a sudden increase in effective cell-mediated immunity. Acute tenderness and swelling at the site of cutaneous and neural lesions with development of new lesions are major manifestations. Ulcerations can occur, but polymorphonuclear leukocytes are absent from the LR-1 lesion. Fever and systemic toxicity are uncommon. Type 2 (erythema nodosum leprosum [LR-2]) occurs in borderline and lepromatous forms as a systemic inflammatory response. Tender, red subcutaneous papules or nodules resembling erythema nodosum can occur along with high fever, migrating polyarthralgia, painful swelling of lymph nodes and spleen, iridocyclitis, and rarely, nephritis.

ETIOLOGY: Leprosy is caused by *M leprae* and *M lepromatosis*. The organisms can be differentiated only genetically. They manifest an identical spectrum of clinical symptoms and are equally susceptible to antibiotics typically used to treat leprosy. They are obligate intracellular, rod-shaped bacteria that can have variable findings on Gram stain and are weakly acid-fast on standard Ziehl-Neelsen staining. They are best visualized using the Fite stain. Leprosy bacilli have not been cultured successfully in vitro. They are the only bacteria known to infect Schwann cells of peripheral nerves, and demonstration of acid-fast bacilli in peripheral nerves is pathognomonic for leprosy.

EPIDEMIOLOGY: Leprosy is considered a neglected tropical disease and is most prevalent in tropical and subtropical zones. It is not highly infectious. Several human genes have been identified that are associated with susceptibility to *M leprae*, and a minority of people appear to be genetically susceptible to the infection. Accordingly, spouses of leprosy patients are not likely to develop leprosy, but biological parents, children, and siblings who are household contacts of untreated patients with leprosy are at higher risk.

Transmission is believed to be most effective through long-term close contact with an infected individual and likely occurs through respiratory shedding of organisms. The 9-banded armadillo (*Dasypus novemcinctus*) is a recognized nonhuman reservoir of *M leprae*, and zoonotic transmission has been reported in the southern United States. There are reports of *M leprae* infection among 9-banded armadillos as well as the 6-banded armadillo (*Euphractus sexcinctus*) in both Central and South America, mainly Argentina and Brazil. In addition, red squirrels (*Sciurus vulgaris*) in the British Isles may carry *M leprae* and *M lepromatosis*, and groups of chimpanzees in East Africa also have been found to carry *M leprae*. People living with human immunodeficiency virus (HIV) infection do not appear to be at increased risk of becoming infected with *M leprae*. However, concomitant HIV infection and leprosy can lead to worsening of leprosy symptoms during HIV treatment and resulting immune reconstitution inflammatory syndrome. Like many other chronic infectious diseases, onset of leprosy is associated

increasingly with use of anti-inflammatory autoimmune therapies and immunologic senescence among elderly patients. Little is known about transmission during pregnancy and in the peripartum period. Further guidance on managing pregnant people and infants is available at <http://internationaltextbookofleprosy.org/chapter/pregnancy-and-children>.

More than 200 000 cases including 15 000 children are diagnosed with leprosy annually worldwide. More than 65% of the world's patients with leprosy reside in South and Southeast Asia, primarily India. Other areas of high endemicity include Angola, Brazil, the Central African Republic, Democratic Republic of Congo, Madagascar, Mozambique, the Republic of the Marshall Islands, South Sudan, the Federated States of Micronesia, and the United Republic of Tanzania. Approximately 6500 people with leprosy currently live in the United States, with approximately 150 to 200 new cases presenting each year. The majority of leprosy cases reported in the United States occur among residents of Arkansas, California, Florida, Hawaii, Louisiana, New York, and Texas or among immigrants and other people who lived or worked in countries with endemic leprosy.

The **incubation period** usually is 3 to 5 years but may range from 1 to 20 years. The average age at onset varies according to endemicity within a population. All age groups are susceptible.

DIAGNOSTIC TESTS: There are no diagnostic tests or methods to detect subclinical leprosy. Histopathologic examination of a skin biopsy by an experienced pathologist is the best method of establishing the diagnosis and establishing disease classification. Formalin fixed or paraffin embedded biopsies can be sent to the National Hansen's Disease (Leprosy) Program (NHDP [800-642-2477; www.hrsa.gov/hansens-disease/diagnosis/biopsy.html]). Acid-fast bacilli may be found in slit smears or biopsy specimens of skin lesions from patients with lepromatous (multibacillary) forms of the disease but rarely are visualized from patients with the paucibacillary tuberculoid and indeterminate (first lesion with slightly diminished sensation) forms of disease. A nucleic acid amplification test (NAAT) for *M leprae* and *M lepromatosis* is available at the NHDP, as are molecular tests for genetic mutations associated with drug resistance and strain typing based on single nucleotide polymorphisms and other genomic elements. Tuberculin skin tests and interferon-gamma release assays are not used to diagnose leprosy.

TREATMENT: Leprosy is curable. Therapy for patients with leprosy should be undertaken in consultation with an expert in leprosy. The NHDP (www.hrsa.gov/hansens-disease; 800-642-2477) provides consultation on clinical and pathologic issues and information about local Hansen's disease clinics and clinicians who have experience with the disease. The open access International Textbook of Leprosy (<http://internationaltextbookofleprosy.org/>) is another valuable resource. Prevention of permanent nerve damage and disability is an important goal of treatment and requires education of and self-awareness by the patient. Combination antimicrobial therapy can be obtained free of charge from the NHDP in the United States and from the World Health Organization in other countries (www.hrsa.gov/hansensdisease/diagnosis/recommendedtreatment.html).

It is important to treat infections with more than 1 antimicrobial agent to prevent development of antimicrobial-resistant organisms. Most patients are treated with

dapsone and rifampin for 12 months (tuberculoid disease) or dapsone, rifampin, and clofazimine for 24 months (lepromatous disease). Regimens and doses for children are available and should be chosen with assistance from NHDP. Resistance to all 3 drugs has been documented but is extremely rare. Before beginning antimicrobial therapy, patients should be tested for glucose-6-phosphate dehydrogenase deficiency, have baseline complete blood cell counts and serum aminotransferase results documented, and be evaluated for any evidence of tuberculosis infection, especially if infected with HIV. This consideration is important to avoid monotherapy of active tuberculosis with rifampin while treating active leprosy. The infectivity of leprosy patients to others ceases within only a few days of initiating standard multidrug therapy.

Management of leprosy reactions is complex and expert guidance should be sought. Reactions should be treated aggressively to prevent peripheral nerve damage. Treatment with prednisone (1 mg/kg per day, orally) can be initiated for short-term management and rescue situations. Long-term use of prednisone should incorporate a sparing agent such as methotrexate. LR-2 may be treated with thalidomide (100–400 mg/day for 4 days). Thalidomide is available through Bristol-Meyers Squibb and is used under strict supervision (www.celgeneriskmanagement.com or 888-423-5436). Thalidomide is not approved for use in children younger than 12 years. Most patients can be treated on an outpatient basis. Rehabilitative measures, including surgery and physical therapy, may be necessary for some patients.

All patients with leprosy should be educated about signs and symptoms of neuritis and cautioned to report them immediately so that corticosteroid therapy can be instituted. Patients should receive counseling because of the social and psychological effects of this disease.

Relapse of disease after completing multidrug therapy is rare (0.01%–0.14%); the presentation of new skin patches usually is attributable to a late type 1 reaction (LR-1). When it does occur, relapse usually is attributable to reactivation of drug-susceptible organisms. People with relapses of disease require another course of multidrug therapy.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are indicated; isolation is not required.

CONTROL MEASURES: Leprosy is a reportable disease in the United States. Newly diagnosed cases should be reported to state public health authorities, the Centers for Disease Control and Prevention, and the NHDP. Household contacts should be examined initially, but long-term follow-up of asymptomatic contacts is not warranted. Chemoprophylaxis is not recommended.

There are no vaccines approved for use in the United States. A single bacille Calmette-Guérin (BCG) immunization is reported to be from 28% to 60% protective against leprosy, and BCG vaccine is used as an adjunct to drug therapy in Brazil. However, BCG vaccine administration also may precipitate leprosy among subclinically infected individuals. The effectiveness of combined drug and immunotherapy is unknown.

Leptospirosis

CLINICAL MANIFESTATIONS: Leptospirosis is an acute febrile disease with varied manifestations. The severity of disease ranges from asymptomatic or subclinical to a self-limited systemic febrile illness (approximately 90% of patients) to a life-threatening

illness that can include jaundice, renal failure (oliguric or nonoliguric), myocarditis, hemorrhage (particularly pulmonary), aseptic meningitis, or refractory shock. Clinical presentation may be mono- or biphasic. Classically described biphasic leptospirosis has an acute septicemia phase usually lasting up to 1 week, when *Leptospira* organisms are present in blood, followed by a second immune-mediated phase that begins 1 to 3 days later and is less likely to respond to antimicrobial therapy. Regardless of its severity, the acute phase is characterized by nonspecific symptoms, including fever, chills, headache, myalgia, nausea, vomiting, or rash. Distinct clinical findings include notable conjunctival suffusion without purulent discharge (28%–99% of cases) and myalgia of the calf and lumbar regions (40%–97% of cases). Manifestations of the immune phase are more variable and milder than the initial illness. The hallmark of the immune phase is aseptic meningitis; uveitis typically is a late finding (4–8 months after the illness has begun) but can occur within 2 weeks. Supportive therapies are appropriate during this phase. Severe manifestations include jaundice and renal dysfunction (Weil syndrome), pulmonary hemorrhage, cardiac arrhythmias, and circulatory collapse. Abnormal potassium (high or low) and/or magnesium (low) levels may require aggressive management. The estimated case fatality rate is 5% to 15% with severe illness, although it can increase to >50% in patients with pulmonary hemorrhage syndrome.

ETIOLOGY: Leptospirosis is caused by pathogenic spirochetes of the genus *Leptospira*. Leptospire are classified by species and subdivided into more than 300 antigenically defined serovars and grouped into serogroups on the basis of antigenic relatedness. Currently, the molecular classification divides the genus into 2 clades: pathogens (consisting of 39 species that cause infection in humans and animals) and saprophytes (consisting of 28 noninfectious species found in the natural environment) as determined by average nucleotide identity (ANI). All leptospire are tightly coiled spirochetes, obligately aerobic, with an optimum growth temperature of 28°C to 30°C.

EPIDEMIOLOGY: Leptospirosis is among the most important zoonoses globally, affecting people in resource-abundant and resource-limited countries in both urban and rural contexts. It has been estimated that more than 1 million people worldwide are infected annually (95% confidence interval [CI], 434 000–1 750 000), with approximately 58 900 deaths (95% CI, 23 800–95 900) occurring each year. The reservoirs for *Leptospira* species include a wide range of wild and domestic animals, including rodents, dogs, livestock (cattle, pigs), and horses that may shed organisms asymptotically for years. *Leptospira* organisms excreted in animal urine may remain viable in moist soil or water for weeks to months in warm climates. Humans usually become infected via entry of leptospire through contact of mucosal surfaces (especially conjunctivae) or abraded skin with urine-contaminated environmental sources such as soil and water. Infection also may be acquired through direct contact with infected animals or their tissues, urine, or other body fluids. Epidemics are associated with seasonal flooding and natural disasters, including hurricanes and monsoons. Populations in regions of high endemicity in the tropics and subtropics likely encounter *Leptospira* organisms during routine activities of daily living. People predisposed by occupation include abattoir and sewer workers, miners, veterinarians, farmers, and military personnel. Recreational exposures and clusters of disease have been associated with adventure travel, sporting events including triathlons, and wading, swimming, or boating in contaminated water, particularly during flooding or following heavy rainfall. Common history includes head

submersion in or swallowing water during such activities. Person-to-person transmission is not described convincingly.

The **incubation period** usually is 5 to 14 days, and the range 2 is to 30 days.

DIAGNOSTIC TESTS: Clinical features and routine laboratory findings are not specific for leptospirosis; a high index of suspicion must be maintained for diagnosis. *Leptospira* organisms can be isolated from blood during the early septicemic phase (first week) of illness, from urine specimens starting approximately 1 week after symptom onset, and from cerebrospinal fluid when clinical signs of meningitis are present. Specialized culture media are required but are not available routinely in most clinical laboratories. *Leptospira* organisms can be subcultured to specific *Leptospira* semi-solid medium (ie, EMJH) from blood culture bottles used in automated systems within 1 week of inoculation. Isolation of the organism may be difficult, requiring incubation for up to 16 weeks, weekly darkfield microscopic examination, and avoidance of contamination. Sensitivity of culture for diagnosis is low. Isolated leptospires are identified either by serologic methods using agglutinating antisera or by molecular methods.

Serum specimens should be obtained to facilitate diagnosis, and paired acute and convalescent sera are recommended, ideally collected 10 to 14 days apart. Antibodies develop by 5 to 10 days after onset of illness, but increases in antibody concentration may not be detected until more than 10 days after onset, especially if antimicrobial therapy is initiated early. Antibodies can be measured by commercially available immunoassays, most of which are based on sonicates of the saprophyte *Leptospira biflexa*. These assays have variable sensitivity according to regional differences of the various *Leptospira* species and timing of patient presentation, as immunoassays are more sensitive in the convalescent phase of illness. In populations with high endemicity, background reactivity requires establishing both regionally relevant diagnostic criteria and diagnostic versus background titers. Antibody increases can be transient, delayed, or absent in some patients, which may be related to antibiotic use, bacterial virulence, immunogenetics of the individual, or other unknown factors. Microscopic agglutination, the reference standard serologic test, is performed only in select reference laboratories.

Immunohistochemical and immunofluorescent techniques can detect leptospiral antigens in infected tissues. Nucleic acid amplification tests (NAATs) for detection of *Leptospira* DNA in clinical specimens, such as polymerase chain reaction (PCR) assays, are available but are sensitive only in acute specimens and sometimes convalescent urine. *Leptospira* DNA can be detected in whole blood during the first 7 days of illness, with highest sensitivity between days 1 and 4; *Leptospira* DNA can be found after 7 days of illness in urine and may be detectable for weeks to months in the absence of antimicrobial treatment. *Leptospira* DNA also can be detected in cerebrospinal fluid from symptomatic patients with clinical signs of meningitis.

TREATMENT: Although most leptospirosis cases are mild and resolve without antibiotics, therapy should be initiated as soon as possible after clinical recognition to prevent disease progression and to reduce urine shedding of organisms. Intravenous penicillin is the drug of choice for patients with severe infection requiring hospitalization. Penicillin G, even when given as late as 7 days into the course of illness, has been shown to decrease the duration of fever, systemic symptoms, and persistence of associated laboratory abnormalities and may prevent development of leptospiruria.

A Jarisch-Herxheimer reaction (an acute febrile reaction accompanied by headache, myalgia, and a worsening of symptoms lasting less than 24 hours) can develop after initiation of penicillin therapy, as with other spirochetal infections. Parenteral cefotaxime, ceftriaxone, and doxycycline have demonstrated equal efficacy to penicillin G for treatment of severe leptospirosis in randomized clinical trials. For patients with mild disease, oral doxycycline has been shown to shorten the course of illness and decrease occurrence of leptospiruria. Doxycycline may be used regardless of patient age. Ampicillin or amoxicillin also can be used to treat mild disease. Azithromycin was reported to be as effective as doxycycline in a clinical trial. Severe cases require appropriate supportive care, including fluid and electrolyte replacement. Patients with oliguric renal insufficiency require prompt dialysis, and those with pulmonary hemorrhage may require mechanical ventilation to improve clinical outcome.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended for patient care. Contact precautions are advised for potential exposure to urine.

CONTROL MEASURES:

- Immunization of livestock, horses, and dogs can prevent clinical disease attributable to infecting serovars contained within the vaccine. Immunization may not prevent the shedding of leptospires in urine of animals and, thus, contamination of environments with which humans may come in contact.
- Rodent-control programs may be useful in areas with endemic infection.
- Swimming, immersion, and swallowing water should be avoided in bodies of potentially contaminated fresh water.
- Appropriate protective clothing, boots, and gloves should be worn by people with exposure to urine or potentially contaminated water or mud, such as during floods.
- Doxycycline, 200 mg, administered orally once a week to adults, may provide effective prophylaxis against clinical disease and could be considered for high-risk groups with short-term exposure, but infection may not be prevented and adverse gastrointestinal tract events are common. Indications for prophylactic doxycycline use for children have not been established.

***Listeria monocytogenes* Infections**

(Listeriosis)

CLINICAL MANIFESTATIONS: Listeriosis is an uncommon infection caused by *Listeria monocytogenes* that manifests as invasive disease or as self-limited gastroenteritis. Transmission predominantly is foodborne. Invasive disease can occur in previously well children but occurs most frequently among pregnant people and their fetuses or newborns, older adults, and people of all ages with impaired cell-mediated immunity. Infection during pregnancy can be asymptomatic or associated with a nonspecific febrile illness with myalgia, back pain, and occasionally gastrointestinal tract symptoms. Common adverse outcomes include spontaneous abortion, fetal death, preterm delivery, and neonatal infection or death. Fetal infection generally results from transplacental transmission following bacteremia in the pregnant person, although other mechanisms include inhalation of infected amniotic fluid and infection ascending from vaginal colonization of the birthing parent. When listeriosis is diagnosed in a neonate,

a history of recent illness in the birthing parent compatible with *Listeria* infection is obtained in approximately 65% of cases. Amnionitis during labor, brown staining of amniotic fluid, or asymptomatic perinatal infection can occur.

Neonates can present with early- or late-onset disease. Preterm birth, pneumonia, and septicemia are common when infection occurs within the first week of life. An erythematous rash with small, pale papules characterized histologically by granulomas, termed “granulomatosis infantisepticum,” can occur in severe newborn infection. Late-onset infections typically occur between 7 to 30 days of age and usually result in meningitis. Late-onset infection may result from acquisition of the organism during passage through the birth canal or, rarely, from environmental sources. Health care-associated nursery outbreaks have been reported.

Beyond the neonatal period, invasive listeriosis usually presents as bacteremia, meningitis with or without parenchymal brain involvement, and less commonly brain abscess or endocarditis. *L. monocytogenes* also can cause rhombencephalitis (brain stem encephalitis) in otherwise healthy adolescents and young adults. Outbreaks of gastroenteritis caused by food contaminated with a very large inoculum of *L. monocytogenes* have been reported.

ETIOLOGY: *L. monocytogenes* is a facultatively anaerobic, nonspore-forming, nonbranching, motile, gram-positive rod that multiplies intracellularly. It has been assigned to the family *Listeriaceae* along with 5 other traditional and several more recently named species. The organism grows readily on blood agar and produces β -hemolysis. *L. monocytogenes* serotypes 1/2a, 4b, and 1/2b grow well at refrigerator temperatures (4°C–10°C).

EPIDEMIOLOGY: *L. monocytogenes* causes approximately 1000 cases of invasive disease annually in the United States, and approximately 15% of cases are associated with pregnancy. Pregnant people have a 10 to 20 times higher risk of infection compared with other healthy adults. The mortality rate is highest among older adults and immunocompromised people, including neonates. The saprophytic organism is distributed widely in the environment and is an important cause of illness in ruminants. Foodborne transmission causes outbreaks and sporadic infections in humans. Common food sources include deli-style, ready-to-eat meats, particularly poultry; unpasteurized milk¹; and soft cheeses, including Mexican-style cheese. Approximately 25% of global outbreaks are attributable to foods not traditionally associated as sources of *L. monocytogenes*, such as ice cream and fresh and frozen fruits and vegetables. Listeriosis is a relatively rare foodborne illness (<1% of reported foodborne illness in the United States) but has the highest case fatality rate (20%) among all foodborne pathogens tracked by the Centers for Disease Control and Prevention (CDC [www.cdc.gov/foodnet/index.html]). The incidence of listeriosis decreased substantially in the United States during the 1990s, when regulatory agencies began enforcing rigorous screening guidelines for *L. monocytogenes* in processed foods and better detection methods became available to identify contaminated foods. The prevalence of stool carriage of *L. monocytogenes* among healthy, asymptomatic adults is estimated to be 1% to 5%.

The **incubation period** for invasive disease is longer for pregnancy-associated cases (2–4 weeks or occasionally longer) than for nonpregnancy-associated cases (1 to

¹ American Academy of Pediatrics, Committee on Infectious Diseases, Committee on Nutrition. Consumption of raw or unpasteurized milk and milk products by pregnant women and children. *Pediatrics*. 2014;133(1):175-179 (Reaffirmed November 2019)

14 days). The **incubation period** for gastroenteritis following ingestion of a large inoculum is 24 hours; illness typically lasts 2 to 3 days.

DIAGNOSTIC TESTS: *L. monocytogenes* can be recovered readily on blood agar from cultures of blood, cerebrospinal fluid (CSF), meconium, placental or fetal tissue specimens, amniotic fluid, and other infected tissue specimens, including joint, pleural, or peritoneal fluid. Attempts to recover the organism from clinical specimens from nonsterile body sites, including stool, should include the use of selective medium such as Oxford agar or PALCM, as well as enrichment in a *Listeria*-selective broth. Gram stain of meconium, placental tissue, biopsy specimens of the rash of early-onset infection, or CSF from an infected patient may demonstrate the organism. Although gram-positive rods, the organisms can be gram-variable and can resemble diphtheroids, cocci, or diplococci.

A multiplex polymerase chain reaction diagnostic panel designed to detect agents of meningitis and encephalitis in CSF is cleared by the US Food and Drug Administration and contains *L. monocytogenes* as one of its target organisms; however, its clinical sensitivity is unknown, and parallel culture of CSF should be performed to allow for molecular characterization, especially for outbreak detection.

Another method for identification of *Listeria* isolates is matrix-assisted laser desorption/ionization–time-of-flight (MALDI-TOF) mass spectrometry.

TREATMENT: No controlled trials have established the drug(s) of choice or duration of therapy for invasive listeriosis. Combination therapy using ampicillin and a second agent (typically gentamicin) in doses appropriate for meningitis is recommended for severe infections. Use of an alternative second agent that is active intracellularly (eg, trimethoprim-sulfamethoxazole [contraindicated in infants younger than 2 months], fluoroquinolones, linezolid, or rifampin) is supported by case reports in adults. If these alternatives are used, susceptibility should be confirmed, because resistance to these agents has been reported. In the penicillin-allergic patient, options include penicillin desensitization or use of either trimethoprim-sulfamethoxazole or a fluoroquinolone, both of which have been used successfully as monotherapy for *Listeria* meningitis and in the setting of brain abscess. Treatment failures with vancomycin have been reported. Cephalosporins are not active against *L. monocytogenes*.

For bacteremia without associated central nervous system infection, 10 to 14 days of treatment is recommended. For *L. monocytogenes* meningitis, most experts recommend a minimum of 3 weeks of treatment. Longer courses are necessary for patients with endocarditis or parenchymal brain infection (cerebritis, rhombencephalitis, brain abscess). Iron may enhance the pathogenicity of *L. monocytogenes*; iron supplements should be withheld until treatment for listeriosis is complete. Brain imaging near the end of the anticipated duration of therapy allows diagnosis of parenchymal involvement of the brain, which may require prolonged therapy.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS: Standard precautions are recommended.

CONTROL MEASURES:

- Antimicrobial therapy for *Listeria* infection diagnosed during pregnancy may prevent fetal or perinatal infection and its consequences.
- Neonatal listeriosis complicating successive pregnancies is virtually unknown, so intrapartum antimicrobial therapy is not recommended for people with a history of perinatal listeriosis.

- General and specific guidelines for preventing listeriosis from foodborne sources are provided in Table 3.29.
- Trimethoprim-sulfamethoxazole, given as pneumocystis prophylaxis for those with acquired immunodeficiency syndrome, transplant recipients, or others on long-term, high-dose corticosteroids, effectively prevents listeriosis.

Public Health Reporting. Listeriosis is a nationally notifiable disease in the United States. Cases should be reported promptly to the state or local health department to facilitate early recognition and control of common-source outbreaks. Clinical isolates should be forwarded to a public health laboratory for genetic sequencing.

Table 3.29. Recommendations for Preventing Foodborne Listeriosis
(www.cdc.gov/listeria/prevention.html)

General recommendations:

Washing and handling food

- **Rinse** raw fruits and vegetables thoroughly under running tap water before eating, cutting, or cooking. Even if the produce will be peeled, it should still be washed first.
- **Scrub** firm produce, such as melons and cucumbers, with a clean produce brush.
- **Dry** the produce with a clean cloth or paper towel.
- **Separate** uncooked meats and poultry from vegetables, cooked foods, and ready-to-eat foods.

Keep your kitchen and environment cleaner and safer

- Wash hands, knives, countertops, and cutting boards after handling and preparing uncooked foods.
- Be aware that *Listeria monocytogenes* can grow in foods in the refrigerator. Use an appliance thermometer, such as a refrigerator thermometer, to check the temperature inside your refrigerator. The refrigerator temperature should be 40°F or colder and the freezer temperature should be 0°F or colder.
- Clean up all spills in your refrigerator right away, especially juices from hot dog and lunch meat packages, raw meat, and raw poultry.
- Clean the inside walls and shelves of your refrigerator with hot water and liquid soap, then rinse.

Cook meat and poultry thoroughly

- Thoroughly cook raw food from animal sources, such as beef, pork, or poultry to a safe internal temperature. For a list of recommended temperatures for meat and poultry, visit the safe minimum cooking temperatures chart at **FoodSafety.gov** (www.foodsafety.gov/keep/charts/mintemp.html).

Safety tips for eating melons

- Consumers and food preparers should wash their hands with warm water and soap for at least 20 seconds *before* and *after* handling any whole melon such as cantaloupe, watermelon, or honeydew.
- Scrub the surface of melons, such as cantaloupes, with a clean produce brush under running water and dry them with a clean cloth or paper towel before cutting. Be sure that your scrub brush is sanitized after each use to avoid transferring bacteria between melons.
- Eat cut melon right away or refrigerate it.
- Keep cut melon refrigerated at 41°F or colder and for no more than 7 days.
- Throw away cut melons left at room temperature for more than 4 hours.

Store foods safely

- Use precooked or ready-to-eat food as soon as you can. Do not store the product in the refrigerator beyond the use-by date; follow USDA refrigerator storage time guidelines, especially for hot dogs and luncheon and deli meats.

Table 3.29. Recommendations for Preventing Foodborne Listeriosis (www.cdc.gov/listeria/prevention.html), continued

- Cover leftovers with airtight lids or enclose in plastic wrap or aluminum foil. Use leftovers within 3 to 4 days.

Choose safer foods

- Do not drink raw (unpasteurized) milk^a (www.cdc.gov/foodsafety/rawmilk/raw-milk-index.html and <http://pediatrics.aappublications.org/content/pediatrics/early/2013/12/10/peds.2013-3502.full.pdf>) and do not eat foods that have unpasteurized milk in them.
- Find more specific information about this topic on the CDC Listeriosis Prevention website (www.cdc.gov/listeria/prevention.html).

Recommendations for people at higher risk, such as pregnant people, people with weakened immune systems, and older adults, in addition to the recommendations listed above:

Meats

- Avoid eating hot dogs, lunch meats, cold cuts, other deli meats (such as bologna), or fermented or dry sausages unless they are heated to an internal temperature of 165°F or until steaming hot just before serving.
- Pay attention to labels. Do not eat refrigerated pâté or meat spreads from a deli or meat counter or from the refrigerated section of a store.
- Do not eat soft cheese, such as feta, queso blanco, queso fresco, brie, Camembert, blue-veined, or panela (queso panela) unless it is labeled as “MADE WITH PASTEURIZED MILK.”
- Be aware that Mexican-style cheeses made from pasteurized milk, such as queso fresco, have caused *Listeria* infections, most likely because they were contaminated during cheese-making.

Seafood

- Do not eat cold smoked fish unless it is canned or shelf-stable or it is in a cooked dish, such as a casserole.
- Do not eat refrigerated smoked fish, such as salmon, trout, whitefish, cod, tuna, and mackerel.

Raw sprouts

- Do not eat raw or lightly cooked sprouts of any kind (including alfalfa, clover, radish, and mung bean sprouts) (www.cdc.gov/foodsafety/foods-linked-illness.html#sprouts).

^aAmerican Academy of Pediatrics, Committee on Infectious Diseases, Committee on Nutrition. Consumption of raw or unpasteurized milk and milk products by pregnant women and children. *Pediatrics*. 2014;133(1):175-179 (Reaffirmed November 2019).

Lyme Disease¹

(Lyme Borreliosis, *Borrelia burgdorferi* sensu lato Infection)

CLINICAL MANIFESTATIONS: Clinical manifestations of Lyme disease are divided into 3 stages: early localized, early disseminated, and late manifestations. Early localized disease, the most common manifestation of Lyme disease in children, is characterized by a distinctive lesion, erythema migrans (EM). An EM lesion appears at the site of the tick bite days to weeks later, beginning as a red macule or papule that usually expands to form a large (≥ 5 cm in diameter) annular, erythematous lesion, classically

¹ Lantos PM, Rumbaugh J, Bockenstedt LK, et al. Clinical practice guidelines by the Infectious Diseases Society of America (IDSA), American Academy of Neurology (AAN), and American College of Rheumatology (ACR): 2020 Guidelines for the prevention, diagnosis and treatment of Lyme disease. *Clin Infect Dis*. 2021;72(1):e1-e48. Available at: www.idsociety.org/practice-guideline/lyme-disease/

with central clearing creating a bull's-eye pattern. The lesion typically is painless and nonpruritic. EM lesions can vary greatly in size and shape and can be confused with other skin conditions (eg, cellulitis or ring worm). For images demonstrating the range of manifestations of EM rashes as well as rashes that can be confused with EM, see www.cdc.gov/lyme/signs_symptoms/rashes.html. Factors that distinguish erythema migrans from a local allergic reaction to a tick bite include larger size, gradual expansion, and lack of pruritis.

Early disseminated Lyme disease can present with multiple EM lesions, cranial neuritis (cranial nerve VII most common), meningitis, radiculitis, or carditis. Lyme meningitis can present with simultaneous cranial neuropathy or papilledema. Lyme carditis can present with syncope, palpations, or fatigue. First-degree atrioventricular block is the abnormality identified on electrocardiography (ECG) most commonly. Systemic symptoms, such as low-grade fever, arthralgia, myalgia, headache, and fatigue, may be present during the early localized or early disseminated stages. Ophthalmic manifestations (eg, conjunctivitis, optic neuritis, keratitis, and uveitis) are uncommon.

The most common manifestation of late Lyme disease in children is mono- or oligoarticular large joint arthritis, most frequently involving the knee. Children with Lyme arthritis have joint swelling out of proportion to pain or disability. If arthrocentesis is performed, synovial fluid white blood cells will be elevated. Children with Lyme arthritis have lower peripheral blood neutrophilia and inflammatory markers compared with children with pyogenic arthritis. Children with early Lyme disease treated with appropriate antimicrobial agents rarely develop late manifestations.

Lyme disease is not believed to produce a congenital infection syndrome. No causal relationship between Lyme disease in a pregnant person and abnormalities of pregnancy or congenital disease caused by *Borrelia burgdorferi* sensu lato complex has been documented. No evidence exists that Lyme disease can be transmitted via human milk.

ETIOLOGY: In the United States, Lyme disease is caused by the spirochete *Borrelia burgdorferi* sensu stricto and rarely, in the upper Midwest, by the recently discovered *Borrelia mayonii*. In Eurasia, *B. burgdorferi*, *Borrelia afzelii*, and *Borrelia garinii* cause borreliosis.

EPIDEMIOLOGY: Almost 35 000 cases of confirmed and probable Lyme disease were reported in the United States in 2019, though the actual number of cases is likely at least 10-fold greater because of underreporting. Lyme disease occurs primarily in 2 distinct geographic regions of the United States, with more than 95% of cases occurring in the Northeast, Mid-Atlantic, and upper Midwestern states. Over the past 2 decades, Lyme disease has expanded considerably into states that border this region. Transmission also occurs at a low level on the West Coast, with some focal areas of endemicity in central and northern California. The occurrence of cases in the United States correlates with the distribution and frequency of infected tick vectors—*Ixodes scapularis* in eastern and Midwest states and *Ixodes pacificus* in western states. Climate change likely has contributed to the expansion of the range of these tick vectors (see www.epa.gov/climate-indicators/climate-change-indicators-lyme-disease). In Southern states, *Ixodes scapularis* ticks do not feed commonly on competent reservoir mammals and are less likely to bite humans because of different questing habits. Individuals with cases reported from states with low endemic transmission most

often are exposed or infected during travel, although some cases may be misdiagnoses resulting from false-positive or misinterpreted test results. History of travel to areas with endemic transmission can guide clinical decision making.

Most cases of early localized and early disseminated Lyme disease occur between April and October, with a peak in June and July. People of all ages can be affected, but incidence in the United States is highest among children 5 through 9 years of age and adults 55 through 69 years of age. Lyme arthritis occurs throughout the year without a seasonal peak.

With lesion(s) similar to erythema migrans, “southern tick-associated rash illness” (STARI) has been reported mainly in south central and southeastern states without endemic *B burgdorferi* infection. The etiology is unknown. STARI results from the bite of the lone star tick, *Amblyomma americanum*, which is abundant in southern states and is biologically incapable of transmitting *B burgdorferi*. Patients with STARI may present with constitutional symptoms in addition to erythema migrans, but STARI has not been associated with any of the disseminated complications of Lyme disease. Appropriate treatment of STARI is unknown.

Lyme disease also is endemic in eastern Canada, Europe, states of the former Soviet Union, China, Mongolia, and Japan. The primary tick vector in Europe is *Ixodes ricinus*, and the primary tick vector in Asia is *Ixodes persulcatus*. Clinical manifestations vary somewhat from those seen in the United States. European Lyme disease can cause the skin lesions borreliolymphocytoma and acrodermatitis chronica atrophicans and is more likely to produce neurologic disease, whereas arthritis is uncommon. These differences are attributable to the different genospecies of *Borrelia* responsible for European Lyme disease.

Patients with Lyme disease can be infected simultaneously with agents of babesiosis, anaplasmosis, and hard tick-borne relapsing fever (see Babesiosis, p 253; *Ehrlichia*, *Anaplasma*, and Related Infections, p 361; and *Borrelia* Infections Other Than Lyme Disease [Relapsing Fever], p 274). These diagnoses should be suspected in patients who manifest high fever, have hematologic abnormalities consistent with these infections, or do not respond as expected to therapy prescribed for Lyme disease, such as fever persisting for more than 1 day after starting treatment. Patients with Lyme disease may be coinfecting with Powassan virus (deer tick virus) in the United States or with tick-borne encephalitis virus if infection was acquired in Europe.

The **incubation period** in the United States for Lyme disease from tick bite to appearance of single or multiple erythema migrans lesions ranges from 3 to 32 days, with a median time of 11 days. Late manifestations such as arthritis can occur months after the tick bite. Most children who develop Lyme disease do not recall a tick bite; absence of tick bite history should not be used to exclude disease.

DIAGNOSTIC TESTS: Diagnosis of Lyme disease rests first and foremost on the recognition of a consistent clinical illness in people who have had plausible geographic exposure. Information on areas of existing and emerging Lyme disease risk is available from the CDC (www.cdc.gov/lyme/datasurveillance/lyme-disease-maps.html). In patients with an EM lesion, Lyme disease is diagnosed based on the characteristic appearance of this skin lesion coupled with likely exposure in areas of known incidence. As the sensitivity of serologic testing is low during early infection (<50% with a solitary EM lesion), treatment should be initiated without serologic testing.

Diagnosis of extracutaneous Lyme disease, including late-stage disease, requires a typical clinical illness, plausible geographic exposure, and a positive serologic test result. The standard testing method for Lyme disease is a 2-tier serologic algorithm. Detailed serologic testing guidelines from the Association of Public Health Laboratories can be found at www.aphl.org/aboutAPHL/publications/Documents/ID-2021-Lyme-Disease-Serologic-Testing-Reporting.pdf. The initial screening test identifies antibodies to a whole-cell sonicate, to peptide antigen, or to recombinant antigens of *B burgdorferi* using an enzyme-linked immunosorbent assay (ELISA or EIA) or immunofluorescent antibody (IFA) test.

If the first-tier EIA result is negative, the patient is considered seronegative and no further testing is indicated. If the result is equivocal or positive, then a second-tier test is required to confirm the result. There are 2 options for second tier testing: (1) a western immunoblot, which is part of the standard 2-tiered testing algorithm; or (2) an EIA test that has been cleared specifically by the US Food and Drug Administration (FDA) for use as a second-tier confirmatory test, which is part of the modified 2-tiered testing algorithm (www.cdc.gov/mmwr/volumes/68/wr/mm6832a4.htm?s_cid=mm6832a4_w).

Two-tier serologic testing is essential because of the characteristics of Lyme antibody tests. False-positive results on first-tier tests are common and can be explained partly by antigenic components of *B burgdorferi* that are not specific to this species. Cross-reactive antibodies may be produced in response to spirochetes in normal oral flora, other spirochetal infections (including syphilis), other acute infections, and certain autoimmune diseases. In areas with endemic infection, previous infection with seroconversion may have occurred, and a seropositive patient's current symptoms may be coincidental. Patients with active Lyme disease almost always have objective signs of infection (eg, an EM lesion, facial nerve palsy, arthritis). Nonspecific symptoms commonly accompany these specific signs but almost never are the only evidence of Lyme disease. Serologic testing for Lyme disease should not be performed for individuals without symptoms or signs suggestive of Lyme disease and plausible geographic exposure.

Second-tier testing with immunoglobulin (Ig) M and IgG immunoassays should be performed only as part of a validated 2-tier serologic testing algorithm. The Western immunoblot assay (performed as part of a standard 2-tier testing algorithm) tests for presence of antibodies to specific *B burgdorferi* antigens, including IgM antibodies to 3 spirochetal antigens (the 23/24, 39, and 41 kDa polypeptides) and IgG antibodies to 10 spirochetal antigens (the 18, 23/24, 28, 30, 39, 41, 45, 60, 66, and 93 kDa polypeptides). Many clinical laboratories report presence of antibody to each of 13 bands, describing each band as positive or negative. However, a positive immunoblot result is defined as presence of at least 2 IgM bands or 5 IgG bands. Physicians must be careful not to misinterpret a positive band as a positive test result or interpret a result as positive despite presence of 4 or fewer IgG bands. IgG antibodies to flagella protein, the p41 band, are present in 30% to 50% of healthy people.

A second-tier IgM result performed as part of standard or modified 2-tier testing can be falsely positive. IgM assays are useful only for patients in the first 4 weeks after symptom onset and should be disregarded in patients who have had symptoms for longer than 4 weeks. Most untreated patients with disseminated Lyme disease will have a positive IgG result by week 4 of symptoms.

Most patients with early disseminated disease and virtually all patients with late Lyme disease have antibodies against *B burgdorferi*. Some patients with early Lyme disease treated with antimicrobial agents never develop detectable antibodies against *B burgdorferi*; they are cured and are not at risk of late disease. Development of antibodies in patients treated for early Lyme disease does not indicate lack of cure or presence of persistent infection. Ongoing infection without development of antibodies (“seronegative Lyme”) has not been demonstrated. Once antibodies develop, they may persist for many years. Tests for antibodies should not be repeated or used to assess success of treatment.

Current evidence indicates that patients with *B mayonii* infection develop a serologic response similar to that of patients infected with *B burgdorferi*. Standardized 2-tier testing can be expected to have positive results in patients with *B mayonii* infection. Some assays marketed in the United States have reduced sensitivity for European strains of *B burgdorferi*. For patients potentially infected in Europe, check with the test provider or laboratory director to select tests that have been validated for this purpose.

Nucleic acid amplification tests (NAATs) for *B burgdorferi* can be performed on synovial fluid or tissue, blood, or cerebrospinal fluid but currently are not cleared by the FDA. Sensitivity of Lyme NAATs of cerebrospinal fluid is very low; this test should not be obtained routinely for diagnosis of central nervous system infections. NAAT of joint fluid or synovial tissue may be considered in addition to serology in patients for whom the diagnosis of Lyme arthritis is being considered.

A number of tests for Lyme disease have been found to be invalid on the basis of independent testing or to be too nonspecific to exclude false-positive results. These include urine tests for *B burgdorferi*, CD57 assay, novel culture techniques, and antibody panels that differ from those recommended as part of standardized 2-tier testing. Although these tests are available from some clinical laboratories, they are not FDA cleared and are not appropriate diagnostic tests for Lyme disease.

TREATMENT: Consensus practice guidelines for assessment, treatment, and prevention of Lyme disease have been published jointly by the Infectious Diseases Society of America, American Academy of Neurology, and American College of Rheumatology and are available at www.idsociety.org/practice-guideline/lyme-disease. Care of children should follow recommendations in Table 3.30. Antimicrobial therapy for nonspecific symptoms or for asymptomatic seropositivity is not recommended. Antimicrobial agents administered for durations not specified in Table 3.30 are not recommended. Alternative diagnostic approaches or therapies without adequate validation and publication in peer-reviewed scientific literature are discouraged.

Early Localized Disease With Erythema Migrans (Single or Multiple). Doxycycline, amoxicillin, or cefuroxime axetil can be used to treat children of any age who present with EM lesions. Azithromycin is a second-line antimicrobial agent for EM, and its use should be limited to patients with EM in whom other antibiotic classes are contraindicated; it has not been studied sufficiently to warrant use in manifestations of Lyme disease other than EM. Selection of an oral antimicrobial agent for treatment of EM should be based on the following considerations: presence of neurologic disease (for which doxycycline is the drug of choice), drug allergy, adverse effects, frequency of administration (doxycycline and cefuroxime axetil are administered twice a day, amoxicillin is administered 3 times a day), ability to minimize sun exposure (photosensitivity may

Table 3.30. Recommended Treatment of Lyme Disease in Children

Disease Category	Drug(s) and Dose
Erythema migrans (single or multiple) (any age)	Doxycycline, 4.4 mg/kg per day, orally, divided into 2 doses (maximum 200 mg/day) for 10 days OR Amoxicillin, 50 mg/kg per day, orally, divided into 3 doses (maximum 1.5 g/day) for 14 days OR Cefuroxime axetil, 30 mg/kg per day, orally, in 2 divided doses (maximum 1 g/day) for 14 days OR , for a patient unable to take a beta-lactam or doxycycline, Azithromycin, ^a 10 mg/kg/day, orally, once daily for 7 days
Isolated facial palsy	Doxycycline, 4.4 mg/kg per day, orally, divided into 2 doses (maximum 200 mg/day), for 14–21 days ^b
Arthritis	An oral agent as for early localized disease, for 28 days
Persistent arthritis after first course of therapy	Retreat using an oral agent as for first-episode arthritis for an additional 28 days OR Ceftriaxone sodium, 50–75 mg/kg, IV, once a day (maximum 2 g/ day) for 14–28 days
Atrioventricular heart block or carditis	An oral agent as for early localized disease, for 14 days (range 14–21 days) OR Ceftriaxone sodium, 50–75 mg/kg, IV, once a day (maximum 2 g/ day) for 14 days (range 14–21 days for a hospitalized patient); oral therapy (using an agent as for early localized disease) can be substituted when the patient is stabilized or discharged, to complete the 14- to 21-day course
Meningitis	Doxycycline, 4.4 mg/kg per day, orally, divided into 1 or 2 doses (maximum 200 mg/day) for 14–21 days OR Ceftriaxone sodium, 50–75 mg/kg, IV, once a day (maximum 2 g/ day) for 14–21 days

IV indicates intravenously.

^a Because of concerns for lower efficacy, macrolide antibiotics including azithromycin are considered second line agents, and should be reserved for patients in whom other antibiotic classes are contraindicated. Azithromycin has not been sufficiently studied for manifestations of Lyme disease other than erythema migrans.

^b There is insufficient evidence on whether corticosteroids are safe with Lyme facial palsy.

be associated with doxycycline use), likelihood of coinfection with *Anaplasma phagocytophilum* or *Ehrlichia muris*-like agent (neither is sensitive to beta-lactam antimicrobial agents), and when *Staphylococcus aureus* cellulitis cannot be distinguished easily from EM (doxycycline is effective against most strains of methicillin-sensitive and methicillin-resistant *S aureus*). EM should be treated orally for 10 days if doxycycline is used and for 14 days if amoxicillin or cefuroxime axetil is used. Treatment of EM results in resolution of the skin lesion within several days of initiating therapy and almost always

prevents development of later stages of Lyme disease. Because STARI may be indistinguishable from early Lyme disease and questions remain about appropriate treatment, some physicians treat STARI with the same antimicrobial agents orally as for Lyme disease.

Early Disseminated Disease. Oral antimicrobial agents are appropriate and effective for most manifestations of disseminated Lyme disease. Doxycycline is preferred therapy for facial nerve palsy caused by *B burgdorferi* in children of any age, because amoxicillin is unlikely to reach therapeutic levels in the central nervous system. The risks and benefits of concurrent corticosteroid therapy for Lyme disease-associated facial nerve palsy are unknown.

A growing body of evidence suggests that oral doxycycline is effective for treatment of Lyme meningitis and may be used as an alternative to hospitalization and parenteral ceftriaxone or penicillin G therapy in children well enough to be treated as outpatients. Lumbar puncture is indicated for a child with a stiff neck and other symptoms of meningitis in whom the possibility of a bacterial (nonspirochetal) meningitis cannot be ruled out. Neurologic disease is treated for 14 to 21 days.

Late Disseminated Disease. Children with Lyme arthritis are treated with oral antimicrobial agents (eg, doxycycline, amoxicillin, or cefuroxime axetil) for 28 days. Children with no or minimal response to an initial course of oral antibiotics should be retreated with a second course of either parenteral or oral therapy; guidelines from multiple societies express a slight preference for parenteral therapy.¹ A second course of treatment may be considered for those with a partial response; specialty consultation may be helpful in these circumstances.

Approximately 10% to 15% of patients treated for Lyme arthritis will develop persistent synovitis that can last for months to years. Theories of pathophysiology include delayed resolution of inflammation because of slow clearance of nonviable bacteria following treatment versus an autoimmune mechanism. Misdiagnosis also should be considered (ie, Lyme antibodies in serum present from a previous infection or cross-reacting because of another disorder). Persisting synovitis following Lyme disease, termed “postantibiotic Lyme arthritis,” is a strongly HLA-associated phenomenon. Patients with persistent synovitis despite repeat treatment should be managed initially with nonsteroidal anti-inflammatory drugs; referral to a rheumatologist may be appropriate for more severe cases. Arthroscopic synovectomy rarely is required for disabling or refractory cases.

Persistent Post-treatment Symptoms. Some patients have prolonged, persistent symptoms following standard treatment for Lyme disease. This phenomenon may not be unique to Lyme disease but rather a more general occurrence during convalescence from systemic illness. Patients with persistent symptoms following Lyme disease usually respond to symptomatic treatment and recover gradually.

Several double-blind, randomized, placebo-controlled trials have found that retreatment with additional antimicrobial agents for patients with residual post-treatment Lyme disease subjective symptoms may be associated with harm and does

¹ Lantos PM, Rumbaugh J, Bockenstedt LK, et al. Clinical practice guidelines by the Infectious Diseases Society of America (IDSA), American Academy of Neurology (AAN), and American College of Rheumatology (ACR): 2020 Guidelines for the prevention, diagnosis and treatment of Lyme disease. *Clin Infect Dis.* 2021;72(1):e1-e48. Available at: www.idsociety.org/practice-guideline/lyme-disease/

not offer benefit.^{1–4} Administration of additional antimicrobial agents to a patient who has been given standard treatment for Lyme disease and continues to have symptoms is discouraged strongly. Retreatment is appropriate for subsequent acute infections caused by *B burgdorferi*.

Pregnancy. Tetracyclines are contraindicated in pregnancy. Doxycycline has not been studied adequately during pregnancy to make a recommendation regarding its use. Otherwise, therapy is the same as recommended for nonpregnant people.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS: Standard precautions are recommended.

CONTROL MEASURES:

Ticks. See Prevention of Mosquito-borne and Tick-borne Infections (p 207).

Chemoprophylaxis. Even in areas of high endemicity (the coastal northeast), where 30% to 50% of *I scapularis* ticks harbor *B burgdorferi*, risk of Lyme disease following a recognized tick bite is low, although it increases with duration of attachment. Testing of the tick for spirochete infection has poor predictive value and is not recommended.

Studies of doxycycline prophylaxis have been conducted in adults and older children (≥ 12 years). Benefits of prophylaxis may outweigh risks when the bite is high risk, defined as those that occur in areas of high endemicity; the bite was from an identified *Ixodes* species tick; the tick was attached for >36 hours; and prophylaxis can be started within 72 hours of tick removal. A single prophylactic 200-mg dose (or 4.4 mg/kg for children weighing less than 45 kg) of doxycycline can be used in children of any age to reduce risk of acquiring Lyme disease after a high-risk tick bite. Amoxicillin prophylaxis has not been studied sufficiently but likely would require a longer course than doxycycline because of its shorter half-life and is not recommended. There are no clinical data to support antibiotic prophylaxis for anaplasmosis, ehrlichiosis, babesiosis, or Rocky Mountain spotted fever.

Blood Donation. No documented cases of *B burgdorferi* transmission have occurred to date as a result of spirochete transmission via blood transfusion. Patients with active Lyme disease should not donate blood, because spirochetemia can occur in early disease. Patients who have been treated for Lyme disease can be considered for blood donation.

Vaccines. Multiple vaccine candidates are currently under development for both adults and children.

Public Health Reporting. Lyme disease is a nationally notifiable disease in the United States.

Lymphatic Filariasis

(Bancroftian, Malayan, and Timorian)

CLINICAL MANIFESTATIONS: Lymphatic filariasis is caused by infection with the filarial parasites *Wuchereria bancrofti*, *Brugia malayi*, or *Brugia timori*. Adult worms cause lymphatic dilatation and dysfunction, which result in abnormal lymph flow and eventually may lead to lymphedema in the legs, scrotal area (for *W bancrofti* only), and arms. Recurrent secondary bacterial infections hasten progression of lymphedema to the more severe form known as elephantiasis. Although the infection occurs commonly in young children living in areas with endemic lymphatic filariasis, chronic manifestations, such as hydrocele and lymphedema, occur infrequently in people younger than 20 years. Most filarial infections remain clinically asymptomatic, causing only subclinical lymphatic dilatation and dysfunction. Lymphadenopathy, most frequently of the inguinal, crural, and axillary lymph nodes, is the most common clinical sign of lymphatic filariasis in children. There can be an acute inflammatory response that progresses from the lymph node distally (retrograde) along the affected lymphatic vessel, usually in the limbs. Accompanying systemic symptoms, such as headache or fever, generally are mild. In postpubertal male individuals, adult *W bancrofti* organisms are found most commonly in the intrascrotal lymphatic vessels; thus, inflammation around dead or dying adult worms may present as funiculitis (inflammation of the spermatic cord), epididymitis, or orchitis.¹ A tender granulomatous nodule may be palpable at the site of dying or dead adult worms. Chyluria can occur as a manifestation of bancroftian filariasis. Tropical pulmonary eosinophilia, characterized by cough, fever, wheezing, marked eosinophilia, and high serum immunoglobulin (Ig) E concentrations, is a rare manifestation of lymphatic filariasis.

ETIOLOGY: Filariasis is caused by 3 filarial nematodes in the family *Filaridae*: *W bancrofti*, *B malayi*, and *B timori*.

EPIDEMOLOGY: The parasite is transmitted by the bite of infected mosquitoes of various genera, including *Culex*, *Aedes*, *Anopheles*, and *Mansonia*. *W bancrofti*, the most prevalent cause of lymphatic filariasis, is found in Haiti, the Dominican Republic, Guyana, northeast Brazil, sub-Saharan and North Africa, and Asia, extending from India through the Indonesian archipelago to the western Pacific islands. Humans are the only definitive host for the parasite. *B malayi* is found mostly in China, Southeast Asia, parts of India, and some Pacific islands. *B timori* is restricted to certain islands at the eastern end of the Indonesian archipelago. Adult worms live for an average of 5 to 8 years, and reinfection is common. They release microfilariae into the bloodstream, which can infect mosquitoes and may be present in a patient's blood for decades, although individual microfilariae have a lifespan between 3 and 12 months. The adult worm is not transmissible from person to person or by blood transfusion; microfilariae can be transmitted by transfusion, but they do not develop into adult worms.

The **incubation period** is not well established; the period from acquisition to the appearance of microfilariae in blood can be 3 to 12 months, depending on the species of parasite.

¹ The term male refers to sex assigned at birth.

DIAGNOSTIC TESTS: Diagnosis requires epidemiologic risk and consistent laboratory findings (identification of microfilariae or antibody). Microfilariae generally can be detected microscopically on blood smears obtained at night (10 PM–4 AM), although variations in the periodicity of microfilaremia have been described depending on the parasite strain and the geographic location. Adult worms or microfilariae can be identified based on general morphology, size, and presence or absence of a sheath in Giemsa-stained fluid or tissue specimens obtained at biopsy. Serologic enzyme immunoassays are available, but interpretation of results is affected by cross-reactions of filarial antibodies with antibodies against other helminths. Antifilarial antibody tests are available through the Laboratory of Parasitic Diseases at the National Institutes of Health (301-496-5399), the Centers for Disease Control and Prevention (CDC [www.cdc.gov/dpdx; 404-718-4745; parasites@cdc.gov]), and commercial laboratories. Assays for circulating filarial antigen of *W bancrofti* are available commercially but are not cleared for use by the US Food and Drug Administration (FDA), nor are they available in the United States. Nucleic acid amplification tests (NAATs) can detect parasite-specific DNA in fluids and tissues with high sensitivity and specificity, but none are FDA cleared. Ultrasonography can be used to visualize adult worms. Patients with lymphedema may no longer have microfilariae or antifilarial antibody present.

TREATMENT: The main goal of treatment of an infected person is to kill the adult worm. Diethylcarbamazine citrate (DEC), which is both microfilaricidal and active against the adult worm, is the drug of choice for lymphatic filariasis (see Drugs for Parasitic Infections, p 1068). DEC can be obtained from the CDC (404-718-4745; parasites@cdc.gov; or www.cdc.gov/parasites/lymphaticfilariasis). DEC is contraindicated in patients who may also have onchocerciasis or loiasis because of the possibility of exacerbation of skin or eye involvement or severe adverse effects. Before DEC therapy for lymphatic filariasis or loiasis, onchocerciasis should be excluded in all patients with a consistent exposure history because of the possibility of severe exacerbations of skin and eye involvement (Mazzotti reaction). People coinfectd with *Lao loa* and *Onchocerca volvulus* should not be treated with DEC until the onchocerciasis is treated. Treatment with DEC should be undertaken by a specialist with experience in treating lymphatic filariasis, because DEC therapy has been associated with life-threatening adverse events, including encephalopathy and renal failure in people with high levels of circulating *L loa* microfilariae. Ivermectin is effective against the microfilariae of *W bancrofti* and the 2 *Brugia* species but has no effect on the adult parasite and is, therefore, not recommended typically. Albendazole also has demonstrated macrofilaricidal activity. Two- or 3-drug combination therapies have been used in the Global Program for Elimination of Lymphatic Filariasis. Doxycycline, a drug that targets *Wolbachia* species, an intracellular rickettsial-like bacterial endosymbiont in adult worms, has been shown to be macrofilaricidal and has been used in combination with DEC.

Antifilarial chemotherapy has been shown to have limited efficacy for reversing or stabilizing lymphedema in its early forms. Doxycycline, in limited studies, has been shown to decrease the severity of lymphedema. Complex decongestive physiotherapy can be effective for treating lymphedema and requires strict attention to hygiene in the affected anatomic areas. Prompt identification and treatment of bacterial superinfections, particularly streptococcal and staphylococcal infections, and careful treatment of

intertriginous and ungual fungal infections are important aspects of therapy for lymphedema. Surgery may be indicated for management of hydrocele. Chyluria originating in the bladder responds to fulguration; chyluria originating in the kidney is difficult to correct.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: Annual mass drug administration of DEC and albendazole; albendazole and ivermectin; or ivermectin, DEC, and albendazole, to decrease or possibly eliminate transmission, has been instituted in selected settings. The use of insecticide-treated bed nets also has been shown to decrease transmission. No vaccine is available for lymphatic filariasis.

Lymphocytic Choriomeningitis Virus

CLINICAL MANIFESTATIONS: Child and adult infections with lymphocytic choriomeningitis virus (LCMV) are asymptomatic in approximately one third of cases. Symptomatic infection may result in a mild to severe illness, which can include fever, malaise, myalgia, retro-orbital headache, photophobia, anorexia, and nausea and vomiting. Sore throat, cough, arthralgia or arthritis, and orchitis also may occur. Initial symptoms may last from a few days to 3 weeks. Leukopenia, lymphopenia, thrombocytopenia, and elevation of lactate dehydrogenase and aspartate aminotransferase occur frequently. A biphasic febrile course is common; after a few days without symptoms, the second phase may occur in up to half of symptomatic patients, consisting of neurologic manifestations that vary from aseptic meningitis to severe encephalitis. Transverse myelitis, eighth nerve deafness, Guillain-Barré syndrome, and hydrocephalus also have been reported. Extraneural disease has included reports of myocarditis and dermatitis. Rarely, LCMV has caused a disease resembling viral hemorrhagic syndrome. Transmission of LCMV through organ transplantation and infection in other immunocompromised populations can result in fatal disseminated infection with multiple organ failure.

Current prevalence and seasonality are not known, because diagnostic testing is not often performed. Recovery without sequelae is the usual outcome, but convalescence may take several weeks, with asthenia, poor cognitive function, headaches, and arthralgia. LCMV infection should be suspected in presence of: (1) aseptic meningitis or encephalitis, especially during periods of colder weather; (2) febrile illness, followed by brief remission, followed by onset of neurologic illness; and (3) cerebrospinal fluid (CSF) findings of lymphocytosis and hypoglycorrhachia.

Infection during pregnancy has been associated with spontaneous abortion. Congenital infection may cause severe CNS abnormalities, including hydrocephalus, chorioretinitis, intracranial calcifications, cortical malformations, cerebellar hypoplasia, microcephaly, and intellectual or developmental disabilities. Extracerebral abnormalities are rare but may include ascites, hepatosplenomegaly, cardiomegaly, myocardial hyperechogenicity, pleural or myocardial effusion, hydrops, skin abnormalities, and fetal growth restriction. Congenital LCMV infection should be included in the differential diagnosis whenever intrauterine infections with toxoplasma, rubella, cytomegalovirus, herpes simplex virus, enterovirus, parechovirus, Zika virus, *Treponema pallidum*, varicella-zoster virus, or parvovirus B19 are being considered.

ETIOLOGY: LCMV is a single-stranded RNA virus that belongs to the family *Arenaviridae*. Other members of this family included in the genus *Mammarenaviruses* are Lassa virus and the New World *Arenaviruses* Junin, Machupo, Guanarito, Sabiá, and Chapare.

EPIDEMIOLOGY: LCMV is a chronic infection of common house mice, which often are infected asymptotically and chronically shed virus in urine and other excretions. Congenital murine infection is common and results in a normal-appearing litter with chronic viremia and particularly high virus excretion. In addition, hamsters, laboratory mice, and guinea pigs can have chronic infection and can be sources of human infection. Humans are infected mostly by inhalation of aerosol generated by rodents shedding virus from the urine, feces, blood, or nasopharyngeal secretions. Other less likely routes of entry of infected secretions include conjunctival and other mucous membranes, ingestion, and cuts in the skin. The disease is observed more frequently in young adults. Transmission has occurred transplacentally and through solid organ transplantation from an infected organ donor. Laboratory-acquired LCMV infections have occurred, both through infected laboratory animals and contaminated tissue-culture stocks.

The **incubation period** usually is 6 to 13 days and occasionally is as long as 3 weeks.

DIAGNOSTIC TESTS: Patients with central nervous system disease have a mononuclear pleocytosis with 30 to 8000 cells in CSF. Hypoglycorrhachia, as well as mild increase in protein, may occur. LCMV usually can be isolated from CSF obtained during the acute phase of illness and, in severe disseminated infections, also from blood, urine, and nasopharyngeal secretion specimens. Nucleic acid amplification tests (NAATs) available through reference or commercial laboratories can be used on serum during the acute stage and on CSF during the neurologic phase; however, none of these assays are cleared by the US Food and Drug Administration (FDA). Serum specimens from the acute and convalescent phases of illness can be tested for increases in antibody titers by enzyme immunoassays and neutralization tests. Demonstration of virus-specific immunoglobulin M antibodies in serum or CSF specimens is useful. In congenital infections, diagnosis usually is suspected when ocular or neurologic signs develop, and diagnosis usually is made by serologic testing. In immunosuppressed patients, seroconversion can take several weeks. Diagnosis can also be made by immunohistochemical assay of fixed tissues.

TREATMENT: Management is supportive. In vitro data suggest that ribavirin and favipiravir have activity against LCMV. However, favipiravir is not approved in the United States for any indication, and intravenous ribavirin is available only from the manufacturer through an emergency investigational new drug (eIND) application.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS: Standard precautions are recommended.

CONTROL MEASURES: Infection can be controlled by preventing rodent infestation in animal and food storage areas. Because the virus is excreted for long periods of time by rodent hosts, attempts should be made to monitor laboratory and commercial colonies of mice and hamsters for infection. Pet rodents or wild mice in a patient's home should be considered likely sources of infection. Guidelines for minimizing risk of

human LCMV infection associated with rodents are available¹ (also see Appendix VII, Diseases Transmitted by Animals [Zoonoses], p 1157). Although the risk of LCMV infection from pet rodents is low, pregnant people should avoid exposure to wild or pet rodents and their aerosolized excreta. Pregnant people also should avoid working in the laboratory with LCMV.

Malaria

CLINICAL MANIFESTATIONS: The classic symptoms of malaria, which may be paroxysmal, are high fever with chills, rigor, sweats, and headache. Young children often present only with fever and nonspecific symptoms, which may include nausea, vomiting, diarrhea, cough, tachypnea, arthralgia, myalgia, and abdominal and back pain. Anemia and thrombocytopenia are common. Hepatosplenomegaly frequently is present in infected children in areas with endemic malaria and may be present in adults and in people previously not infected with malaria. Severe disease occurs more frequently in people without immunity acquired as a result of previous infection; young children; pregnant people, especially primigravidae; and those who are immunocompromised.

Infection with *Plasmodium falciparum*, one of the 5 *Plasmodium* species that naturally infect humans, manifests most commonly as a nonspecific febrile illness often without localizing signs. Severe disease may occur with any of the infecting species but is caused most commonly by *P. falciparum*. Severe *P. falciparum* malaria may manifest as one of the following clinical syndromes, many of which also may be seen with other malaria species, and all of which are medical emergencies and may be fatal unless treated promptly:

- **Impaired consciousness**, characterized by altered mental status, which may progress to **cerebral malaria**, defined by presence of coma (Blantyre coma scale ≤ 2) and often accompanied by multiple seizures; cerebral malaria has a mortality rate of 15% to 20%;
- **Multiple seizures** (2 or more in 24 hours), which, in the absence of coma, have a low mortality rate;
- **Severe anemia** (hemoglobin of ≤ 5 g/dL in children <12 years of age; hemoglobin ≤ 7 g/dL in children ≥ 12 years of age and adults) attributable to dyserythropoiesis, high parasitemia and hemolysis, sequestration of infected erythrocytes to capillaries and venules, coagulopathy, and hemolysis of infected erythrocytes associated with hypersplenism; late-onset hemolytic anemia has been described following treatment of severe disease with artemisinin derivatives;
- **Metabolic acidosis** (base deficit of >8 mEq/L, or, if not available, a bicarbonate of <15 mmol/L or a venous lactate of ≥ 5 mmol/L), usually attributed to lactic acidosis, hypovolemia, liver dysfunction, and impaired renal function, and clinically manifesting as respiratory distress (rapid, deep, labored breathing);
- **Hypoglycemia**, which can present with metabolic acidosis and hypotension associated with hyperparasitemia and is associated with increased mortality; it also can be a consequence of quinine or quinidine-induced hyperinsulinemia;

¹ Centers for Disease Control and Prevention. Update: interim guidance for minimizing risk for human lymphocytic choriomeningitis virus infection associated with pet rodents. *MMWR Morb Mortal Wkly Rep*. 2005;54(32):799–801

- **Acute kidney injury**, which likely is multifactorial, is common in severe malaria in children and associated with increased mortality; acute renal failure, caused by acute tubular necrosis, is more common in adults than children;
- **Pulmonary edema and acute respiratory distress syndrome**, which are more common in adults than children;
- **Prostration**, in which a child is unable to sit, stand, or walk without assistance;
- **Significant bleeding**, including recurrent or prolonged bleeding from the nose, gums, or venipuncture sites; hematemesis; or melena;
- **Vascular collapse and shock or impaired perfusion**, associated with concurrent bacteremia, hypothermia, or adrenal insufficiency;
- **Jaundice** (serum bilirubin >3 mg/dL), secondary to hemolysis of infected blood cells, coagulopathy, and/or hepatic dysfunction; or
- **Hyperparasitemia** (parasitemia >5%).

Syndromes primarily associated with *Plasmodium vivax* and *Plasmodium ovale* infection are as follows:

- **Anemia** attributable to acute parasitemia, leading to hemolysis;
- **Hypersplenism** with risk of splenic rupture;
- **Thrombocytopenia**, which may be severe with *P vivax*;
- **Pulmonary edema**, which may occur after initial treatment of *P ovale*; and
- **Relapse of infection**, for as long as 3 to 5 years after the primary infection, attributable to latent hepatic stages (hypnozoites).

Syndromes associated with *Plasmodium malariae* infection include:

- **Chronic asymptomatic parasitemia**, which persists at undetectable levels for as long as decades after the primary infection; and
- **Nephrotic syndrome** resulting from deposition of immune complexes in the kidney.

Plasmodium knowlesi is a nonhuman primate malaria parasite that also can infect humans and has been misdiagnosed as *P malariae* infection, which causes more benign infection. Disease can be characterized by very rapid replication of the parasite and hyperparasitemia resulting in severe disease. *P knowlesi* infection should be treated aggressively, because hepatorenal failure and subsequent death have been documented.

Congenital malaria resulting from perinatal transmission occurs infrequently, with increased risk among newborn children of primigravidae in areas with endemic infection. Most congenital cases have been caused by *P vivax* and *P falciparum*; *P malariae* and *P ovale* account for fewer than 20% of such cases. Manifestations can resemble those of neonatal sepsis, including fever and nonspecific symptoms of poor appetite, irritability, and lethargy.

ETIOLOGY: The genus *Plasmodium* includes species of intraerythrocytic parasites that infect a wide range of mammals, birds, and reptiles. The 5 species that infect humans are *P falciparum*, *P vivax*, *P ovale*, *P malariae*, and *P knowlesi*. Coinfection with multiple species has been documented.

EPIDEMIOLOGY: Malaria is endemic throughout tropical areas of the world and is acquired primarily from the bite of the female *Anopheles* genus of mosquito. Half of the world's population lives in areas where transmission occurs. Worldwide, 247 million cases and 619 000 deaths were reported in 2021 (www.who.int/publications/i/item/9789240064898). Approximately 10% of cases are severe malaria, which have

a significantly higher chance of death. Most deaths occur in children younger than 5 years. Infection by the malaria parasite poses substantial risks to pregnant people and their fetuses, especially primigravidae in areas with endemic infection, and may result in spontaneous abortion and stillbirth. Malaria contributes to low birth weight in countries where *P falciparum* or *P vivax* is endemic.

Risk of malaria is highest, but variable, for residents of and travelers to sub-Saharan Africa, Papua New Guinea, and the Solomon Islands; risk is intermediate on the Indian subcontinent, and is low in most of Southeast Asia and Latin America. Potential for malaria reintroduction exists in areas where malaria has been eliminated, and local transmission has recently been detected in the United States (<https://emergency.cdc.gov/han/2023/han00494.asp>). Climate change and interannual variation also affect the geographic range of malaria. Health care professionals can check the Centers for Disease Control and Prevention (CDC) website for the most current information (www.cdc.gov/malaria) to determine malaria endemicity when providing pretravel malaria advice or evaluating a febrile returned traveler.

Nearly all of the 1823 malaria cases reported in the United States in 2018 resulted from infection acquired outside the United States.¹ Locally acquired cases of malaria have been identified in Texas and Florida in 2023, the first such local transmission in 20 years (<https://emergency.cdc.gov/han/2023/han00494.asp>). Uncommon modes of malaria transmission are congenital, through transfusion or transplant, or through use of contaminated needles or syringes.

P falciparum and *P vivax* are the most prevalent species worldwide. *P falciparum* malaria is prevalent in Africa, Papua New Guinea, and on the island of Hispaniola (Haiti and the Dominican Republic). *P vivax* malaria is prevalent on the Indian subcontinent and in Central America. *P vivax* and *P falciparum* species are the most common malaria species in southern and Southeast Asia, Oceania, and South America. *P malariae*, although much less common, has a wide distribution. *P ovale* malaria occurs most frequently in West Africa but has been reported in other areas. Reported cases of human infections with *P knowlesi* have been from certain countries of Southeast Asia, specifically Borneo, Malaysia, Philippines, Thailand, Myanmar, Singapore, and Cambodia.

Relapses may occur in *P vivax* and *P ovale* infections because of a persistent hepatic (hypnozoite) stage of infection. Recrudescence of *P falciparum* and *P malariae* infection occurs when a persistent low-density parasitemia produces recurrence of symptoms of the disease, such as when incomplete treatment or drug resistance prevents elimination of the parasite. Asymptomatic parasitemia can occur in individuals with partial immunity.

Drug resistance in both *P falciparum* and *P vivax* has been evolving throughout areas with endemic malaria, generally proportional to the use of particular drugs in a population. The spread of chloroquine-resistant *P falciparum* strains throughout the world dates back to the 1960s. Chloroquine-resistant *P vivax* has been reported in Indonesia, Papua New Guinea, the Solomon Islands, Myanmar, India, and Guyana. *P falciparum* resistance to sulfadoxine-pyrimethamine is distributed throughout Africa and other endemic regions as well. Mefloquine resistance has been documented in Myanmar (Burma), Lao People's Democratic Republic (Laos), Thailand, Cambodia, and Vietnam. Resistance to artemisinin compounds has been reported across the same

¹ Centers for Disease Control and Prevention. Malaria surveillance—United States, 2018. *MMWR Surveill Summ*. 2022;71(8):1-29

region, and there are now reports of artemisinin resistance in Africa, although most such strains have, to date, still responded to artesunate or artemisinin combination treatment.

The **incubation period** (time to onset of malaria symptoms) in most cases ranges from as soon as 7 days after being bitten by an infected mosquito to about 30 days and is shortest for *P falciparum* and longest for *P malariae*. Antimalarial drugs discontinued before completing the recommended course of prophylaxis for *P falciparum* may delay symptoms for weeks to months. Relapses of *P vivax* and *P ovale* may occur months after initial infection.

DIAGNOSTIC TESTS: Definitive parasitologic diagnosis historically has been based on identification of *Plasmodium* parasites microscopically on stained blood films (Giemsa stain preferred). There is an increasing range of rapid diagnostic test methods available that detect specific malaria antigens in blood, one of which is approved by the US Food and Drug Administration (FDA) and is available for use by many hospitals and commercial laboratories. Rapid diagnostic testing is recommended to be conducted in parallel with routine microscopy to provide further information needed for patient treatment, such as the percentage of erythrocytes harboring parasites. Both positive and negative rapid diagnostic test results should be confirmed by microscopic examination, because low-level parasitemia may not be detected (ie, false-negative result), some *P falciparum* strains may not express the HRP-2 antigen targeted by many rapid test platforms, false-positive results occur, and mixed infections may not be detected accurately. Both thick and thin blood films should be examined. The thick film allows for concentration of the blood to find parasites that may be present at low density, whereas the thin film is most useful for species identification and determination of the density of red blood cells infected with parasites. If initial blood smears test negative for *Plasmodium* species but malaria remains a possibility, the smear should be repeated every 12 to 24 hours during a 72-hour period, ideally with at least 3 smears.

Confirmation and identification of the species of malaria parasites on the blood smear is essential in guiding therapy. Serologic testing generally is not helpful, except in epidemiologic surveys. A nucleic acid amplification test (NAAT) is available in reference laboratories and many state health departments, but same-day results may not be available to make treatment decisions. NAATs are most useful to confirm species of malaria and may be useful in cases in which there is a high clinical suspicion for malaria but blood smears are read as negative, as infections with *P ovale* and *P malariae* or infections in patients with treatment prior to obtaining blood smears may be present at very low levels of parasitemia that are difficult to detect with microscopy. Information about sensitivity of rapid diagnostic tests for the 3 less common species of malaria, *P ovale*, *P malariae*, and *P knowlesi*, is limited, but available data suggest low sensitivity. Additional information about rapid diagnostic testing for malaria is available on the CDC website. Species confirmation and antimalarial drug resistance marker testing is available at the CDC for all cases of malaria diagnosed in the United States (www.cdc.gov/malaria/diagnosis_treatment/index.html).

TREATMENT: Choice of malaria treatment is based on the infecting species, possible drug resistance, and severity of disease. Assistance with management of malaria is available 24 hours a day through the CDC Emergency Operations Center (770-488-7100).

Treatment for malaria should not be delayed if malaria is suspected and rapid diagnosis is not available. Guidance on appropriate therapy for uncomplicated and severe malaria is presented in Table 4.11, *Drugs for Parasitic Infections*, beginning on p 1087. Patients with severe malaria require intensive care and parenteral treatment with intravenous (IV) artesunate. IV quinidine is no longer available in the United States. Use of artesunate without laboratory confirmation of malaria should be reserved for cases in which there is a strong clinical suspicion of severe malaria and prompt laboratory diagnosis is not available. Sequential blood smears to determine percentage of erythrocytes infected with parasites may be monitored to assess therapeutic efficacy. A review of available literature suggests exchange transfusion for severe disease is not efficacious in patients with end-organ involvement.

For patients with severe malaria in the United States or patients with malaria who are unable to tolerate an oral medication despite attempts, IV artesunate is the treatment of choice. CDC distribution of investigational IV artesunate was discontinued in September 2022, and IV artesunate now needs to be procured commercially and stocked by hospitals. Artesunate in the United States currently is very expensive, so every hospital should have a plan for stocking artesunate, obtaining artesunate if not stocked, or referring to a regional hospital that does stock artesunate. At hospitals where IV artesunate is not in stock, patients should receive an effective oral antimalarial in the interim while IV artesunate is obtained emergently from a commercial source, or should be referred to a regional hospital with artesunate available. If the patient is unable to tolerate oral medications, the medical team will need to consider alternative ways to administer oral medications while awaiting IV artesunate (eg, antiemetics before administering the antimalarial drug, or administering the drug via nasogastric tube). The preferred antimalarial for interim oral treatment is artemether-lumefantrine (Coartem) because of its fast onset of action. Other oral options include atovaquone-proguanil (Malarone), quinine, and mefloquine. Oral or intravenous clindamycin and tetracyclines, such as doxycycline, are not adequate for interim treatment. When IV artesunate arrives, the oral medication should be discontinued and parenteral treatment initiated.

Additional information on artesunate and guidelines for the treatment of malaria are available on the CDC website (www.cdc.gov/malaria/diagnosis_treatment/artesunate.html and www.cdc.gov/malaria/resources/pdf/Malaria_Treatment_Table_202306.pdf).

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

Standard precautions are recommended.

CONTROL MEASURES: Malaria is a nationally reportable disease in the United States. The RTS,S vaccine for malaria is used for malaria control in children living in endemic areas and is not available for travelers. Effective measures to reduce risk of acquiring malaria include control of *Anopheles* mosquito populations, protection against mosquito bites, treatment of infected people, and chemoprophylaxis (see Table 3.31). Measures to prevent contact with mosquitoes, especially from dusk to dawn (because of the nocturnal biting habits of most female *Anopheles* mosquitoes), include use of bed nets impregnated with insecticide, mosquito repellents (see *Prevention of Mosquito-borne and Tick-borne Infections*, p 207), and protective clothing. The most current information on country-specific malaria transmission, drug resistance, and

Table 3.31. Drugs to Consider for Use in Children for Malaria Prophylaxis^a

Locale	Drug	Dosing	Timing	Adverse Effects and Contraindications	Other Considerations
Only chloroquine-sensitive areas	Chloroquine or hydroxychloroquine	Chloroquine dose: 5 mg/kg base (8.3 mg/kg salt), orally, once weekly, up to maximum adult dose 300 mg base Hydroxychloroquine dose: 5 mg/kg base (6.5 mg/kg salt), orally, once weekly, up to maximum 310 mg base	Begin 1–2 weeks before travel and take weekly throughout and for 4 weeks after leaving area	Most common adverse effects: gastrointestinal tract disturbance, headache, dizziness, blurred vision, pruritus, insomnia Can exacerbate psoriasis	Take with meals
Only mefloquine-sensitive areas	Mefloquine	≤9 kg: 4.6 mg/kg base (5 mg/kg salt), once weekly >9–19 kg: 1/4 tablet, once weekly >19–30 kg: 1/2 tablet, once weekly >30–45 kg: 3/4 tablet, once weekly >45 kg: 1 tablet, once weekly Each tablet contains 228 mg base (250 mg salt)	Begin ≥2 weeks before travel, then weekly on same day each week throughout and for 4 weeks after leaving area Initiating 2–3 weeks before travel can help assess tolerability	Most common adverse effects: gastrointestinal tract disturbance, headache, insomnia, vivid dreams, visual disturbance, anxiety, dizziness CONTRAINDICATED in travelers with a known hypersensitivity to the drug, and in those with active or recent history of depression, anxiety disorder, psychosis, schizophrenia, other major psychiatric disorder or seizures Do not use in those with cardiac conduction defects	Black box warning for neurologic (dizziness, vestibular problems, tinnitus) and psychiatric (anxiety, paranoia, depression, hallucinations) adverse effects that may occur at any time during drug use, and may last for months to years after the drug is stopped. Patients must be given copy of FDA medication guide May be given in all trimesters of pregnancy

Table 3.31. Drugs to Consider for Use in Children for Malaria Prophylaxis,^a continued

Locale	Drug	Dosing	Timing	Adverse Effects and Contraindications	Other Considerations
All areas	Atovaquone-proguanil	Pediatric tablets, 62.5 mg atovaquone and 25 mg proguanil hydrochloride 5–8 kg: ½ tab >8–10 kg: ¾ tab >10–20 kg: 1 tab >20–30 kg: 2 tabs >30–40 kg: 3 tabs >40 kg: 1 adult tab (250 mg atovaquone/100 mg proguanil)	Start 1–2 days before travel, take daily throughout travel and for 7 days after leaving area	Most common adverse effects: abdominal pain, nausea, vomiting, headache Do not use in those with creatinine clearance <30 mL/min; not recommended for infants <5 kg, pregnant people, or people who are breastfeeding infants <5 kg	Take with meals Generally well tolerated Proguanil can increase warfarin effect; dosage adjustment may be needed
All areas	Doxycycline	2.2 mg/kg, up to maximum adult dose 100 mg/day	Start 1–2 days before travel, take daily throughout travel, and for 4 weeks after leaving area Licensed for use for 4 months but may be safely given up to 2 years	Most common adverse effects: photosensitivity, gastrointestinal disturbance Not recommended for pregnant people	Take with meals Also active against rickettsiae and leptospirae (hikers, campers, fresh water swimmers) Complete oral typhoid vaccine >72 hours before starting doxycycline

Table 3.31. Drugs to Consider for Use in Children for Malaria Prophylaxis,^a continued

Locale	Drug	Dosing	Timing	Adverse Effects and Contraindications	Other Considerations
Short-duration travel (<6 months) to all areas	Primaquine	0.5 mg/kg base (0.8 mg/kg salt) up to adult dose of 30 mg base (52.6 mg salt) daily	Start 1–2 days before travel, take daily throughout travel, and for 7 days after leaving area	CONTRAINDICATED in those with G6PD deficiency and pregnant people Should not be given to lactating person unless infant has normal G6PD level	Test for G6PD deficiency before prescribing Also used for presumptive therapy (ie, terminal prophylaxis) to decrease risk of <i>P vivax</i> or <i>P ovale</i> relapse
Short-duration travel (<6 months) to all areas	Tafenoquine	In travelers 18 years and older: Loading dose: 200 mg once daily for 3 days before departure Maintenance regimen (while in malaria transmission area): 200 mg weekly Post-trip dose: 200 mg once, 7 days after the last weekly dose	Start 3 days before travel, weekly during the trip, and a single dose during the week after returning.	CONTRAINDICATED in those with G6PD deficiency and pregnant people Should not be given to lactating person unless infant has normal G6PD level	Test for G6PD deficiency using a quantitative test before prescribing Approved for 18 years and older for prophylaxis (and for antirelapse therapy in people ≥ 16 years) Also used for presumptive therapy (ie, terminal prophylaxis) to decrease risk of <i>P vivax</i> or <i>P ovale</i> relapse (different formulation and dosing schedule)

G6PD indicates glucose-6-phosphate dehydrogenase.

^aNo drug is 100% effective; always combine chemoprophylaxis with personal protection measures.

recommendations for travelers can be obtained by accessing the chapter on malaria in the *2024 CDC Yellow Book: Health Information for International Travel* (wwwnc.cdc.gov/travel/yellowbook/2024/infections-diseases/malaria).

Chemoprophylaxis for Travelers to Areas With Endemic Malaria.¹ Drugs for prevention of malaria currently available in the United States include chloroquine, mefloquine, doxycycline, atovaquone-proguanil, primaquine, and tafenoquine (ages ≥ 18 years). Table 3.31 details use of these drugs for prophylaxis against malaria.

The appropriate chemoprophylactic regimen is determined by the traveler's risk of acquiring malaria at their destination(s) and by local prevalence of drug resistance. The travel itinerary should be reviewed in detail and compared with information on where malaria transmission occurs within a given country to determine whether the traveler will be traveling in a part of the country where malaria occurs and if antimalarial drug resistance has been reported in that location (see wwwnc.cdc.gov/travel/yellowbook/2024/preparing/yellow-fever-vaccine-malaria-prevention-by-country). Additional factors to consider are the patient's other medical conditions (including pregnancy), medications (to assess potential drug interactions), cost of the medicines, and potential adverse effects. Indications for prophylaxis for children are the same as those for adults. Pediatric dosages should be calculated based on the child's current weight, and children's dosages should never exceed adult dosages. Drugs used for malaria chemoprophylaxis generally are well tolerated, although adverse reactions can occur. Minor adverse reactions do not require stopping or adjusting drug dosage. Those who provide malaria chemoprophylaxis should provide travelers with information about management of mild adverse events, what to do in the event of serious adverse reactions, and what to do if doses are missed.

Medications for chemoprophylaxis of malaria should not be obtained at the destination, as quality of these products is unknown. Travelers also should avoid medications and combinations that are commonly prescribed abroad but not recommended in the United States. Chemoprophylaxis should begin before arrival in the area with endemic malaria.

Prophylaxis During Pregnancy and Lactation. Malaria during pregnancy carries significant risks for both the pregnant person and fetus. Malaria increases the risk of adverse outcomes in pregnancy, including abortion, preterm birth, and stillbirth. For these reasons and because no chemoprophylactic regimen is absolutely effective, people who are pregnant or likely to become pregnant should try to avoid travel to areas where they could contract malaria.

Pregnant people traveling to areas where chloroquine-resistant malaria has not been reported may take chloroquine prophylaxis. Harmful effects on the fetus have not been demonstrated when chloroquine is given in recommended doses for malaria prophylaxis. Pregnancy and lactation, therefore, are not contraindications for malaria prophylaxis with chloroquine.

Mefloquine chemoprophylaxis is recommended in all trimesters of pregnancy when exposure to chloroquine-resistant *P. falciparum* is unavoidable. Lactating parents of infants may use mefloquine, or, when their infant weighs more than 5 kg, atovaquone-proguanil for prophylaxis when exposure to chloroquine-resistant

¹ For further information on prevention of malaria in travelers, see the biennial publication: *2024 CDC Yellow Book: Health Information for International Travel* (wwwnc.cdc.gov/travel/yellowbook/2024/infections-diseases/malaria).

P. falciparum is unavoidable. Primaquine and tafenoquine are contraindicated in pregnancy because of the unknown glucose-6-phosphate dehydrogenase (G6PD) status of the fetus.

Assessment for Malaria During Travel. Travelers to areas with endemic malaria should seek medical attention immediately if they develop fever. Malaria treatment is most effective if begun early in the course of disease, and delay of appropriate treatment can have serious or even fatal consequences. Travelers who develop malaria despite taking chemoprophylaxis should be treated with an appropriate antimalarial drug other than the one used for chemoprophylaxis. Although most cases of imported malaria are diagnosed ≤ 3 months from return to the United States, travelers should be advised that any fever or influenza-like illness that develops up to 1 year from departure from an area with endemic malaria requires medical evaluation, including appropriate blood testing to rule out malaria.

Prevention of Relapses. There is no test to determine the potential for relapses of *P. vivax* or *P. ovale* infection. Antirelapse therapy can be provided along with treatment of symptomatic infection or after leaving an endemic area following a prolonged stay. Presumptive antirelapse therapy, also known as terminal prophylaxis, uses a medication toward the end of the exposure period or immediately thereafter to prevent relapses or delayed onset clinical presentations of malaria caused by hypnozoites. Primaquine and tafenoquine (Krintafel, in patients 16 years and older, and only if coadministered with chloroquine or hydroxychloroquine) are approved for use to prevent relapses of *P. vivax*. Both can be used to prevent *P. ovale* relapse, but tafenoquine is not approved by the FDA for this use. Screening for G6PD deficiency using a quantitative test must be performed before using primaquine and tafenoquine, because both drugs can cause hemolysis in patients with G6PD deficiency.

Personal Protective Measures. All travelers to areas where malaria is endemic should be advised to use personal protective measures, including the following: (1) insecticide-impregnated mosquito nets while sleeping; (2) remaining in well-screened or air-conditioned areas at dusk and at night; (3) protective clothing, preferably permethrin treated; and (4) mosquito repellents (see Prevention of Mosquito-borne and Tick-borne Infections, p 207).

Measles

CLINICAL MANIFESTATIONS: Measles is an acute viral disease characterized by fever, cough, coryza, and conjunctivitis, followed by a maculopapular rash beginning on the face and spreading cephalocaudally and centrifugally. During the prodromal period, a pathognomonic enanthema (Koplik spots) may be present. Complications of measles, including otitis media, bronchopneumonia, laryngotracheobronchitis (croup), and diarrhea, occur commonly in young children and immunocompromised hosts. Acute encephalitis, which often results in neurologic deficits, occurs in approximately 1 of every 1000 cases. In the postelimination era in the United States, death, predominantly resulting from respiratory and neurologic complications, has occurred in 1 to 3 of every 1000 cases reported. Case fatality rates are increased in children younger than 5 years, pregnant people, and immunocompromised children, including children with leukemia, human immunodeficiency virus (HIV) infection, and severe malnutrition

(including vitamin A deficiency). Sometimes the characteristic rash does not develop in immunocompromised patients.

Measles inclusion body encephalitis (MIBE) is a rare manifestation of measles infection in immunocompromised individuals usually presenting within 1 year of measles infection. Disease onset is subacute with progressive neurologic dysfunction occurring over weeks to months. Subacute sclerosing panencephalitis (SSPE) is a rare degenerative central nervous system disease characterized by behavioral and intellectual deterioration and seizures that generally occurs 7 to 11 years after wild-type measles virus infection. The highest rates occur in children infected before 2 years of age.

Several recent studies suggest that children who have had measles have blunted immune responses to other pathogens and increased mortality for several years after infection. This has been attributed to measles-induced suppression of cell-mediated immune function leading to immune amnesia and susceptibility to previously encountered antigens, including vaccine antigens. This effect is another reason why measles prevention is so important.

ETIOLOGY: Measles virus is an enveloped RNA virus with 1 serotype, classified as a member of the genus *Morbillivirus* in the *Paramyxoviridae* family.

EPIDEMIOLOGY: The only natural host of measles virus is humans. Measles virus is transmitted by direct contact with infectious droplets or by airborne spread. Measles is one of the most highly communicable of all infectious diseases; the attack rate in a susceptible individual exposed to measles is 90% in close-contact settings. Population immunity as high as 95% or greater is often needed to stop ongoing transmission. In temperate areas, the peak incidence of infection usually occurs during late winter and spring. In the prevaccine era, most cases of measles in the United States occurred in preschool- and young school-aged children, and few people remained susceptible by 20 years of age. Following implementation of routine childhood vaccination in the United States at 12 to 15 months of age, measles occurred more often in infants younger than 1 year and in older adolescents and adults who had not been adequately vaccinated. Infant susceptibility increases around the time when transplacentally acquired antibodies are no longer present. The childhood and adolescent immunization program in the United States began with licensure of the measles vaccine in 1963 and has resulted in a greater than 99% decrease in the reported incidence of measles, with declaration of measles elimination (ie, absence of endemic measles transmission for more than 1 year) in 2000.

From 1989 to 1991, the incidence of measles in the United States increased because of low immunization rates in preschool-aged children, especially in urban areas, and because of primary vaccine failures in children who had received 1 measles-containing vaccine dose. Following improved coverage in preschool-aged children and implementation of a routine second dose of measles, mumps, and rubella (MMR) vaccine for children, the incidence of measles has declined to extremely low levels (<1 case per 1 million population). Unfortunately, increasing numbers of cases and outbreaks of measles have occurred in many states in more recent years. The majority of these cases are linked to importation of measles by nonvaccinated international United States travelers from countries where measles is endemic, including countries in Western Europe, and subsequent internal spread among unimmunized subpopulations, including intentionally unimmunized children.

Progress continues toward global control and regional measles elimination, with a 94% drop in estimated measles deaths worldwide between 2000 and 2020.¹ By the end of 2021, 76 countries had been verified by independent regional commissions as having achieved or maintained measles elimination status. However, none of the World Health Organization (WHO) regions had achieved and sustained elimination, and no African Region country has yet been verified to have eliminated measles. WHO's Region of the Americas achieved verification of measles elimination in 2016; however, endemic measles transmission was reestablished in Venezuela (2016) and Brazil (2018).

Estimated coverage of first dose of measles-containing vaccine decreased from 86% in 2019 to 84% in 2020 and 81% in 2021 during the COVID-19 pandemic.²² Worsening of suboptimal surveillance coupled with increased population susceptibility attributable to vaccine hesitancy and decreased routine vaccination during the COVID-19 pandemic remain major threats to global elimination of measles.

Lack of response to vaccine (ie, primary vaccine failure) occurs in as many as 7% of people who receive a single dose of measles-containing vaccine at 12 months or older. Most cases of measles in previously immunized children are attributable to primary vaccine failures, but waning immunity after immunization (ie, secondary vaccine failure) may be a factor in some cases. Primary vaccine failure was the main reason that in 1989 a 2-dose vaccine schedule was recommended routinely for children and high-risk adults.³

Patients infected with wild-type measles virus are contagious from 4 days before the rash through 4 days after appearance of the rash. Immunocompromised patients who may have prolonged excretion of the virus in respiratory tract secretions can be contagious for the duration of the illness. Patients with SSPE are not contagious.

The **incubation period** averages 11 to 12 days from exposure to onset of prodromal symptoms, and the average interval between exposure and appearance of rash is 14 days, with a range of 7 to 21 days. In SSPE, the mean **incubation period** of 84 cases reported between 1976 and 1983 was 10.8 years.

DIAGNOSTIC TESTS: Measles virus infection can be confirmed by: (1) detection of measles viral RNA by nucleic acid amplification test (NAAT); (2) detection of measles virus-specific immunoglobulin (Ig) M; (3) a fourfold increase in measles IgG antibody concentration in paired acute and convalescent serum specimens (collected at least 10 days apart); or (4) isolation of measles virus in cell culture. Detection of IgM in serum samples by enzyme immunoassay has been the preferred method for case confirmation; however, as the incidence of disease decreases, the positive predictive value of IgM detection decreases. For this reason, detection of viral RNA in throat, nasal, and posterior nasopharyngeal swab specimens; bronchial lavage samples; blood or urine samples (respiratory samples are preferred specimens, and sampling more than 1 site may increase sensitivity) is playing an increasing role in case confirmation. A serum sample as well as a throat swab specimen should be obtained from

² Minta AA, Ferrari M, Antoni S, et al. Progress toward regional measles elimination—worldwide, 2000–2021. *MMWR Morb Mortal Wkly Rep.* 2022;71(47):1489–1495

³ Centers for Disease Control. Measles prevention. *MMWR Suppl.* 1989;38(9):1–18

any patient in whom measles is suspected. Many state public health laboratories, the Association of Public Health Laboratories Vaccine Preventable Disease Reference Centers (VPD-RCs), and the Measles Laboratory at the Centers for Disease Control and Prevention (CDC) can perform reverse transcriptase polymerase chain reaction (RT-PCR) assays to detect measles RNA. Isolation of measles virus in cell culture is not recommended for routine case confirmation, because isolation can take up to 2 weeks to complete.

The sensitivity of measles IgM assays varies by timing of specimen collection, immunization status of the patient, and the assay method itself. Up to 20% of assays for IgM may have a false-negative result in the first 72 hours after rash onset. If the measles IgM result is negative and the patient has a generalized rash lasting more than 72 hours, the measles IgM test should be repeated. Measles IgM is detectable for at least 1 month after rash onset in unimmunized people but might be absent or present only transiently in people immunized with 1 or 2 measles-containing vaccine doses. Therefore, a negative IgM test result should not be used to rule out the diagnosis in immunized people.

Detection of viral RNA by NAAT provides a rapid and sensitive method for case confirmation. It is important to collect samples for RNA detection as soon as possible after rash onset, because viral shedding declines with time after rash. Specimen timing and quality greatly influence the results of NAATs, so a negative result should not be the only criterion used to rule out a case of measles. Another advantage of collecting samples for molecular detection of the virus is that these samples can also be used to genotype the virus, which is important to determine patterns of importation and transmission.

In populations with high rates of measles-containing vaccine coverage, such as those in the United States, comprehensive serologic and virologic testing generally is not available locally and requires submitting specimens to state public health laboratories or the CDC. Individuals with a febrile rash illness who are seronegative for measles IgM and have negative NAAT results for measles should be tested for rubella using the same specimens.

TREATMENT: No specific antiviral therapy is available. Measles virus is susceptible in vitro to ribavirin, which has been administered by the intravenous and aerosol routes to treat severely affected and immunocompromised children with measles. However, no controlled trials have been conducted, and ribavirin is not licensed by the US Food and Drug Administration for treatment of measles. Intravenous ribavirin is available only from the manufacturer through an emergency investigational new drug (eIND) application.

Vitamin A. The WHO currently recommends vitamin A for all children with measles, regardless of their country of residence. Many US experts concur with administering vitamin A to all children in the United States with measles, regardless of hospitalization status. Vitamin A treatment of children with measles in resource-limited countries has been associated with decreased morbidity and mortality rates. Low serum concentrations of vitamin A also have been found in children in the United States, and children with more severe measles illness may have lower vitamin A concentrations. Vitamin A for treatment of measles is administered once daily for 2 days (ie, immediately on diagnosis and repeated the next day), at the following doses:

- 200 000 IU (60 000 µg retinol activity equivalent [RAE]) for children 12 months or older;
- 100 000 IU (30 000 µg RAE) for infants 6 through 11 months of age; and
- 50 000 IU (15 000 µg RAE) for infants younger than 6 months.
- An additional (ie, a third) age-specific dose of vitamin A should be given 2 through 6 weeks later to children with clinical signs and symptoms of vitamin A deficiency.

INFECTION PREVENTION AND CONTROL MEASURES IN HEALTH CARE SETTINGS:

In addition to standard precautions, airborne transmission precautions are indicated for 4 days after the onset of rash in otherwise healthy children and for the duration of illness in immunocompromised patients. Exposed susceptible patients should be placed on airborne precautions for 21 days after last exposure (28 days if the patient received immune globulin as postexposure prophylaxis).¹

CONTROL MEASURES:

Evidence of Immunity to Measles.² Evidence of immunity to measles includes any of the following:

1. Documentation of age-appropriate vaccination with a live measles-containing vaccine:
 - Preschool-aged children: 1 dose administered after the first birthday;
 - School-aged children (grades K–12): 2 doses; the first dose administered after the first birthday and the second dose administered at least 28 days after the first dose;
 - Adults not at high risk: 1 dose administered after the first birthday;
 - Adults at high risk (eg, students in postsecondary education institutions, health care workers, international travelers): 2 doses; the first dose administered after the first birthday and the second dose administered at least 28 days after the first dose;
2. Laboratory evidence of immunity;
3. Laboratory confirmation of disease; or
4. Born before 1957.

Care of Exposed People. Table 3.32 and Table 3.33 summarize the use of vaccine and immune globulin (IG) for postexposure prophylaxis in people who are not immunocompromised or pregnant and people who are immunocompromised or pregnant, respectively.

Use of Vaccine. Available data suggest that measles vaccine, if administered within 72 hours of measles exposure to susceptible individuals, will provide protection or disease modification in some cases. Measles-containing vaccine should be considered in all exposed individuals who are vaccine eligible and who have not been vaccinated or have received only 1 dose of vaccine (the second measles vaccine dose can be administered ≥28 days after the first measles vaccine dose). If the exposure does not result in infection, the vaccine should induce protection against subsequent measles exposures. Immunization is the intervention of choice for control of measles outbreaks in schools and child care centers and for vaccine-eligible people 12 months and older and has been used starting at 6 months of age with good efficacy in previous measles epidemics in the United States.
